THE

DISPENSATORY

OF THE

UNITED STATES OF AMERICA.

BY

GEORGE B. WOOD, M.D.,

PRESIDENT OF THE AMERICAN PHILOSOPHICAL SOCIETY;
PRESIDENT OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA;
EMERITUS PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA, ETC. ETC.,

AND

FRANKLIN BACHE, M.D.,

LATE PROFESSOR OF CHEMISTRY IN JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA;
LATE VICE-PRESIDENT OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA;
LATE PRESIDENT OF THE AMERICAN PHILOSOPHICAL SOCIETY, ETC. ETC.

By George B. Wood, M.D.,

In the Clerk's Office of the District Court of the United States in and for the Eastern District of Pennsylvania.

PREFACE

TO

THE FIRST EDITION.

THE objects of a Dispensatory are to present an account of medicinal substances in the state in which they are brought into the shops, and to teach the modes in which they are prepared for use. The importance of these objects, and the general value and even necessity of a work of this nature, will not be disputed. It may, however, be a question, how far the wants of the medical and pharmaceutical community in this country are supplied by the Dispensatories already in circulation; and whether such a deficiency exists as to justify the offer of a new one to the public attention. The great merits of the works severally entitled "The Edinburgh New Dispensatory" and "The London Dispensatory," the former edited by the late Andrew Duncan, M.D., the latter by Anthony Todd Thomson, M.D., are well known wherever the English language is spoken. Founded, as they both are, upon the excellent basis laid by Lewis, they are nevertheless entitled, from the great addition of valuable materials, and the distinctive character exhibited in the arrangement of these materials, to be considered as original works; while the style in which they have been executed speaks strongly in favour of the skill and industry of their authors. But they were calculated especially for the sphere of Great Britain, and are too deficient in all that relates exclusively to this country, to admit of being received as standards here. In the history of our commerce in drugs, and of the nature, growth, and collection of our indigenous medical plants; in the chemical operations of our extensive laboratories; and in the modes of preparing, dispensing, and applying medicines, which have gradually grown into use among us; there is much that is peculiar, a knowledge of which is not to be gained from foreign books, and is yet necessary to the character of an accomplished American pharmaceutist. We have, moreover, a National Pharmacopœia, which requires an explanatory commentary, in order that its precepts may be fully appreciated, and advantageously put into practice. On these accounts it is desirable

that there should be a Dispensatory of the United States, which, while it embraces whatever is useful in European pharmacy, may accurately represent the art as it exists in this country, and give instruction adapted to our peculiar wants. It appears due to our national character that such a work should be in good faith an American work, newly prepared in all its parts, and not a mere edition of one of the European Dispensatories, with here and there additions and alterations, which, though they may be useful in themselves, cannot be made to harmonize with the other materials so as to give to the whole an appearance of unity, and certainly would not justify the assumption of a new national title for the book. Whether, in the Dispensatories which have been published in the United States, these requisites have been satisfactorily fulfilled, it rests with the public to determine. That valuable treatises on Materia Medica and Pharmacy have been issued in this country, no candid person, acquainted with our medical literature, will be disposed to deny. In offering a new work to the medical and pharmaceutical professions, the authors do not wish to be considered as undervaluing the labours of their predecessors. They simply conceive that the field has not been so fully occupied as to exclude all competition. The pharmacy of continental Europe is ground which has been almost untouched; and much information in relation to the natural history, commerce, and management of our own drugs, has lain ungathered in the possession of individuals, or scattered in separate treatises and periodicals not generally known and read. Since the publication of the last edition of our National Pharmacopœia, no general explanation of its processes has appeared, though required in justice both to that work and to the public. The hope of being able to supply these deficiencies may, perhaps, be considered a sufficient justification for the present undertaking.

The Pharmacopœia of the United States has been adopted as the basis of this Dispensatory. It is followed both in its general division of medicines, and in its alphabetical arrangement of them under each division. Precedence is, in every instance, given to the names which it recognises, while the explanations by which it fixes the signification of these names are inserted in immediate connection with the titles to which they severally belong. Every article which it designates is more or less fully described; and all its processes, after being literally copied, are commented on and explained wherever comment and explanation appeared necessary. Nothing, in fine, has been omitted, which, in the estimation of the authors, could serve to illustrate its meaning, or promote the ends which it was intended to subserve. This course of proceeding appeared to be due to the national character of the Pharmacopœia, and to the important object of establishing, as far as possible, throughout the United States, uniformity, both in the nomenclature and preparation of medicines. In one particular, conveni-

ence required that the plan of the Pharmacopœia should be departed from. The medicines belonging to the department of MATERIA MEDICA, instead of being arranged in two divisions, corresponding with the *Primary* and *Secondary Catalogues* of that work, have been treated of indiscriminately in alphabetical succession; and the place which they respectively hold in the Pharmacopœia is indicated by the employment of the term *Secondary*, in connection with the name of each of the medicines included in the latter catalogue.

But, though precedence has thus been given to the Pharmacopœia of the United States, those of Great Britain have not been neglected. The nomenclature adopted by the different British Colleges, and their formulas for the preparation of medicines, have been so extensively followed throughout the United States, that a work intended to represent the present state of pharmacy in this country would be imperfect without them; and the fact that the writings of British physicians and surgeons, in which their own officinal terms and preparations are exclusively employed and referred to, have an extensive circulation among us, renders some commentary necessary in order to prevent serious mistakes. The Pharmacopœias of London, Edinburgh, and Dublin have, therefore, been incorporated, in all their essential parts, into the present work. Their officinal titles are uniformly given, always in subordination to those of the United States Pharmacopœia, when they express the same object; but in chief, when, as often happens, no corresponding medicine or preparation is recognised by our national standard. In the latter case, if different names are applied by different British Colleges to the same object, that one is generally preferred which is most in accordance with our own system of nomenclature, and the others are given as synonymes. The medicines directed by the British Colleges are all described, and their processes either copied at length, or so far explained as to be intelligible in all essential particulars.

Besides the medicinal substances recognised as officinal by the Pharmacopœias alluded to, some others have been described, which, either from the lingering remains of former reputation, from recent reports in their favour, or from their important relation to medicines in general use, appear to have claims upon the attention of the physician and apothecary. Opportunity has, moreover, been taken to introduce incidentally brief accounts of substances used in other countries or in former times, and occasionally noticed in medical books; and, that the reader may be able to refer to them when desirous of information, their names have been placed with those of the standard remedies in the Index.

In the description of each medicine, if derived immediately from the animal, vegetable, or mineral kingdom, the attention of the authors has been directed to its natural history, the place of its growth or production, the method of collecting and preparing it for market, its commer-

cial history, the state in which it reaches us, its sensible properties, its chemical composition and relations, the changes which it undergoes by time and exposure, its accidental or fraudulent adulterations, its medical properties and application, its economical uses, and the pharmaceutical treatment to which it is subjected. If a chemical preparation, the mode and principles of its manufacture are indicated in addition to the other particulars. If a poison, and likely to be accidentally taken, or purposely employed as such, its peculiar toxicological effects, together with the mode of counteracting them, are indicated; and the best means of detecting its presence by reagents are explained.

The authors have followed the example of Dr. A. T. Thomson, in giving botanical descriptions of the plants from which the medicines treated of are derived. In relation to all indigenous medicinal plants, and those naturalized or cultivated in this country, the advantages of such descriptions are obvious. The physician may often be placed in situations, in which it may be highly important that he should be able to recognise the vegetable which yields a particular medicine; and the apothecary is constantly liable to imposition from the collectors of herbs, unless possessed of the means of distinguishing, by infallible marks, the various products presented to him. A knowledge of foreign medicinal plants, though of less importance, will be found useful in various ways, independently of the gratification afforded by the indulgence of a liberal curiosity in relation to objects so closely connected with our daily pursuits. The introduction of these botanical notices into a Dispensatory appears to be peculiarly appropriate; as they are to be considered rather as objects for occasional reference than for regular study or continuous perusal, and therefore coincide with the general design of the work, which is to collect into a convenient form for consultation all that is practically important in relation to medicines. The authors have endeavoured to preserve a due proportion between the minuteness of the descriptions, and their value as means of information to the student; and, in pursuance of this plan, have generally dwelt more at length upon our native plants than upon those of foreign growth; but, in all instances in which they have deemed a botanical description necessary, they have taken care to include in it the essential scientific character of the genus and species, with a reference to the position of the plant in the artificial and natural systems of classification; so that a person acquainted with the elements of botany may be able to recognise it when it comes under his observation.

In preparing the Dispensatory, the authors have consulted, in addition to many of the older works of authority, the greater number of the treatises and dissertations which have recently appeared upon the various subjects connected with Pharmacy, and especially those of the French writers, who stand at present at the head of this department of medical science. They have also endeavoured to collect such de

tached facts, scattered through the various scientific, medical, and pharmaceutical journals, as they conceive to be important in themselves, and applicable to the subjects under consideration; and have had frequent recourse to the reports of travellers in relation to the natural and commercial history of foreign drugs. The occasional references in the body of the work will indicate the sources from which they have most largely drawn, and the authorities upon which they have most relied. In relation to our own commerce in drugs, and to the operations of our chemical laboratories, they are indebted for information chiefly to the kindness of gentlemen engaged in these branches of business, who have always evinced, in answering their numerous inquiries, a promptitude and politeness which merit their warm thanks, and which they are pleased to have this opportunity of acknowledging.*

It has not been deemed necessary to follow the example of the British Dispensatories, by inserting into the work a treatise upon Chemistry, under the name of Elements of Pharmacy. Such a treatise must necessarily be very meagre and imperfect; and, as systems of chemistry are in the hands of every physician and apothecary, would uselessly occupy the place of valuable matter of less easy access.

The authors may, perhaps, be permitted to observe, in relation to themselves, that they have expended much time and labour in the preparation of the work; have sought diligently for facts from every readily accessible source; have endeavoured, by a comparison of authorities, and a close scrutiny of evidence, to ascertain the truth whenever practicable; and have exerted themselves to the extent of their abilities to render the Dispensatory worthy of public approbation, both for the quality and quantity of its contents, and the general accuracy of its statements. They are conscious, nevertheless, that, in so great a multiplicity of details, numerous errors and deficiencies may exist, and that the faults of undue brevity in some cases, and prolixity in others, may not have been entirely avoided; but they venture to hope that a candid public will make all due allowances; and they take the liberty to invite, from all those who may feel interested in the diffusion of sound pharmaceutical knowledge, the communication of friendly suggestions or criticisms in relation to the objects and execution of the work.

Philadelphia, January, 1833.

* The authors deem it proper to state that they are peculiarly indebted for assistance to Mr. Daniel B. Smith, president of the Philadelphia College of Pharmacy, to whom, besides much important information in relation to the various branches of the apothecary's business, they owe the prefatory remarks on Pharmacy which are placed at the commencement of the second part of the work, and the several articles, in the Materia Medica, upon *Leeches*, *Carbonate of Magnesia*, and *Sulphate of Magnesia*.

PREFACE

TO THE

TWELFTH AND THIRTEENTH EDITIONS.

In the preface to the twelfth edition of the Dispensatory, the changes which had taken place after the first publication of the work, and its various existing relations, were so fully stated, and so little has since occurred to modify those relations, that it has been deemed advisable to retain that preface unaltered. What especially concerns the present edition may be briefly noticed at the close of it.

Preface to the Twelfth Edition.

In the foregoing preface to the first edition of this work, sufficient has been said of its objects, the plan upon which it was written, and the sources whence the materials composing it were originally derived. A modification of its arrangement was made in the second edition, by the introduction of an Appendix, containing an account of drugs not recognised by the American or British Pharmacopœias, yet possessing some interest from their former or existing relations to Medicine and Pharmacy. This Appendix was so much enlarged by the numerous additions made to it in successive editions, that the authors at length deemed it worthy of being considered as a third part of the Dispensatory; and, in the edition immediately preceding the present, this change was carried into effect, so that the work as then arranged, and as it now continues, consists of three divisions, the first treating exclusively of the medicines included in the Materia Medica catalogues of the Pharmacopœias, the second of the Preparations, and the third of substances not strictly officinal. An Appendix, however, is still retained, in which are introduced various tables and other subjects of interest or use to the apothecary and physician, for which a place could not conveniently be found in the body of the work. A precision has thus been given to the arrangement of the Dispensatory which was at first wanting.

In the several successive editions, it has been the aim of the authors to keep pace with the progress of Materia Medica and Pharmacy, making changes corresponding with those of the officinal codes acknowledged by them as authoritative, and introducing more or less in detail all the new facts, views, and processes, as they came to public notice. In the ninth edition, that, namely, of 1851, it was necessary to make a thorough revision of the whole work, and in a considerable degree to rearrange the materials, in consequence of the then recent appearance of new and greatly altered editions of our national Pharmacopœia, and of those of the London and Dublin Colleges. On this occasion, attention was called to a new division of weights adopted by the Dublin College, which, though the same in terms as those in general use, differed from them materially in value, and, therefore, required much caution, on the part of the authors, to guard against serious mistakes. Happily, these Dublin weights have been abandoned in the existing British Pharmacopœia, and one great source of inconvenience, if not of error, has been removed. The British Council, in the revision

of the former London, Edinburgh, and Dublin Pharmacopœias, resulting in their consolidation into one work, which, under the name of the British Pharmacopœia, is hereafter to serve as a standard for the whole empire, have retained the Imperial gallon and its subdivisions, differing more or less in value from the similar denominations of the wine measure used in the U. S. Pharmacopœia. They have, moreover, adopted the avoirdupois pound and ounce, abandoning entirely the Troy pound and its divisions, which are still retained in our national standard. To secure the practical pharmaceutist from misapprehension and mistakes in fulfilling the directions of the officinal formulas, arising from this want of uniformity in the meaning of the terms employed, it has been deemed necessary, in this work, to make a special reference to the value, in U. S. denominations, of the British measure or weight employed, in every formula in which entire accuracy is essential.

In regard to the present edition of the Dispensatory, it is thought desirable to enter into some detail. Few of our readers require to be informed of the decease of Dr. Bache, one of the authors of this work. This deplorable loss, by which long existing ties of friendship and joint labour have been broken, has thrown the whole responsibility of the revision upon the surviving author; and at a time, moreover, when circumstances called for an unusual exercise of judgment, and rendered necessary an extraordinary amount of labour in preparing a new edition.

In the first place, an unprecedented length of interval has occurred between the present and immediately preceding revisions of the work; the eleventh and latest edition having been published in February, 1858, more than seven years ago. It is true that, in this interval, it has been necessary to reprint the work twice to meet the public demand; but no material change could be made; and, with the exception of some errors corrected, the book remained the same as before. This delay of the revision was caused by the unfinished state of the Pharmacopœias, which were to constitute the basis of the new edition, as the old Pharmacopœias had done of the preceding. It was known that the U. S. Pharmacopœia was undergoing a thorough revision, with many and important changes; and it was equally notorious that the three British Pharmacopœias were in the course of consolidation into one, which, it was supposed, would retain few features of the former works, and almost none unaltered. Under these circumstances, it would have been folly to undertake a new revision of the Dispensatory, which, when completed, would in a short time have had its whole foundation undermined, and in all probability been left as useless lumber upon the hands of the publishers. This long period allowed materials to accumulate beyond all precedent, and thus increased in proportion the necessary labour of revision.

In the second place, the changes made both in our own and the British Pharmacopœias rendered indispensable similar changes in the Dispensatory. One not familiar with the subject can scarcely appreciate the constant vigilance, the unceasing attention to the minutest details running through every part of the work, which were necessary to obviate confusion and prevent embarrassing mistakes, in making the book conform to the present standards. Not only was it requisite to introduce all that was new, to alter positions in conformity with the changes in the standards, and to notice and discuss all modifications whether in substance or form; but there was a constantly recurring necessity to solve the various practical problems arising from the substitution of a single one for the three former British Pharmacopœias, which were referred to, at greater or less length, in almost every page.

Taking the above circumstances into consideration, and reflecting, in the third place, how greatly the field of labour has been extended for the surviving author by the decease of his colleague, the reader will understand that he has had a very heavy task upon his hands, and will not be disposed to censure him for a delay in the appearance of the present edition, which could have been shortened only at the expense of the usefulness and trustworthiness of

the work itself. Independently of the attention given, ever since the publication of the preceding edition, to the collection of materials for the one to follow, he has, during the last six months, devoted his whole time and energy to the business of revision, at the sacrifice even of ordinary social enjoyments, in order that he might have nothing to regret in future from errors or deficiencies in a book in which accuracy is so important to the general good.

It is, however, with pleasure that he acknowledges his indebtedness, for material assistance in the prosecution of the revision, to his friends, Mr. William Procter, Jun., Professor of Pharmacy in the Philadelphia College of Pharmacy, and Dr. Robert Bridges, Professor of Chemistry in the same Institution. By the suggestion of new subjects for investigation and new points of inquiry, by a careful watchfulness to prevent or correct error, and by valuable information particularly connected with their special departments; though thereby rather increasing than diminishing the labours of the author, they have contributed no little to extend the usefulness, and secure the accuracy of the work. But with all these advantages it would be expecting too much from human fallibility to look for a faultless production. No one is more sensible than the author of possible errors and omissions; and he can only reiterate the invitation for friendly suggestion or criticism, given at the close of the original preface.

Some idea may be formed of the amount of new matter added to the Dispensatory in this revision, when it is understood that, notwithstanding the very considerable space gained by the consolidation of the three British Pharmacopœias into one, and the consequent substitution, in many instances, of a single process and its necessary commentary for three, and notwithstanding the effort made to compress everything to be said into the fewest possible words, and to leave no part of the space unoccupied, it has nevertheless been found necessary to extend the limits of the work by more than one hundred pages. Among the more important additions, independently of those made in conformity with the Pharmacopœias, in the first and second parts of the Dispensatory, and the various new or modified pharmaceutical processes in the preface to the second part, or scattered here and there throughout that division, may be particularized the articles in the third part upon *Anilin*, *Calabar Bean*, *Carbolic Acid*, *Coal Tar*, *Peroxide of Hydrogen*, *Petroleum*, *Propylamia*, *Sorghum*, *Thallium*, the *Upas*, &c., with numerous brief notices of plants, especially the indigenous, intended to call attention to them rather as objects worthy of inquiry by the physician, than from their known value. The reader who may be already in any degree familiar with the work will be struck with one change, for which he may probably not perceive, at first sight, sufficient necessity in all cases. Reference is here made to the transfer of various articles from one part of the Dispensatory to another, as for example the articles on coffee, gutta-percha, ignatia, leptandra, permanganate of potassa, &c., from the third into the first part, and origanum, sponge, tin, &c., from the first to the third. But all these and analogous changes have been made in accordance with the Pharmacopœias adopted as the basis of the work, and will be explained when necessary in connection with the several articles themselves. On the whole, it may be said truly of this revision, that there has been no one, since the Dispensatory was originally published, which has been attended with so much labour, or in which so many modifications and additions have been introduced.

Finally, it may be permitted to the surviving author to say that, considering his advanced age, it is hardly probable that he will live to see or at least participate in another revision, and, under these circumstances, to express his warm thanks to the members of the Medical and Pharmaceutical Professions, who have in so many ways evinced a kind regard for him personally, and a disposition to judge favourably if not partially of his works.

Philadelphia, March 14th. 1865.

In reference to the thirteenth edition it is only requisite to say that, in consequence of the rapid advance in pharmacological knowledge since the preceding revision, it has been necessary to add much new matter to the work, which, notwithstanding the enlarged leaf, has been increased by about one hundred pages. Some modifications were also rendered necessary by the publication of a second edition of the British Pharmacopœia, which differs in so many important particulars from the first edition, that, without corresponding changes in the Dispensatory, great injustice would have been done to the British authorities.

The author may claim the merit of an honest effort to maintain the Dispensatory in all its former accuracy and fulness, and has pleasure in acknowledging his indebtedness to his former assistants for aid on the present occasion. The reader will probably have noticed, at the close of the preface to the twelfth edition, that the author expressed some doubt as to the probability of his participating in another revision. That his anticipations in this respect have not been realized, may be ascribed to the very unexpected rapidity of the sale of the last edition, which has been exhausted several years before the expected time, and to the favour of a kind Providence, which has permitted sufficient health and strength to remain to support him in the necessary fatigues of the work.

Philadelphia, Feb. 1870.

ABBREVIATIONS EMPLOYED IN THE WORK.

U. S.—"The Pharmacopœia of the United States of America. By authority of the National Convention for revising the Pharmacopœia, held at Washington, A. D. 1860."

U. S. 1850.—The same, by authority of the Convention of 1850.

Br.—The British Pharmacopœia, published under the direction of the General Council, A. D. 1867.

Lond.—London Pharmacopœia, A. D. 1851.

Ed.—Edinburgh Pharmacopœia, A. D. 1841.

Dub.—Dublin Pharmacopœia, A. D. 1850.

Off. Syn.—Officinal Synonymes, or the titles employed by the Pharmacopœias with the accompanying explanations, when these titles are not given in chief.

Sex. Syst.—The Sexual System, or the artificial system of Linnæus, founded on the sexual organization of plants.

Nat. Ord.—The Natural Order to which any particular genus of plants belongs. When not otherwise stated, it is to be understood that the natural orders referred to are those recognized by Professor Lindley, of the University of London, in his "Introduction to the Natural System of Botany."

Gen. Ch.—The Generic Character, or scientific description of any particular genus of plants under consideration.

Pharm. Uses.—Use of the substance referred to in the preparation of officinal medicines, without entering into the constitution of the medicines prepared.

Off. Prep.—Officinal Preparations; including all the preparations into which any particular medicine directed by the U. S. or British Pharmacopœia enters. When the same preparation is contained in both Pharmacopœias, neither is referred to; but when only in one, this is designated by its representative abbreviation at the end of the preparation named.

Sp. Gr.—Specific Gravity.

Equiv., or *Eq.*—Chemical Equivalent, or the number representing the smallest quantity in which bodies usually combine.

Linn., Linnæus.—*Juss.*, Jussieu.—*De Cand.*, De Candolle.—*Willd. Sp. Plant.*, Willdenow's edition of the Species Plantarum of Linnæus.—*Woodv. Med. Bot.*, Woodville's Medical Botany, 2d edition.—*B.*, Baumé's Hydrometer.

Fr., French.—*Germ.*, German.—*Ital.*, Italian.—*Span.*, Spanish.—*Arab.*, Arabic.

Journ. de Pharm.— Journal de Pharmacie et de Chimie.

Pharm. Journ.—London Pharmaceutical Journal and Transactions.

When, in referring to a journal in parenthesis, the word See is placed before the name of the journal, it is generally intended to intimate that the article referred to is not original.

THE

DISPENSATORY

OF

THE UNITED STATES.

PART I.

MATERIA MEDICA.

The Materia Medica, in its most comprehensive sense, embraces all those substances which are capable of making sanative impressions on the human system; but, as the term is employed in this work, it has a more restricted signification. The Pharmacopœia of the United States very appropriately arranges medicines in two distinct divisions; one including all those which are furnished immediately by nature, or thrown into commerce by the manufacturer; the other, those which are prepared by the apothecary, and are the objects of officinal directions. The former are enumerated under the title of "Materia Medica;" the latter, under that of "Preparations." In Dispensatories, which may be considered as commentaries on the Pharmacopœias, the same arrangement is usually followed; and the authors of the present work adopt it the more willingly, as, independently of the weight of authority in its favour, it has the recommendation of being the most convenient. By this plan, all the directions which relate to the practical operations of the apothecary are collected in one place, and are thus more easily referred to than if mixed indiscriminately with other matters, as they must be by any mode of arrangement which makes no distinction between the original medicinal substances and their preparations. Under the head of Materia Medica, therefore, in this Dispensatory, we treat of medicines in the state only in which they are produced by nature, or come into the hands of the apothecary. Of these medicines, such as are recognised by our National Pharmacopœia are most minutely described; but we consider also all that are included in the British officinal catalogue.

Another point in which we accord with the Pharmacopœias is the alphabetical arrangement of the objects of the Materia Medica. As a Dispensatory is intended rather for reference than for regular perusal it is important that its contents should be so disposed as to facilitate consultation. Medicines, in a work of this kind, are considered as independent objects, to be studied separately, and without any reference to community of source, or similarity of character. Their scientific classification belongs to works which treat of them rather in their relations than their essential properties; and different systems have been adopted, according to the set of relations towards which the mind of the author has been especially directed. Thus, the naturalist classifies them according to the affinities of the several objects in nature from which they are

derived; the chemist, according to their composition; the practitioner of medicine, according to their effects upon the system in a state of health and disease. But none of these classifications is without imperfections; and a simple alphabetical arrangement is decidedly preferable, in every case in which the medicines are considered solely in their individual capacity. Yet, as it comes within the scope of this work to treat of their physiological and therapeutical effects, and as the terms by which these effects are expressed are also the titles of classes to which the medicines belong, it will not be amiss to present the reader with the outlines of a system of classification, by consulting which he will be enabled to ascertain the precise meaning we attach to the terms employed to designate the peculiar action of different medicinal substances.

Remedies are divided into general and local; the former acting on the whole system, the latter on particular parts or organs.

I. GENERAL REMEDIES include 1. ARTERIAL STIMULANTS, sometimes called INCITANTS, which, while they raise the actions of the system above the standard of health, exhibit their influence chiefly upon the heart and arteries; 2. NARCOTICS, which especially affect the cerebral functions, and are either *stimulant* or *sedative* according as they increase or diminish action; 3. ANTISPASMODICS, or NERVOUS STIMULANTS, which, with a general stimulant power, exert a peculiar influence over the nervous system, exhibited in the relaxation of spasm, the calming of nervous irritation, &c., without any special and decided tendency to the brain; 4. TONICS, which moderately and permanently exalt the energies of all parts of the frame, without necessarily producing any apparent increase of the healthy actions; and 5. ASTRINGENTS, which have the property of producing contraction in the living tissues with which they may come in contact.

II. LOCAL REMEDIES may be divided into four sections: *a. Those affecting the function of a part*, namely, 1. EMETICS, which act on the stomach, producing vomiting; 2. CATHARTICS, which act on the bowels, producing a purgative effect; 3. DIURETICS, which act on the kidneys, producing an increased flow of urine; 4 ANTILITHICS, which act on the same organs, preventing the formation of calculous matter; 5. DIAPHORETICS, which increase the cutaneous discharge; 6. EXPECTORANTS, which augment the secretion from the pulmonary mucous membrane, or promote the discharge of the secreted matter; 7. CHOLAGOGUES, which increase the flow of bile; 8. EMMENAGOGUES, which excite the menstrual secretion; 9. UTERINE MOTOR-STIMULANTS, or OXYTOCICS, which specially promote uterine contraction; 10. SIALAGOGUES, which increase the flow of saliva; and 11. ERRHINES, which increase the discharge from the mucous membrane of the nostrils: *b. Those affecting the organization of a part*, including 1. RUBEFACIENTS, which produce redness and inflammation of the skin; 2. EPISPASTICS or VESICATORIES, which produce a serous discharge beneath the cuticle, forming a blister; and 3. ESCHAROTICS or CAUSTICS, which destroy the life of the part upon which they act: *c. Those operating by a mechanical agency*, consisting of 1. DEMULCENTS, which lubricate the surface to which they are applied, and prevent the contact of irritating substances, or mingle with these and diminish their acrimony; 2. EMOLLIENTS, which serve as vehicles for the application of warmth and moisture; and 3. PROTECTIVES, which operate by excluding the air: *d. Those which act on extraneous matters contained within the organs*, including 1. ANTACIDS, which neutralize acid, whether existing in the alimentary canal, or circulating with the blood; 2. ABSORBENTS, which absorb, and thus in some degree counteract certain irritant or poisonous substances; 3. SOLVENTS, which promote the solution of indigestible matters in the stomach; 4. DISINFECTANTS, which destroy or prevent noxious and offensive effluvia, and counteract other injurious influences originating in animal or vegetable decomposition; 5. ANTHELMINTICS, which destroy, worms, or expel them from the bowels; and 6. ANTIZYMOTICS, which destroy or render inert, all microscopic organized beings which are hostile to human health by promoting the fermenting processes.

It is believed that all substances employed as medicines, with the exception of a very few which are so peculiar in their action as scarcely to admit of classification, may be distributed without violence among the above classes. Some substances, however, in addition to the properties of the classes to which they are severally attached, possess others in common, which give them practical value, and authorize their association in distinct groups, not recognised in the system of classification, but constantly referred to in medical language. Thus, we have REFRIGERANTS, which, when internally administered, diminish animal temperature; ALTERATIVES, which change, in some inexplicable and insensible manner, certain morbid actions or states of the system; and CARMINATIVES, which, by promoting contraction in the muscular coat of the stomach and bowels, cause the expulsion of flatus. It is customary, moreover, to attach distinct names to groups of remedies, with reference to certain effects which are incident to the properties that serve to arrange them in some more comprehensive class. Thus, NARCOTICS frequently promote sleep, relieve pain, and produce insensibility, and, in relation to these properties, are called SOPORIFICS, ANODYNES, and ANÆSTHETICS; and various medicines, which, by diversified modes of action, serve to remove chronic inflammation and enlargements of the glands or viscera, are called DEOBSTRUENTS. These terms are occasionally employed in the following pages, and are here explained, in order that the sense in which we use them may be accurately understood. W.

ABSINTHIUM. *U. S.*

Wormwood.

The tops and leaves of Artemisia Absinthium. *U. S.*

ARTEMISIA. *Sex. Syst* Syngenesia Superflua. — *Nat. Ord.* Compositæ Senecionideæ. *De Cand.* Asteraceæ. *Lindley.*

Gen. Ch. Receptacle sub-villous, or nearly naked. *Seed-down* none. *Calyx* imbricate, with roundish, converging scales. *Corollas of the ray* none. *Willd.*

Several species of Artemisia have enjoyed some reputation as medicines. The leaves of *A. Abrotanum,* or *southernwood,* have a fragrant odour, and a warm, bitter, nauseous taste; and were formerly employed as a tonic, deobstruent, and anthelmintic. Similar virtues have been ascribed to *A. Santonica. A. pontica* has been occasionally substituted for common wormwood, but is weaker. *A. vulgaris,* or *mugwort,* formerly enjoyed considerable reputation as an emmenagogue, and some years since came into notice, in consequence of the recommendation of its root in epilepsy by Dr. Burdach, of Germany. For this purpose, it should be collected in autumn or early in the spring, and the side roots only dried for use. These should be powdered as they are wanted, the ligneous portion being rejected. The dose is about a drachm, to be administered in some warm vehicle in anticipation of the paroxysm, and to be repeated once or twice, at intervals of half an hour, till perspiration is produced, the patient being confined to bed. In the intervals, it may be given every second day. This is merely the revival of an old practice in Germany. Dr. Neumeister, of Arneburg, has used mugwort, in connection with assafetida, successfully in chorea. He adds a pound of the tops to a gallon of water, digests for three days, then strains, adds three ounces of assafetida, and gives a teacupful for a dose. The proportion of assafetida might be reduced to one-third, if well mixed. *A. vulgaris* of this country is thought by Nuttall to be a distinct species. In China, *moxa* is said to be prepared from the leaves of *Artemisia Chinensis* and *A. Indica.* The medicine known in Europe by the name of wormseed, is the product of different species of Artemisia. The only species which requires particular description here is *A. Absinthium.*

Artemisia Absinthium. Willd. *Sp. Plant.* iii. 1844; Woodv. *Med. Bot.* p. 54, t. 22. Wormwood is a perennial plant, with branching, round, and striated or furrowed stems, which rise two or three feet in height, and are panicled at their summit. The lower portion of the stem lives several years, and annually sends up herbaceous shoots, which perish in the winter. The radical leaves are triply pinnatifid, with lanceolate, obtuse, dentate divisions; those of the stem, doubly or simply pinnatifid, with lanceolate, somewhat acute divisions; the floral leaves are lanceolate; all are hoary. The flowers are of a brownish-yellow colour, hemispherical, pedicelled, nodding, and in erect racemes. The florets of the disk are numerous, those of the ray few. The plant is a native of Europe, where it is also cultivated. It is among our garden herbs, and has been naturalized in the mountainous districts of New England. The leaves and flowering summits are employed; the larger parts of the stalk being rejected. They should be gathered in July or August, when the plant is in flower. They preserve their peculiar sensible properties long when dried.

Wormwood has a strong odour, and an intensely bitter, nauseous taste, which it imparts to water and alcohol. It yields by distillation a volatile oil (*oleum absinthii*), usually dark-green, sometimes yellow or brownish, having a strong odour of the plant, an acrid peculiar taste, and the sp. gr. 0·972. It is sometimes adulterated with alcohol, oil of turpentine, &c., which lessen its specific gravity The dried herb yields much more than the fresh. (*Zeller.*) The other constituents, according to Braconnot, are a very bitter, and an almost insipid azotized matter, an excessively bitter resinous substance, chlorophyll, albumen, starch, saline matters, and lignin. The cold infusion becomes olive-green and turbid on

the addition of sesquichloride of iron, indicating the probable existence of a little tannic acid. (*Pereira.*) Among the salts, Braconnot found one consisting of potassa, and an acid which he supposed to be peculiar, and denominated *absinthic acid*, but which is said to be identical with the succinic. This acid may be recognised among the products of the dry distillation of wormwood. The substance formerly called *salt of wormwood* (*sal absinthii*) was impure carbonate of potassa, obtained by lixiviating the ashes of the plant. By precipitating an infusion of wormwood with acetate of lead, separating the excess of lead by sulphuretted hydrogen, evaporating the liquor to dryness, digesting the residue in a mixture of alcohol and ether, and submitting the resulting tincture to slow evaporation, Caventou obtained a very bitter, imperfectly crystalline substance, which he considered as the active principle, and which has been named *absinthin*. Dr. E. Luck has procured pure absinthin by a process which may be seen in the *Am. Journ. of Pharm.* (xxiii. 358).

Medical Properties and Uses. Wormwood was known to the ancients. It is highly tonic; and its active principles probably enter the circulation, as it is said to render the flesh and milk of animals fed with it bitter. It formerly enjoyed great reputation in numerous complaints, attended with a debilitated condition of the digestive organs, or of the system generally. Before the introduction of Peruvian bark, it was much used in the treatment of intermittents. It has also been supposed to possess anthelmintic virtues. At present, however, it is little used in regular practice on this side of the Atlantic. A narcotic property has been ascribed to it by some writers, in consequence of its tendency to occasion headache, and, when long continued, to produce disorder of the nervous system. This property is supposed to depend on the volatile oil, and, therefore, to be less obvious in the decoction than in the powder or infusion. A case is recorded in the *Lancet* (Dec. 6, 1862, p. 619) in which half an ounce of the oil, swallowed by a male adult, produced insensibility, convulsions, foaming at the mouth, and a tendency to vomit; though the patient recovered under the use of emetics, with stimulants and demulcents. In large doses, wormwood irritates the stomach, and excites the circulation. The herb is sometimes applied externally, by way of fomentation, as an antiseptic and discutient. The dose in substance is from one to two scruples; of the infusion, made by macerating an ounce in a pint of boiling water, from one to two fluidounces.* W.

* *Oil of Wormwood.* The possession of narcotic properties by this volatile oil referred to in the text, has been confirmed by experiments on the lower animals. Among its effects, one of the most striking and characteristic are epileptiform convulsions, which seem to occur uniformly from a certain dose. Recovery after the convulsions often takes place; but large doses are capable of producing fatal effects. M. Marcé, in a communication to the Academy of Sciences, in Paris, A.D. 1864, states, as the result of experiments on dogs and rabbits, that two or three grammes (30 or 45 grs.) given by the stomach, produce trembling, stupor, hebetude, insensibility, and all the appearances of extreme terror; that from three to eight grammes induce epileptiform convulsions, with involuntary evacuations, foaming at the mouth, and stertorous breathing; but that these symptoms are transient, and do not cause death. (*Bulletin Gén. Thérap.*, Mai 15, 1864.) Similar experiments were afterwards made by M. Magnan, with similar results, except that in the case of guinea-pigs, death followed convulsions from a dose of two grammes of the oil with three grammes of alcohol. (*L'Union Méd.*, Août 4 et 9, 1864.) Dr. R. Amory, of Boston, subsequently repeated these experiments on guinea-pigs and rabbits with confirmatory results. Dr. Amory, on post-mortem examination, found no apparent lesion except slight cerebral congestion. (*Boston Med. and Surg. Journ.*, March 12, 1868, p. 83.)

Absinthe. Under this name, a *liqueur* is much used in France, consisting essentially of alcohol mixed with volatile oil of wormwood, and some other less active ingredients, especially oil of anise. It has for some time been noticed that the effects of this liqueur differ essentially from those of pure alcoholic drinks, constituting a series of symptoms, which have been designated by the name of *absinthism*. From a case recorded by M. Magnan, in which the patient, having habituated himself to the use of brandy, and afterwards substituted *absinthe*, gave an opportunity of comparing the effects of the two kinds of drink, it appears that the characteristic symptoms of the latter, taken in excess, are restlessness at night with disturbing dreams, nausea and vomiting in the morning, with great trembling of the hands and tongue, vertigo, and a tendency to epileptiform

ACACIA. *U. S.*

Gum Arabic.

The concrete juice of Acacia vera and of other species of Acacia. *U. S.*

Off. Syn. ACACIÆ GUMMI. A gummy exudation from the stems of one or more undetermined species of Acacia. *Br.*

Gomme Arabique, *Fr.;* Arabisches Gummi, *Germ.;* Gomma Arabica, *Ital.;* Goma Arabiga, *Span.;* Samagh Arabee, *Arab.*

ACACIA. *Sex. Syst.* Polygamia Monœcia.—*Nat. Ord.* Leguminosæ. *Trib.* Mimoseæ.

This genus is one of those into which the old genus Mimosa of Linnæus was divided by Willdenow. The name *Acacia* was employed by the ancient Greeks to designate the gum-tree of Egypt, and has been appropriately applied to the new genus in which that plant is included.

Gen. Ch. HERMAPHRODITE. *Calyx* five-toothed. *Corolla* five-cleft, or formed of five petals. *Stamens* 4–100. *Pistil* one. *Legume* bivalve. MALE. *Calyx* five-toothed. *Corolla* five-cleft, or formed of five petals. *Stamens* 4–100. *Willd.*

Several species of Acacia contribute to furnish the gum arabic of the shops. Among the most important are *A. vera* and *A. Arabica*, confounded together by Linnæus under the title of *Mimosa Nilotica.*

Acacia vera. Willd. *Sp. Plant.* iv. 1805; Hayne, *Darstel. und Beschreib. &c.* x. 34. This is a tree of middling size, with numerous scattered branches, of which the younger are much bent, and covered with a reddish-brown bark. The leaves are alternate and bipinnate, with two pairs of pinnæ, of which the lower are usually furnished with ten pairs of leaflets, the upper with eight. The leaflets are very small, oblong-linear, smooth, and supported upon very short footstalks. On the common petiole is a gland between each pair of pinnæ. Both the common and partial petiole are smooth. Two sharp spines, from a quarter to half an inch long, of the colour of the smaller branches, and joined together at their base, are found at the insertion of each leaf. The flowers are yellow, inodorous, small, and collected in globular heads, supported upon slender peduncles, which rise from the axils of the leaves, in number from two to five together. The fruit is a smooth, flat, two-valved legume, divided by contractions, occurring at regular intervals, into several roundish portions, each containing one seed. This species flourishes in Upper Egypt and Senegal, and is probably scattered over the whole intervening portions of Africa.

A. Arabica. Willd. *Sp. Plant.* iv. 1805; Hayne, *Darstel. und Beschreib.* x. 32; Carson, *Illust. of Med. Bot.* i. 31.—*Acacia Nilotica,* Delille, *Illust. Flor. de l'Egypte,* p. 79. This species, though often little more than a shrub, attains in favourable situations the size of a considerable tree, being sometimes forty feet high, with a trunk a foot or more in diameter. The leaves are alternate and doubly pinnate, having from four to six pairs of pinnæ, each of which is furnished with from ten to twenty pairs of minute, smooth, oblong-linear leaflets. The common petiole has a gland between the lowest pair of pinnæ, and often also between the uppermost pair. Both the common and partial petioles, as well as the young branches, are downy. The thorns are straight, and disposed as in the former species. The flowers are also arranged as in A. vera, and the fruit is of a similar shape. A. Arabica is perhaps the most widely diffused of

convulsions, in which the patient loses consciousness, falls, bites his tongue, foams at the mouth, makes facial grimaces, throws about his limbs, &c., but from which he usually recovers. Experiments made with alcohol and oil of wormwood, separately, on the lower animals, have demonstrated that these latter effects are ascribable to the wormwood; and the inference is, that the abuse of absinthe is more dangerous than that of alcoholic drink in its purer forms. From the fatal effects produced by the oil of wormwood, recorded in the preceding paragraph and in the text, it is highly probable that absinthe is capable of producing immediately fatal convulsions, in quantities in which ordinary spirituous drinks, containing a similar amount of alcohol, might be taken with present impunity. (*Boston Med. and Surg. Journ.*, March 5, 1868, p. 69.)—*Note to the thirteenth edition.*

the gum-bearing species. It grows in Upper and Lower Egypt, Senegal, and other parts of Africa, flourishes also in Arabia, and is abundant in Hindostan, where its gum is used for food. It has been introduced into Algeria. (*Am. Journ. of Pharm.*, Sept. 1865, p. 337.)

Besides the two species above described, the following afford considerable quantities of gum:—*A. Karroo* of the Cape of Good Hope, formerly considered by some as identical with A. vera; *A. Senegal*, a small tree, inhabiting the hottest regions of Africa, and said to form vast forests in Senegambia; *A. gummifera*, seen by Broussonet in Morocco near Mogador; *A. Ehrenbergiana*, a shrub six or eight feet high, named in honour of the German traveller Ehrenberg, who observed it in the deserts of Libya, Nubia, and Dongola; *A. Seyal*, growing in the same region, and also in Upper Egypt and Senegambia; *A. Adansonii*, of the *Flore de Sénégambie*, said to contribute a portion of the Senegal gum; and *A. tortilis*, which sometimes attains the height of sixty feet, and inhabits Arabia Felix, Nubia, Dongola, and the Libyan desert. It is highly probable that gum is obtained from other species not hitherto described, growing in the hot latitudes of Africa. *A. decurrens* and *A. floribunda* are said to yield it in New Holland. Trees, moreover, not belonging to the genus, afford a similar product, especially *Feronia elephantum* of Hindostan, the gum of which, according to Ainslie, is used for medical purposes in Lower India, and *Algarobia glandulosa* of New Mexico, supposed to be the source of the *mezquite gum*.

The gum-bearing Acacias are all thorny or prickly trees or shrubs, calculated by nature for a dry and sandy soil, and flourishing in deserts where few other trees will grow. We are told that camels, attached to the caravans, derive from them their chief sustenance in many parts of those desolate regions in which Africa abounds. In these situations, they have a stunted growth, and present a bare, withered, and uninviting aspect; but in favourable situations, as on the banks of rivers, they are often luxuriant and beautiful.

Their bark and unripe fruit contain tannic and gallic acids, and are sometimes used in tanning. An extract was formerly obtained from the immature pods of *A. Arabica* and *A. vera*, by expression and inspissation. It was known to the ancients by the name of *acaciæ veræ succus*, and was highly praised by some of the Greek medical writers; but is at present little used. It is a solid, heavy, shining, reddish-brown substance, of a sweetish, acidulous, styptic taste, and soluble in water. Its virtues are probably those of a mild astringent. On the continent of Europe, a preparation is said to be substituted for it called *acacia nostras*, obtained by expression and inspissation from the unripe fruit of *Prunus spinosa*, or the wild plum-tree.

The gum of the Acacias exudes spontaneously from the bark, and hardens on exposure; but incisions are sometimes made in order to facilitate the exudation. This is supposed to be favoured by disease; and it is stated by Jackson that, in Morocco, the greatest product is obtained in the driest and hottest weather, and from the most sickly trees. An elevated temperature appears to be essential; for in cooler climates, though the tree may flourish, it yields no gum. According to Ehrenberg, the varieties in the characters of the gum do not depend upon difference in the species of the plant. Thus, from the same tree, it will exude frothy or thick, and clear or dark-coloured, and will assume, upon hardening, different shapes and sizes; so that the pieces, when collected, require to be assorted before being delivered into commerce.

Commercial History and Varieties. The most common varieties of this drug are the *Turkey*, the *Barbary*, the *Senegal*, and the *India gum;* to which may be added the *Cape* and the *Australian gum.*

1. Turkey Gum. Gum arabic was formerly procured, chiefly if not exclusively, from Egypt and the neighbouring countries; and much is still obtained from the same sources. It is collected in Upper Egypt, Nubia, Kordofan, and Darfur, whence it is taken down the Nile to Alexandria. We obtain it in this country through Smyrna, Trieste, Marseilles, or some other entrepot of the Mediterranean commerce. Two varieties have long been noticed, one more or

less coloured, the other white, which were formerly distinguished by the titles of *gum gedda* and *gum turic*, derived from the ports of the Red Sea, Jidda and Tor, from which the varieties were erroneously supposed to be respectively exported.* The gum from Egypt is commonly called *Turkey gum*, and is the kind with which apothecaries are usually supplied. Though interspersed with roundish pieces of various sizes, it consists chiefly of small, irregular fragments, commonly whitish, or slightly tinged with yellow or reddish-yellow. It is, on the whole, lighter coloured, more brittle, more readily soluble, and freer from impurities than the other commercial varieties, and contains much of that form of gum arabic which is characterized by innumerable minute fissures pervading its substance, and impairing its transparency.

2. Barbary Gum. Much gum arabic is obtained from Barbary; and Mogador, a port of Morocco, is the chief entrepot of the trade. It is probably derived, in part at least, from *Acacia gummifera*. According to Jackson, the natives call the tree which affords it *attaleh*. They gather it in July and August, when the weather is hot and very dry. Two kinds are brought to Mogador, one from the neighbouring provinces, the other by caravans from Timbuctoo. This may account for the fact, that Barbary gum in part resembles the Turkey, in part the Senegal. When first deposited in the warehouses, it has a faint smell, and makes a crackling noise, occasioned by the rupture of the small masses as they become more dry. Barbary gum is exported in casks, and reaches the United States through English commerce.

3. Senegal Gum. This variety was introduced into Europe by the Dutch. The French afterwards planted a colony on the western coast of Africa, and took possession of the trade; but, since the last great European war, it has been largely shared by the English. St. Louis, at the mouth of the Senegal, and Portendic, considerably further north, are the ports in which the commerce in gum chiefly centres. Immense forests of Acacia exist in the interior. These are composed chiefly of two trees, called by the natives *vereck* or *nereck*, and *nebuel* or *nebued;* the former yielding a white gum, the latter a red. These are probably distinct species; the vereck being, according to M. Rain, *A. vera*, and the nebuel, *A. Senegal*. According to Adanson, there are several other gum-bearing species in the neighbourhood. The juice begins to exude in November. The dry winds, which prevail after the rainy season, cause the bark to crack; the juice flows out, and hardens in masses, which are often as large as a pigeon's egg, and sometimes as that of the ostrich. At this period, the Moors and negroes proceed to the forests in caravans, collect the gum in leather sacks, and convey it to the coast. Senegal gum is imported into the United States chiefly from Bordeaux. It is usually in roundish or oval unbroken pieces, of various sizes, sometimes whitish, but generally yellowish, reddish, or brownish-red, larger than those of Turkey gum, less brittle and pulverizable, and breaking with a more conchoidal fracture.†

* Bayard Taylor states that Turkey gum is obtained almost entirely from Kordofan, where 30,000 cwt. are annually gathered. (*Journey to Central Africa*, N. Y. 1854, p. 387.)

† An interesting account is given by M. J. Leon Soubeiran of the varieties of gum sold under the name of Senegal. The following is an abstract from his paper, published in the *Journ. de Pharm. et de Chim.* (Juillet, 1856, p. 53).

Hard gum Galam (*gomme dure de Galam*) is the name given to the product of the two species mentioned in the text. That of *A. vereck* is white, wrinkled, and dull externally, of a vitreous fracture, sometimes vermicular or tortuous, but in general roundish or oval, two inches in diameter, of a sweetish slightly acidulous taste, and wholly soluble in water, with which it forms a mucilage much clearer and less consistent than that of Turkey gum, and reddening the tincture of litmus. The product of *A. nebued* differs only in being more frequently of a reddish colour, almost always in roundish lumps from six lines to an inch in diameter, transparent, of a slightly bitter taste, and yielding a mucilage thicker than that of Turkey gum, and but very slightly reddening the tincture of litmus.

Mixed with the Galam gum are two other varieties, named *Bondou gum* and *Gonakié gum;* the former closely resembling the Galam gum, but differing by its decidedly bitter taste, which renders it unfit for medical use; the latter derived from *A. Adansonii*, redder than the red Galam gum, drying readily and becoming vitreous like the better varieties,

4. India Gum. Large quantities of gum have been imported from India, derived from *A. Arabica*, and probably other species of Acacia. Most of it is taken to Bombay in Arab vessels from Cape Gardafui and Berbera on the north-eastern coast of Africa, where it is collected, or from the ports of the Red Sea. It is in pieces of various size, colour, and quality, some resembling the broken fragments of Turkey gum, though much less chinky; others large, roundish, and tenacious, like the Senegal. It is usually much contaminated, containing, besides genuine gum arabic, portions of a different product, having the characteristic properties of Bassora gum. This is distinguished by its insolubility in water, with which, however, it unites, swelling up, and forming a soft viscid mass. It owes its properties to the presence of *bassorin*. Besides this impurity in the India gum, there are often others more readily detected. Among these, we have observed a yellowish-white resinous substance, which has the sensible properties of the turpentines. If care be used in assorting this commercial variety, it may be employed for all the purposes of good gum arabic. India gum is brought to this country, partly from Calcutta or Bombay, and partly by way of England. It usually comes in large cases. We have seen a parcel said to have come directly from the Red Sea, enclosed in large sacks made of a kind of matting, and bearing a close resemblance to the gum from Calcutta, except that it was more impure, and contained numerous large, irregular, very brittle masses, not much less than the fist in size.*

5. Cape Gum. Pereira mentions that gum is imported into Great Britain from the Cape of Good Hope, where it is collected probably from *Acacia Karroo*, which grows abundantly on the banks of the Gariep, and in other parts. Dr. Pappe, of Cape Town, refers it to *Acacia horrida* of Willdenow. (*Flor. Capens.* 8.) It is of a pale-yellow colour, in tears or fragments, and is considered an inferior variety. According to Mr. Simmons, the importation has nearly ceased; this gum having been superseded by the artificial product called British gum or dextrin. (See *Am. Journ. of Pharm.*, xxix. 75.)

6. Australian Gum. Considerable quantities of gum have been imported into England from South Australia. It is in pieces elongated or globular, rough and even wrinkled upon the surface, and of a violaceous tint, which distinguishes

but unfortunately so bitter as much to lessen the value of the gum with which it may be mixed, and from which it is not easy to distinguish it.

Brittle gum, *Saiabreda*, or *Sadra-beida*, is supposed to be obtained from *A. albida* of the Flora of Senegambia, which is much smaller than *A. vereck*, and characterized by its white bark. The gum is usually in small, irregular pieces like coarse salt, probably the fragments of larger lumps, but sometimes in vermicular pieces about as thick as a goose-quill, and of variable length. It is dull and often wrinkled externally, of a vitreous fracture, and of different tints of colour, white, green, yellow, or orange. It is always somewhat bitter. Very easily soluble in its weight of water, it affords a mucilage of little consistence, which has but a slight effect on the tincture of litmus. When the solution is evaporated to the consistence of a paste, it absorbs moisture so as to become viscid; and this property detracts much from its value. It is much less esteemed than the Galam gum. (*Note to the eleventh edition.*)

* In the *Journ. de Pharm. et de Chim.* (Oct. 1867, p. 270), a variety of India gum, imported into France, by way of London, in boxes containing about 400 pounds, is described as follows. It is a mixture of tears of various tints with impurities. In assorting it for use, the lightest coloured tears are selected. These are less perfectly transparent than gum arabic, less fissured on the surface, which is brilliant and often mammillated, and are also much less friable. But the most important distinctive character of this gum consists in its relations to water. If agitated with twice or thrice its weight of cold water, instead of forming, like ordinary gum arabic, a homogeneous, slightly mucilaginous solution, it forms a thick, transparent, very tenacious magma, which cannot be diluted with a larger quantity of water, but may, after a long time, be coarsely divided, still, however, retaining its viscid, ropy aspect, which never entirely disappears, whatever may be the quantity of water added. It imparts to syrup a very thick and very viscid consistence. It is important that the apothecary should be able to distinguish it, as it is unfit for ordinary pharmaceutic use, being employed exclusively by the manufacturer in the preparation of cloths. All that is necessary is to add a few pieces to twice their weight of cold water, and allow the mixture to stand. After some hours, the peculiar, very viscid mucilage above described is developed, betraying the character of the gum. (*Note to the thirteenth edition.*)

it from other varieties. It is not entirely soluble in water, to which it imparts less viscidity than ordinary gum arabic.*

General Properties. Gum arabic is in roundish or amorphous pieces, or irregular fragments of various size, more or less transparent, hard, brittle, pulverizable, and breaking with a shining fracture. It is usually white, or yellowish-white; but frequently presents different shades of red, and is sometimes of a deep-orange or brownish colour. It is bleached by exposure to the sun. In powder it is always white. It is inodorous, has a feeble, slightly sweetish taste, and when pure dissolves wholly in the mouth. The sp. gr. varies from 1·31 to 1·48. Gum arabic consists essentially of a peculiar proximate principle usually called *gum*, but for which the name of *arabin* has been adopted. In describing its chemical relations, therefore, we describe those of the principle alluded to. Water, either cold or hot, dissolves it, and forms a viscid solution called mucilage, which, when evaporated, yields the gum unchanged. (See *Mucilago Acaciæ.*) It is insoluble in alcohol, ether, and the oils; and alcohol precipitates it from its aqueous solution. Diluted acids dissolve it, but not more freely than water. The concentrated acids decompose it. Triturated with sulphuric acid at ordinary temperatures, it is converted into a product similar to the gummy substance resulting from the action of the same acid on linen rags and sawdust. Heated with concentrated sulphuric acid, it is decomposed with the evolution of carbon. The diluted acid, when boiled with it, gives rise to the formation of a saccharine substance. Strong nitric acid converts it into mucic acid, and at the same time produces oxalic and malic acids. It combines with several salifiable bases. With the alkalies and earths it forms soluble compounds. By the subacetate of lead it is precipitated from its solution, in the form of a white insoluble compound of gum and protoxide of lead; and a delicate test of its presence in any liquid is thus afforded. It enters into combination with several salts. A solution of borax coagulates it. When added to a solution of silicate of potassa, it precipitates a compound of gum, potassa, and silica; while a compound of gum and potassa remains dissolved. Its solution yields a precipitate with nitrate of mercury, and forms a brown, semi-transparent jelly with a strong solution of sesquichloride of iron. In solu-

* Much confusion has existed in the use of the word *gum*, which has been employed to express various concrete vegetable juices, and, at the same time, a peculiar proximate principle of plants. It is now proposed to restrict the term to the former of these applications, and to designate the principle alluded to by the name of arabin. The subject of the gums was investigated by M. Guérin, who repeated and corrected the experiments of former chemists, and threw new light upon the nature of these substances. Several of the facts mentioned in the text were derived from his memoir, published in the *Ann. de Chim. et de Phys.* (t. xlix. p. 248). M. Guérin considers as characteristic of gums, the property of affording mucic acid, when acted on by nitric acid. He recognises in the different gums three distinct proximate principles; namely, 1. *arabin*, or the pure gum of chemical writers, which is the essential constituent of gum arabic; 2. *bassorin*, which enters largely into the composition of Bassora gum and tragacanth; and 3. *cerasin*, which constitutes the portion of cherry gum insoluble in cold water. Of arabin sufficient is said in the text. Bassorin will be treated of under the head of Bassora gum. (See *Part Third.*) Of *cerasin* it may be proper to say a few words in this place. The gums which exude from the cherry, apricot, peach, and plum trees, and which the French call *gomme du pays*, appear to be identical in composition, consisting of a portion soluble in cold water, which is arabin, and a portion insoluble, which was formerly thought to be bassorin, but has been proved by M. Guérin to be different, and is appropriately denominated *cerasin*. This principle is colourless, semi-transparent, tasteless, inodorous, uncrystallizable, insoluble in alcohol, insoluble in cold water in which it softens and swells a little, and convertible by the action of boiling water into arabin, with which it appears to be isomeric. In this last property it differs from bassorin, which is not changed by boiling water. M. Guérin suggests that the heat of the climate, in tropical countries, produces the same effect upon the exuded gums as artificial heat in colder regions, and that consequently the acacia gum consists chiefly of arabin. (*Note to the third edition.*)

From the observations of Dr. Kützing, it would appear that the spontaneously exuded gum of the plum, cherry, &c., is sometimes at least the product of a diseased cell-action, and contains remains of the cells, probably analogous to the epithelial constituent of animal mucus. (See *Am. Journ. of Pharm.*, xxv. 39.)—*Note to the tenth edition.*

tion it unites with sugar; and the liquid, when evaporated, yields a transparent, solid substance, insusceptible of crystallization.*

Gum arabic undergoes no change by time, when kept in a dry place. Its aqueous solution, if strong, remains for a considerable time unaltered, but ultimately becomes sour, from the production of acetic acid. The tendency to become sour is increased by employing hot water to dissolve it. Mixed with chalk and cheese, at ordinary temperatures, it undergoes a fermentation, resulting in the production of alcohol, without an antecedent formation of sugar. (*Journ. de Pharm. et de Chim.*, 3e sér., xxxii. 261.) Between 300° and 400°, the gum softens, and may be drawn into threads. At a red heat it is decomposed, yielding, among other substances, a minute proportion of ammonia. When burnt, it leaves about 3 per cent. of ashes, consisting, according to Guérin, of carbonates of potassa and lime, a little phosphate of lime, chloride of potassium, oxide of iron, alumina, magnesia, and silica. The lime is now supposed to exist in the gum combined with gummic or arabic acid, and this compound constitutes pure gum or arabin. In consequence of the presence of lime, oxalate of ammonia occasions a precipitate with the solution. Besides pure gum, gum arabic contains a very small proportion of an azotized body, which is thought to occasion a slight opalescence in its solution, several saline substances, and 16 to 17 per cent. of uncombined water. (*Guérin.*) Pure gum (or more properly gummic acid) may be obtained by treating the compound of gum and protoxide of lead with sulphuretted hydrogen. Its ultimate constituents are carbon, hydrogen, and oxygen; its generally admitted formula being $C_{12}H_{11}O_{11}$.

The properties above enumerated belong to gum arabic generally. There

* *Arabin or Pure Gum. Gummic Acid. Arabic Acid.* At the time of the publication of the eleventh edition of this work, experiments by Löwenthal, reported by Neubauer, had led to the supposition that arabin or pure gum, instead of being a distinct proximate principle, was really complex, consisting of an insoluble acid united with a small proportion of lime or other base, forming a soluble compound. Since that period, the subject of the gums generally, and of gum arabic in particular, has received a new and interesting development through the researches of M. Fremy. The following are the conclusions to which these researches have led.

1. Pure gum or arabin consists of a substance soluble in water, having acid properties, and hence called *gummic acid* (*arabic acid*, Gmelin, Handbook, xv. 193), combined with about 3 per cent. of lime, forming a soluble salt. In other words, the arabin of Guérin is *gummate of lime*. Gummic acid may be obtained in a soluble state by decomposing gum arabic by means of oxalic acid, which separates the lime without modifying the condition of the acid.

2. Under the influence of concentrated sulphuric acid, applied in a peculiar manner, or of a heat of about 300° F. maintained for several hours, gummic acid undergoes a molecular change, by which it is converted into an isomeric substance, also feebly acid, which M. Fremy calls *metagummic acid*, and of which the distinctive property is that it swells up with water without dissolving, acting in this respect like cerasin and bassorin.

3. When this insoluble metagummic acid is exposed to the action of boiling water alone, it undergoes no change; but, if small quantities of a base, such as potassa, soda, ammonia, baryta, or lime are added, it is immediately dissolved, having been reconverted, under the influence of these bases, into gummic acid, which forms soluble salts with them; and the salt thus formed has all the characters of gum arabic.

4. Gum arabic itself, as ascertained by M. Gélis, undergoes the same change under the operation of a high temperature; being converted from a gummate into a metagummate of lime, which swells up in cold water without dissolving, but by boiling water is rendered again soluble, being reconverted into gummate of lime.

5. According to M. Fremy, *cerasin* is nothing more than *metagummate of lime*, being, as is well known, changed by boiling with water into arabin, in other words, gummate of lime, or gum arabic.

6. Hence, M. Fremy supposes that, in plants, metagummic acid is first formed, which in the progress of vegetation is more or less completely changed into gummic acid, thus giving rise to different varieties of gum, distinguished by the greater or less proportion of the soluble to the insoluble ingredients.

7. Bassorin, however, when boiled with water and an alkali, though rendered soluble, is not, like cerasin, converted into gum arabic or arabin; the soluble gum which results being precipitated from its aqueous solution by neutral acetate of lead, which is not the case with gum arabic. (*Journ. de Pharm. et de Chim.*, Fev. 1860, p. 81.)—*Note to the twelfth edition.*

are, however, pharmaceutic varieties with differences which deserve notice. 1. *Gum that is transparent and readily soluble.* This constitutes by far the greater portion of the commercial varieties distinguished by the names of Turkey and Senegal gum. It is characterized by its transparency, ready solubility, and the comparatively slight degree of thickness and viscidity of its solution. Under this head may be included the *gomme blanche fendillée* of Guibourt. It is distinguished by the whiteness and deficient transparency of the pieces, attributable to the minute cracks or fissures with which they abound, and which render them very brittle and easily pulverizable. This peculiar structure is generally ascribed to the influence of solar heat and light; but is conjectured by Hayne to arise from the exudation of the juice in the frothy state noticed by Ehrenberg. Though the unbroken pieces are somewhat opaque, each minute fragment is perfectly transparent and homogeneous. This variety, in consequence of its prompt and entire solubility, is usually preferred for medical use, and for most purposes in pharmacy. 2. *Gum less transparent and less soluble.* Guibourt has proposed for portions of this gum the name of *gomme pelliculée*, from the circumstance that the masses are always apparently covered, on some part of their surface, by a yellowish opaque pellicle. Other portions of it have a mammillary appearance on the surface. It is less transparent than the former variety, is less freely and completely dissolved by water, and forms a more viscid solution. It melts with difficulty in the mouth, and adheres tenaciously to the teeth. It is found in all the commercial varieties of gum, but least in that from Egypt. Its peculiarities have been ascribed to variable proportions of *bassorin* or *cerasin* associated with the soluble *arabin*. Between these two varieties of gum there are insensible gradations, so that it is not always easy to classify specimens.

Impurities and Adulterations. In parcels of gum arabic there are sometimes pieces of a dark colour, opaque, and incorporated with ligneous, earthy, or other impurities. The inferior are often mixed with or substituted for the better kinds, especially in powder; and portions of insoluble gum, bdellium, and other concrete juices of unknown origin, are found among the genuine. Flour or starch is sometimes fraudulently added to the powder, but is easily detected by the blue colour which it produces with tincture of iodine. In consequence of the impurities and difference in quality, gum arabic should generally be assorted for pharmaceutic use. A foreign substance sometimes adheres to its surface, giving it a bitter taste, from which it may be freed by washing in water.* *Dextrin*, broken into small fragments, has been mingled with parcels of gum. It may be known by yielding, in solution, a reddish-purple colour with solution of iodine. It does not, like gum, produce a yellowish or brownish jelly with solutions of the sesquisalts of iron.

Medical Properties and Uses. This gum is used in medicine chiefly as a demulcent. By the viscidity of its solution, it serves to cover and sheathe inflamed surfaces; and, by blending with and diluting irritating matters, blunts their acrimony. Hence, it is advantageously employed in catarrhal affections and irritation of the fauces, by being held in the mouth and allowed slowly to dissolve. Internally administered, it has been found useful in inflammations of

* *Bleaching of gum.* M. Picciotto proposes to purify coloured gum by dissolving it in six or eight parts of a strong and pure solution of sulphurous acid, heating the solution, treating it with carbonate of baryta in excess, then filtering, and evaporating at a moderate heat. (*Pharm. Journ. and Trans.*, ix. 16.)—*Note to the ninth edition.*

M. Picciotto has since proposed a better method, consisting in dissolving the gum in 6 to 18 parts of water, passing the solution through linen, and then mixing it with gelatinous alumina freshly precipitated. A pap-like substance is formed; and the colouring matter is so fixed by the alumina, that when the mixture is placed on a linen strainer, the mucilage escapes colourless; or, if not entirely so at first, becomes so on a repetition of the process. The alumina may be used a second time. To recover the alumina, it may be washed with hot water to separate the remaining gum, then treated with chlorine water, or hypochlorite of lime, and finally washed with boiling water. (*Journ. de Pharm. et de Chim.*, Juillet, 1867, p. 55.)—*Note to the thirteenth edition.*

the gastric and intestinal mucous membrane; and its employment has even been extended to similar affections of the lungs and urinary organs. Whether it is beneficial, in the latter cases, in any other manner than by the dilution resulting from its watery vehicle, is doubtful. By some it has been thought to possess a positively sedative influence over inflamed surfaces to which it may be applied in the state of solution. It is a good article of diet in cases of high febrile and inflammatory action, requiring a very rigid regimen. If not positively sedative, it is certainly not in the least irritating; while it is sufficiently nourishing to prevent the injurious action of the organs upon themselves. Its nutritive properties have been denied; but the fact of their existence rests on incontrovertible evidence. The Moors and negroes live on it almost exclusively during the period of its collection and conveyance to market; the Bushman Hottentots, in times of scarcity, support themselves upon it for days together; and we are told that the apes of South Africa are very fond of it. Six ounces a day are said to be sufficient to sustain life for a time in a healthy adult. In many cases of disease, its solution may constitute, for a short period, the exclusive drink and food of the patient. It is best prepared by dissolving an ounce of the gum in a pint of boiling water, and allowing the solution to cool. An excellent demulcent, called *gum-pectoral*, is made by dissolving equal parts of gum arabic and sugar in water, and evaporating by means of a water-bath. It is held in the mouth, and allowed slowly to dissolve.* In pharmacy, gum arabic is extensively used for the suspension of insoluble substances in water, and for the formation of pills and troches.

ACETUM. *U. S., Br.*

Vinegar.

Impure dilute Acetic Acid prepared by fermentation. *U. S.* An acid liquid, prepared from malt and unmalted grain by the acetous fermentation. *Br.*

Vinaigre, *Fr.;* Essig, *Germ.;* Aceto, *Ital.;* Vinagre, *Span.*

Vinegar is a sour liquid, the product of the acetous fermentation. Viewed chemically, it is a very dilute solution of acetic acid, containing certain foreign matters.

The *acetous fermentation* may be induced in all liquors which have undergone or are susceptible of the vinous fermentation. Thus sugar and water, saccharine vegetable juices, infusion of malt, cider, and wine may be converted into vinegar, if subjected to the action of a ferment, and exposed, with access of air, to a temperature between 75° and 90°. During the acetous fermentation, a microscopic vegetable growth has been noticed, which Pasteur has shown to be a cryptogam of the genus *Mycoderma*, and which appears to be essential to the process. By the presence and influence of this plant, the germs of which exist in the atmosphere, alcohol sufficiently diluted with water is converted into acetic acid, as sugar in solution is, through the agency of an analogous growth, converted into alcohol.

Vinegar is generally made by the *German process*, by which the time con-

* *Jujube paste. Marsh-mallow paste. Iceland moss paste.* Under these names, preparations are sold in the shops which are essentially the *gum-pectoral* of the text, containing little or none of the substances which give them distinctive names. Prof. Procter has favoured us with the following formula, according to which they are made. Take of gum arabic 8 lbs., of sugar 12 lbs. avoirdupois, the whites of two dozen eggs, and 5 pints of water. Heat together the gum and water, by means of steam, to 220°, stir till dissolved, strain forcibly, stir in the sugar quickly, and, when it is dissolved, add the white of eggs previously well beaten, stirring constantly, and at the same time remove from the fire. If made in real accordance with the name, decoction of marsh-mallow or Iceland moss must be substituted for the water. (*Note to the twelfth edition.*)

sumed in its formation is greatly abridged. A mixture is prepared of one part of alcohol of 80 per cent., four or six parts of water, and one-thousandth of honey or extract of malt, to act as a ferment. This mixture is allowed to trickle through a mass of beech shavings, previously steeped in vinegar, and contained in a deep oaken tub, called a *vinegar generator*. The tub is furnished, near the top, with a wooden diaphragm perforated with numerous small holes, which are loosely filled with packthread about six inches long, prevented from slipping through by a knot at one end. The alcoholic mixture, heated to between 75° and 83°, is placed on the diaphragm, and slowly percolates the beech shavings, whereby it becomes minutely divided. It is essential to the success of the process that a current of air should pass through the tub. In order to establish this current, eight equidistant holes are pierced near the bottom of the tub, forming a horizontal row, and four glass tubes are inserted vertically in the diaphragm, of sufficient length to project above and below it. The air enters by the holes below, and passes out by the tubes. The contact of the air with the minutely divided liquid rapidly promotes the acetification, which consists, essentially, in the oxidation of the alcohol. During the process the temperature rises to 100° or 104°, and remains nearly stationary while the process is going on favourably. The liquid is drawn off by a discharge pipe near the bottom, and must be passed three or four times through the tub, before the acetification is completed, which generally occupies from twenty-four to thirty-six hours. According to Wimmer, pieces of charcoal, about the size of a walnut, may be substituted for the beech shavings in the process, with the effect of expediting the acetification. The charcoal must be deprived of saline matter by dilute muriatic acid, and afterwards washed with water. M. Pasteur denies that the more rapid acetification, produced by enlarging the surface of contact with the atmosphere, by means of packthread, beech shavings, &c., is owing to the direct influence of the air, and ascribes it to the presence of mycoderms upon the surface of these substances.

In England vinegar is made from the infusion of malt by the German process, which is said to have originated with Mr. Ham, of Bristol, England, as early as 1822. The fermented wort is made to fall in a shower upon a mass of fagots of birch twigs, occupying the upper part of a large vat, and, after trickling down to the bottom, is pumped up repeatedly to the top, to be again allowed to fall, until the acetification is completed. This mode of oxidizing the alcohol in the fermented wort has the advantage of rendering insoluble certain glutinous and albuminous principles, which, if not removed, would cause a muddiness in the vinegar, and make it liable to spoil.

In the United States, vinegar is often prepared from cider. When it is made on a large scale, the cider is placed in barrels with their bung-holes open, which are exposed during the summer to the heat of the sun. The acetification is completed in the course of about two years. The progress of the fermentation, however, must be watched; and, as soon as perfect vinegar is formed, it should be racked off into clean barrels. Without this precaution, the acetous fermentation would run into the putrefactive, and the vinegar be spoiled. Cider vinegar contains no aldehyd. It contains malic acid, and therefore yields a precipitate with acetate of lead. The want of such a precipitate would indicate that the supposed cider vinegar is probably a manufactured substitute.

Vinegar may be clarified, without impairing its aroma, by throwing about a tumblerful of boiling milk into from fifty to sixty gallons of the liquid, and stirring the mixture. This operation has the effect, at the same time, of rendering red vinegar pale.

The series of changes which occur during the *acetous fermentation* is called *acetification*. During its progress, there is a disengagement of heat; the liquor absorbs oxygen and becomes turbid; and filaments form, which are observed to move in various directions, until, finally, upon the completion of the fermentation, they are deposited in a mass of a pultaceous consistence. The liquor now becomes transparent, its alcohol has disappeared, and acetic acid has been

formed in its place. How is this change of alcohol into acetic acid effected? Liebig supposes that it takes place in consequence of the formation of aldehyd, into which the alcohol is changed by the loss of a part of its hydrogen. The alcohol, consisting of four eqs. of carbon, six of hydrogen, and two of oxygen, loses two eqs. of hydrogen through the influence of the atmosphere, and becomes aldehyd, composed of four eqs. of carbon, four of hydrogen, and two of oxygen. This, by the absorption of two eqs. of oxygen, becomes four eqs. of carbon, four of hydrogen, and four of oxygen; that is, hydrated acetic acid ($C_4H_3O_3,HO$). Thus the conversion of alcohol into acetic acid consists in, first, the removal of two eqs. of hydrogen, and afterwards the addition of two eqs. of oxygen. *Aldehyd* is a colourless, very inflammable, ethereal liquid, having a pungent taste and smell. Its density is 0·79. It absorbs oxygen with avidity, and is thus converted into acetic acid, as just stated. Its property of absorbing oxygen gives it a reducing power, like that possessed by glucose. Hence, Trommer's test for glucose may be applied to the detection of aldehyd. A few drops of solution of sulphate of copper is added to the solution suspected to contain aldehyd, and then a solution of potassa in excess. The liquid is next heated nearly to the boiling point, which will cause the precipitation of red suboxide of copper, if aldehyd be present. The name, aldehyd, alludes to its relation to alcohol, *al*cohol *dehyd*rogenated. Its aqueous solution is decomposed by caustic potassa, with formation of *aldehyd resin*. This is a soft, light-brown mass, which, heated to 212°, gives off a nauseous soapy smell.*

Properties. Vinegar, when good, is of an agreeable penetrating odour, and pleasant acid taste. According to Magnes Lahens, wine vinegar always contains a little aldehyd. The better sorts of vinegar have a grateful aroma, which is probably due to the presence of an ethereal substance, perhaps acetic ether. The colour of vinegar varies from pale yellow to deep red. When long kept, especially if exposed to the air, it becomes muddy and ropy, acquires an unpleasant smell, putrefies, and loses its acidity.

The essential ingredients of vinegar are acetic acid and water; but, besides

* To the above account of acetous fermentation by Dr. Bache, the progress of science requires that some addition should be made. It has been shown that, as the alcoholic and most other fermentative processes, the acetous is necessarily connected with the presence of a microscopic plant, which is generally believed to be the real cause of the changes by which the alcohol is converted into acetic acid. The organism is, in this instance, the *Mycoderma aceti*, which is one of the simplest of vegetables, consisting of articulated structures, somewhat compressed at the middle, about $\frac{1}{3000}$ of a millimeter in diameter, and twice as long. Without the presence of this mycoderm, alcohol, so far as is known, never undergoes acetification, whatever quantity of albuminoid matter, formerly supposed to act as the ferment, may be present; and, with the mycoderm, the process will take place, even in the absence of albuminoid matter, provided there exist in the liquid a little alkaline and earthy phosphate. Hence it is inferred that the albuminoid substances, usually employed as ferment, act merely as nourishment for the mycoderm. The pultaceous mass referred to in the text, formed during the fermentation, and commonly called *mother of vinegar*, because vulgarly supposed to be essential to its production, consists of this mycoderm, portions of which, spread over the beechwood shavings, in the German process for manufacturing vinegar, produce acetification. The mycoderm probably acts by oxidizing the alcohol, deriving oxygen itself from the air; and hence it is necessary that it should be at the surface of the liquid; and the fermentation is suspended on its submersion. When the whole of the alcohol has been consumed in the process, the mycoderm, if it continues present, extends its oxidizing influence to the acetic acid, which is thus converted into water and carbonic acid. For the development of these facts in reference to the acetous fermentation, science is indebted to the researches of Pasteur. (See *Am. Journ. of Pharm.*, Sept. 1865, p. 343.)

It is well known that, in certain kinds of vinegar, little eel-like animals may be seen in great numbers. Their origin has been unknown, until they were shown by M. Davaine to be developed in most fruits, as the apple, plum, peach, cherry, &c., in great numbers, and thus their presence in cider-vinegar can easily be explained. These little animals need air for their support; and a curious contest may sometimes be noticed between them and the mycoderm upon the surface, which, as it tends to consume all the oxygen absorbed, the little eels combine their efforts to submerge, so as to expose the liquid freely to the air. (*Ibid.*, also *Neues Repert. für Pharm.*, 1865, band xiv., no. 809, s. 427.)—*Note to the thirteenth edition.*

these, it contains various other substances, derived from the particular vinous liquor from which it may have been prepared. Among these may be mentioned, colouring matter, gum, starch, gluten, sugar, a little alcohol, and frequently malic and tartaric acids, with a minute proportion of alkaline and earthy salts. According to the U.S. Pharmacopœia, vinegar should be devoid of lead and copper and of free sulphuric acid, as shown by its not being discoloured by sulphuretted hydrogen, and yielding no precipitate when boiled with a solution of chloride of calcium; and of such a strength that a fluidounce would require, for saturation, not less than thirty-five grains of crystallized bicarbonate of potassa. After saturation it should be free from acrid taste, indicating the absence of acrid substances, the taste of which may have been concealed by that of the acetic acid.

In the late Edinburgh Pharmacopœia, two kinds of vinegar were officinal, malt vinegar and wine vinegar, under the names of *British vinegar* and *French vinegar*. The present British Pharmacopœia now recognises only the former.

Malt vinegar (Acetum Britannicum) has a brown colour, and a sp. gr. from 1·006 to 1·019. The strongest kind, called *proof vinegar*, contains from 4·6 to 5 per cent. of acetic acid. That of British manufacture usually contains sulphuric acid, which the manufacturer is allowed by law to add in a proportion not exceeding one part in a thousand. This addition was at one time thought necessary to preserve the vinegar; but it is now admitted that, if the vinegar be properly made, it does not require to be thus protected.

As ordered by the British Pharmacopœia, "it has a sp gr. of 1·017 to 1·019; one fluidounce of it (445·4 grains) require at least 402 grain-measures of the *volumetric solution of soda* for neutralization, corresponding to 4·6 per cent. of anhydrous acetic acid. If ten minims of solution of chloride of barium be added to a fluidounce of the vinegar, and the precipitate, if any, be separated by filtration, a further addition of the test will give no precipitate. Sulphuretted hydrogen causes no change of colour." *Br.* The chloride of barium test admits the presence of 1 part in 1000 of sulphuric acid. The non-action of sulphuretted hydrogen indicates the absence of metals generally.

Wine vinegar (Acetum Gallicum) is nearly one-sixth stronger than pure malt vinegar. It is of two sorts, the white and the red, according as it is prepared from white or red wine. *White wine vinegar* is usually preferred, and that made at Orleans is the best. *Red wine vinegar* may be deprived of its colour, and rendered limpid, by being passed through animal charcoal. According to the late Edinburgh Pharmacopœia, wine vinegar may be distinguished from malt vinegar by the addition of ammonia in slight excess, which causes in the former "a purplish muddiness, and slowly a purplish precipitate," and in the latter, either no effect, or a dirty-brownish precipitate.

Adulterations. The principal foreign substances which vinegar is liable to contain, are sulphuric and sulphurous acids, certain acrid substances, and copper and lead, derived from improper vessels used in its manufacture. Tin has been found in it after standing a short time in tin vessels. Muriatic and nitric acids are but rarely present. Chloride of calcium will detect free sulphuric acid, when boiled with the vinegar, without causing the least precipitate with the minute quantity of sulphates, almost always present in the liquid. (*Boettger.*) Chloride of barium is not a suitable test here; as it will cause a precipitate with these sulphates, when no free sulphuric acid is present. Sulphurous acid may be detected and estimated by first precipitating the sulphates and free sulphuric acid by baryta-water, next acting on the vinegar with arsenic acid, which converts sulphurous into sulphuric acid, and finally precipitating the newly formed sulphuric acid by chloride of barium. From the sulphuric acid in the last precipitate, its equivalent of sulphurous acid is easily calculated. (*Laroque.*) Muriatic acid may be discovered by adding to a distilled portion of the suspected vinegar a solution of nitrate of silver, which will throw down a curdy white precipitate, insoluble in nitric acid. If nitric acid be present, an improbable impurity, it may be detected by producing a yellow colour, when the sus-

pected vinegar is boiled with indigo. The acrid substances usually introduced into vinegar are red pepper, long pepper, pellitory, grains of paradise, and mustard seed. These may be detected by evaporating the vinegar to an extract, which will have an acrid, biting taste, if any one of these substances be present. By far the most dangerous impurities in vinegar are copper and lead. The former may be detected by a brownish precipitate on the addition of ferrocyanide of potassium to the concentrated vinegar; the latter, by a blackish precipitate with sulphuretted hydrogen, and a yellow one with iodide of potassium. Pure vinegar is not discoloured by sulphuretted hydrogen. According to Chevallier, wine vinegar, which has been strengthened with acetic acid from wood, sometimes contains a minute proportion of arsenic. The deleterious metal is probably derived from arseniferous sulphuric acid, employed in preparing the acetic acid.

Medical Properties. Vinegar acts as a refrigerant and diuretic. With this view it is added to diluent drinks in inflammatory fevers. It is sometimes used as a clyster, diluted with twice or thrice its bulk of water. It has been supposed to be a powerful antidote to the narcotic poisons, but this is a mistake. In the case of opium, the best authorities unite in considering it worse than useless; as it gives activity to the poison rather than neutralizes it. Externally it is employed as a fomentation in bruises and sprains. Diluted with water, it forms the best means of clearing the eye from small particles of lime. Mixed with an equal measure of water, strong cider-vinegar was successfully used by Dr. A. H. Hunt, of Wayne Co., Ohio, by injection into the bladder, for breaking up and removing clotted blood from the cavity of that viscus. (*Med. and Surg. Reporter*, Sept. 14, 1867, p. 222.) Its vapour is inhaled in certain states of sorethroat, and it is diffused through sick rooms under the impression that it destroys unwholesome effluvia, though, in fact, it has no other effect than to cover unpleasant smells. The dose is from one to four fluidrachms; as a clyster, the quantity used is one or two fluidounces.

Achillea Millefolium. Willd. *Sp. Plant.* iii. 2208; Woodv. *Med. Bot.* p. 36, t. 15. Milfoil or yarrow is a perennial herb, common to the old and new continents, though supposed to have been introduced into this country from Europe. It abounds in old fields, along fences, and on the borders of woods and of cultivated grounds, throughout the United States. It is from a foot to eighteen inches high, and is specifically distinguished by its doubly pinnate, downy, minutely divided leaves, with linear, dentate, mucronate divisions, from which it derived the name of milfoil, by its furrowed stem and calyx, and by its dense corymb of whitish flowers, which appear throughout the summer, from June to September. The whole herb is medicinal.

Properties. Both the flowers and leaves have an agreeable, though feeble aromatic odour, which continues after drying, and a bitterish, astringent, pungent taste. The aromatic properties are strongest in the flowers, the astringency in the leaves. The plant owes its virtues to a volatile oil, a bitter extractive, and tannin. It contains also a peculiar acid, denominated *achilleic acid.* The oil, which may be obtained separate by distillation with water, has a beautiful

azure-blue colour, and the peculiar flavour of milfoil. The active principles are extracted both by water and alcohol.

Medical Properties. The medical properties of the herb are those of a mild aromatic tonic and astringent. In former times it was much used as a vulnerary, and was given internally for the suppression of hemorrhages, and of profuse mucous discharges. It was employed also in intermittents, and as an antispasmodic in flatulent colic and nervous affections. It has recently been highly recommended by M. Richart, of Soissons, in low forms of exanthematous fevers with difficult eruption, in colic, painful menstruation, and infantile convulsions. He uses the infusion at once as a drink, an injection, and fomentation. (*Journ. de Pharm. et de Chim.*, xviii. 62.) Dr. B. H. Coates, of Philadelphia, has found it useful in hemorrhage (*Trans. of Philad. Col. of Phys.*, N. S., ii. 334); and Dr. R. Joly, of France, has used it very advantageously as an emmenagogue, and states that it is much employed popularly, in his neighbourhood, for the same purpose. (*Bullet. Gén. de Thérap.*, Mars, 1857.) He has also found it useful in the suppressed lochia. In some parts of Sweden it is said to be employed as a substitute for hops in the preparation of beer, which it is thought to render more intoxicating. It is most conveniently administered in the form of infusion, which may be made in the proportion of an ounce to the pint, and given in the dose of a wineglassful or more. The volatile oil has been given in the dose of twenty or thirty drops. W.

ACIDUM ACETICUM. *U. S., Br.*

Acetic Acid.

Acetic acid of the sp. gr. 1·047, and containing 36 per cent. of *monohydrated* acetic acid. *U. S.* An acid liquid prepared from wood by destructive distillation and subsequent purification; 100 parts by weight contain 33 parts of the acetic acid, $HO,C_4H_3O_3$, corresponding to 28 parts of anhydrous acetic acid, $C_4H_3O_3$. *Br.*

ACIDUM ACETICUM GLACIALE. *Br.*

Glacial Acetic Acid.

Concentrated Acetic Acid, corresponding to at least 84 per cent. of anhydrous acid, $C_4H_3O_3$. *Br.*

Exclusively of *Acidum Aceticum Dilutum*, which will be noticed in the second part of this work, two strengths of acetic acid are now officinal in the U. S. and British Pharmacopœias, assuming those acids to be identical which approach most nearly to equality in specific gravity. These are the *Acidum Aceticum Glaciale*, Br., of the sp. gr. 1·065 to 1·066, and the *Acidum Aceticum*, U. S , Br., of the sp. gr. 1·047 as directed by our officinal standard, and 1·044 by the British.

We shall consider these grades separately, in the order of their strength.

Acidum Aceticum Glaciale, sp. gr. 1·065 to 1·066. *Br.* A process for this preparation was given in the British Pharmacopœia of 1864, which consisted in first heating acetate of soda so as to drive off all its water of crystallization, then, after cooling, distilling it with concentrated sulphuric acid, and, finally, if the resulting acetic acid, upon being tested with a mixture of solution of iodate of potassa and a little mucilage of starch, was found to contain sulphurous acid, agitating the distilled acid with perfectly dry black oxide of manganese, and again distilling. The object of the process was to furnish an acid of the maximum strength, containing one eq. of dry acid with one of water derived from the sulphuric acid. But, on trial, it was not found to be satisfactory, as the resulting acid was not truly glacial, and always contained sulphurous acid. (C. H. Wood, *Pharm. J. and Trans.*, July, 1867, p. 17.) The acetate of lead, which was employed for the same purpose by the Edinburgh

and Dublin Colleges, is said to yield a purer product, though objectionable from the liability of being by accident contaminated with lead. In the Dublin method, well-dried acetate of lead was decomposed by dry muriatic acid gas, and the liberated acetic acid distilled over. It is said that acetate of lime is preferable to either of the salts mentioned, because better able to bear without decomposition the heat necessary to dry it. (*Ibid.*)* It is affirmed, however, by Prof. Redwood, that the true monohydrated acetic acid cannot be produced by this process, nor by any other on a small scale, and that to obtain it recourse must be had to the manufacturer, who operates on large quantities of the material. (*Pharm. Journ. and Trans.*, March, 1864, p. 411.) It was, therefore, wise in the revisers of the British Pharmacopœia to abandon the process, and trust to the manufacturer, securing a proper purity and strength of the acid by giving precise directions on these points.

Acetic acid of maximum strength may be obtained by distilling binacetate of potassa at a heat between 390° and 570°. One eq. of monohydrated acetic acid distils over, and neutral acetate of potassa is left. The binacetate may be formed by evaporating a mixture of the neutral acetate with an excess of watery acetic acid. In this process, the same acetate of potassa serves repeatedly for conversion into binacetate, and subsequent decomposition. This process is said to be employed by manufacturers on a large scale in some parts of the continent of Europe. It originated with M. Melsens.

Acidum Aceticum, *U. S.*, *Br.* (sp. gr. 1·047, *U. S.*, 1·044, *Br.*). This is the acid resulting from the purification of the crude acetic acid, obtained by the destructive distillation of wood. It is the acid most useful to the apothecary, and which gives the first heading to this article. As this grade of acid has its source in the impure acetic acid, obtained by the destructive distillation of wood, it will be proper to premise some account of the crude acid, called *crude pyroligneous acid.*

Wood, when charred, yields many volatile products, among which are an acid liquor, an empyreumatic oil, and tar containing creasote and some other proximate principles. When the carbonization is performed in close vessels, these products, which are lost in the ordinary process of charring, may be collected, and, at the same time, a large amount of charcoal is obtained.

The carbonization of wood in close vessels, with a view to collect the condensible products, was first put in practice by Mollerat in France. The apparatus employed at Choisy, near Paris, is thus described by Thenard. It consists of 1st, a furnace with a movable top; 2d, a strong sheet-iron cylinder, standing upright, sufficiently capacious to contain a cord of wood, and furnished with a sheet-iron cover; 3d, a sheet-iron tube, proceeding horizontally from the upper and lateral part of the cylinder to the distance of about a foot; 4th, a copper tube connected with the last, which is bent in such a manner as to plunge successively to the bottom of two casks filled with water, and, after rising out of the second, is bent back, and made to terminate in the furnace. At the bottom of each cask, the tube dilates into a ball, from the upper part of which another tube proceeds, which, passing water-tight through the cask, terminates above a vessel intended to receive the condensible products.

* The process of the late British Pharmacopœia is contained, in detail, in the 12th edition of the U. S. Dispensatory (*page* 17), that of the Dublin College in the 11th edition (*page* 17), and that of the Edinburgh College, in which acetate of lead was decomposed by sulphuric acid, in the same place. The process said to have been principally followed by the British manufacturer is the following. One cwt. of purified acetate of soda, which had previously been deprived of water by fusion, and broken up after cooling, was digested with 60 lbs. of sulphuric acid, of sp. gr. 1·848, and then heated in a still till all the acetic acid was driven over. This was redistilled, in a chloride of calcium or oil bath, with peroxide of manganese, and afterwards again distilled from charcoal and peroxide of lead. The acid thus procured, being placed in ice, was in great measure solidified; and, the liquid portion being decanted, the solid residue, when melted, had the sp. gr. 1·067, and contained 98 per cent. of the monohydrated acid. (Heathfield, *Pharm. Journ. and Trans.*, 2d ser., vii. 188.)—*Note to the thirteenth edition.*

The sheet-iron cylinder, being filled with wood, in the state of billets, or, as some prefer, in that of sawdust, and closed by luting on its cover with fire clay, is let down into the furnace by the help of a crane. The fire is then applied; and, when the process is completed, the cylinder is removed by the same means, to be replaced by another. During the carbonization, the volatile products are received by the tube; and those which are condensible, being an acid liquor and tar, are condensed by the water in the casks, and collect in the lower bends of the tubes, from which they run into the several recipients; while the incondensible products, being inflammable gases, are discharged into the furnace, where, by their combustion, they assist in maintaining the heat. Eight hundred pounds of wood afford, on an average, thirty-five gallons of acid liquor, weighing about three hundred pounds.

This is the crude pyroligneous acid, sometimes called *pyroligneous vinegar*. It is a dark-brown liquid, having a strong smoky smell, and consists of acetic acid diluted with more or less water, and holding in solution chiefly tar and empyreumatic oil, with pyroxylic spirit, and probably a small proportion of creasote. It is from this crude acid that the U. S. and British acetic acid, corresponding to the acetic acid of commerce, is obtained. The purification is effected as follows. The acid is saturated with cream of lime, whereby acetate of lime is formed in solution, and a good deal of the tarry matter precipitated. The solution of acetate of lime is then mixed with a concentrated solution of sulphate of soda, and, by double decomposition, acetate of soda is formed in solution, and sulphate of lime precipitated. The solution of acetate of soda is next subjected to evaporation, during which further impurities that separate on the surface are skimmed off. The solution, being duly concentrated, is set aside to crystallize; and the impure salt thus obtained, after having been partially purified by solution and recrystallization, is fused in an iron vessel, stirred until it dries, and, the heat being carefully raised, subjected to incipient carbonization, whereby remaining empyreumatic matters are carbonized, with little damage to the salt. The mass is then dissolved in water, and the solution, being strained and recrystallized, furnishes pure acetate of soda. (See *Sodæ Acetas*.) Finally, this salt is distilled with from 34 to 35 per cent. of its weight of sulphuric acid, when it yields the acetic acid of commerce, the residue being sulphate of soda, which is reserved for decomposing fresh portions of acetate of lime. The acid has still an empyreumatic flavour, which is removed by filtering it through animal charcoal.

Sometimes the acetate of lime is distilled with sulphuric acid directly, without having been previously converted into acetate of soda, by which mode of proceeding a step in the process is saved. But this is attended with many inconveniences, and the acetic acid obtained is apt to contain sulphuric acid. The same step is saved, and without this risk, by distilling the acetate of lime with hydrochloric acid, as recommended by Christl; and, if the acid be not in excess, the acetic acid obtained scarcely contains a trace of chlorine.*

The sp. gr. of the different acetic acids increases with their strength up to the density of 1·0735 (maximum), after which it decreases until it reaches 1·063. the density of the strongest acid (*glacial acid*). The following table, condensed from one given by Pereira on the authority of Mohr, exhibits the sp. gr. of acetic acid of different strengths, including the officinal Acidum Aceticum Dilutum. The officinal and commercial acids are noted opposite to their several densities, and the corresponding number in the column on the left gives the percentage of *monohydrated* acid in each.

* M. Richter prefers the acetate of baryta to that of soda, because the fusibility of the latter somewhat interferes with the operation; but adds to the baryta salt 2 per cent. of the acetate of soda, in order in some measure to obviate its tendency to become pulverulent. (*Journ. de Pharm. et de Chim.*, 4 sér., v. 159.)—*Note to the thirteenth edition.*

Per cent. of Acid.	Specific Gravity.		Per cent. of Acid.	Specific Gravity.

54	1·063	Acid corresponding in sp. gr. to the strongest.	20	1·027	
			10	1·015	
52	1·062		6	1·008	Diluted acetic acid, *Lond.*
50	1·060		5	1·006	Diluted acetic acid, *U.S.*, *Br.*
40	1·051		4	1·0055	
39	1·050	English acid of commerce.	3	1·004	Diluted acetic acid, *U.S.* 1850.

Up to the specific gravity 1·062, the density of acetic acid is a pretty accurate index of its strength; but above that specific gravity, two acids of different strengths may coincide in density. Thus, by the table, it is seen that an acid weighing 1·063 may be either the strongest possible liquid acid, or an acid containing only 54 per cent. of such acid. The ambiguity may be removed by diluting the acid with a portion of water, when, if the density be increased, the given specimen is the stronger acid of the two having the same density. Hence the test, in the British Pharmacopœia, of adding 10 per cent. of water to their glacial acetic acid. The density of the English and Scotch acetic acids of commerce is given on the authority of Dr. Christison.

Properties of the Glacial Acid (Acidum Aceticum Glaciale, *Br.*). This acid, sometimes called *radical vinegar*, is a colourless, volatile, inflammable liquid, possessing a corrosive taste, and an acetous, pungent, and refreshing smell. It crystallizes when cooled to 34°, and remains crystalline until heated above 48°. (*Br.*). Its sp. gr. is 1·063 (1·065 to 1·066, *Br.*), and is increased by adding 10 per cent. of water; an apparent anomaly, which has been already noticed. It possesses the property of dissolving a number of substances, such as volatile oils, camphor, resins and gum-resins, fibrin, albumen, &c. As it attracts humidity from the atmosphere, it should be preserved in well-stopped bottles. Its combinations with salifiable bases are called acetates. A drachm of it, "mixed with a fluidounce of distilled water, requires for neutralization at least 990 grain-measures of the *volumetric solution of soda*. If a fluidrachm of it, mixed with half a [fluid]ounce of distilled water and half a drachm of pure hydrochloric acid, be put into a small flask with a few pieces of granulated zinc, and while the effervescence continues a slip of bibulous paper wetted with solution of subacetate of lead be suspended in the upper part of the flask above the liquid for about five minutes, the paper will not become discoloured" (*Br.*); showing the absence of sulphurous acid. (See *Liquor Sodæ*.) It consists of one eq. of dry acid 51, and one of water 9 = 60. The dry acid has been isolated by C. Gerhardt, who finds it to be a limpid liquid, heavier than water, and having the constant boiling point of 279°. Its formula is $C_4H_4O_3$.

Properties of the Acid of Commerce (Acidum Aceticum, *U.S.*, *Br.*). This acid has similar properties to those of the glacial, but milder in degree. It is a colourless, volatile liquid, having a sharp taste and pungent smell. It unites in all proportions with water, and to a certain extent with alcohol. It is incompatible with the alkalies and alkaline earths, both pure and carbonated, with metallic oxides, and with most substances acted on by other acids. It is wholly volatilized by heat, and yields no precipitate with chloride of barium or nitrate of silver. Any fixed residue is impurity; and precipitates by the tests men-

* Varies to 1·065. The abbreviations used in this table, *Lond.*, *Ed.*, and *Dub.*, have reference to the Pharmacopœias of the several British Colleges, now no longer in use.

tioned show the presence of sulphuric and muriatic acids. Sulphohydrate of ammonia does not discolour it. Sometimes the acid is contaminated with empyreumatic oil arising from its mode of preparation. Much of this impurity would betray itself to the senses of smell and taste. When too minute in proportion to be sensible, it may be detected, according to Mr. John Lightfoot, by neutralizing the acid with carbonate of potassa, and adding solution of permanganate of potassa, when if the acid is pure the latter retains its pinky colour, but if in the slightest degree empyreumatic, the permanganate is decolorized, and after standing a brown precipitate occurs. (*Chem. News*, Nov. 30, 1861, p. 290.) If sulphuretted hydrogen produces a milkiness, sulphurous acid is present. When saturated with ammonia, the acid gives no precipitate with iodide or ferrocyanide of potassium, which proves the absence of lead and copper. If silver be digested in it, and chlorohydric acid afterwards added, no precipitate will be produced. The negative indication of this test shows the absence of nitric acid. Of the U. S. acid (sp. gr. 1·047) "100 grains saturate 60 grains of crystallized bicarbonate of potassa, and contain 36 grains of monohydrated acetic acid." This corresponds exactly with the percentage given in the foregoing table. Of the British acid (sp. gr. 1·044) the strength in anhydrous acetic acid is 28 per cent., in the monohydrated acid, according to the table is 33 per cent. "By weight 182 grains require for neutralization 1000 grain-measures of the *volumetric solution of soda*." Br. It should respond in the same manner as the glacial acid to the test of hydrochloric acid and granulated zinc. The U. S. officinal is somewhat stronger than the British.

It is difficult to ascertain the strength of acetic acid by saturating it with the carbonated alkalies, when the operator depends upon test paper for ascertaining the point of neutralization. The difficulty is caused by the fact that the acetates of potassa and soda, though neutral in composition, are alkaline to test paper. Hence the liquid begins to be alkaline to test paper, while some free acid yet remains, but insufficient to overcome the alkaline reaction of the salt formed. It follows, therefore, that, by the use of test paper, the strength of the acetic acid will be underrated. The degree of inaccuracy, where test paper is used, is much diminished by saturating the acid with a solution of saccharate of lime, of a known strength, as proposed by Mr. C. G. Williams. (*Pharm. Journ. & Trans.*, May, 1854, p. 594.) A still better way is to add to the acid a weighed excess of carbonate of baryta, and to calculate its strength by the amount of the carbonate decomposed, ascertained by deducting the undissolved from the total used. (*Redwood.*) Equally accurate results may be obtained by the use of carbonate of lime in a similar manner. (E. C. Nicholson and D. S. Price, *Chem. Gaz.*, Jan. 15, 1856.)

Uses of Crude Pyroligneous Acid. This acid having been incidentally described as the source of the acetic acid of commerce, it may be proper in this place to notice its uses. It has been employed as an application to gangrene and ill-conditioned ulcers. It acts on the principle of an antiseptic and stimulant; the former property being probably chiefly due to the presence of creasote. Several cases in which it was successfully employed are reported in a paper by Dr. T. Y. Simons, of Charleston, S. C. (*Am. Journ. of Med. Sci.*, O. S., v. 310.)

The crude acid is advantageously applied to the preservation of animal food. Mr. William Ramsey made some interesting experiments with it for that purpose. Herrings and other fish, simply dipped in the acid and afterwards dried in the shade, were effectually preserved, and, when eaten, were found very agreeable to the taste. Herrings, slightly cured with salt by being sprinkled with it for six hours, then drained, next immersed in pyroligneous acid for a few seconds, and afterwards dried in the shade for two months, were found by Mr. Ramsey to be of fine quality and flavour. Fresh beef, dipped in the acid in summer for the space of a minute, was perfectly sweet in the following spring. Professor Silliman states that one quart of the acid, added to the common pickle for a barrel of hams, at the time they are laid down, will impart to them the smoked flavour as perfectly as if they had undergone the ordinary process of smoking.

Medical Properties of Acetic Acid of Commerce (Acidum Aceticum, *U. S., Br.*). Acetic acid of about this strength acts as a stimulant. When diluted sufficiently, it is refrigerant, diaphoretic, and diuretic. Owing to its volatility and pungency, its vapour is frequently applied to the nostrils as an excitant in syncope, asphyxia, and headache. When employed in this manner, it is generally added to a small portion of sulphate of potassa, so as to moisten the salt, and the mixture is put into small glass bottles with ground stoppers.

Acetic acid, more or less diluted, has been proposed by Dr. Broadbent, of London, as a local remedy in cancer, being injected by means of a syringe into the diseased tissue. Some instances have been reported of good effects in cancroid tumours; but the general result has not been favourable, and the remedy will probably be abandoned ere long.

In large doses it is capable of producing poisonous effects; and a case is recorded in the *Lancet* (July 27, 1867, p. 98), in which an adult man, by swallowing two or three ounces of the undiluted acid, was brought into a condition of great danger, from which he was with difficulty rescued. The prominent symptoms were at first slight collapse, and asphyxia from closure of the glottis, from which he was recovered by tracheotomy, and, after reaction, great thirst, salivation, pain in the fauces, and inability to swallow, but without any evidence of serious gastric, pulmonary, or cardiac disturbance.

Medical Properties of the Glacial Acid. This acid is used only externally, and acts as a rubefacient, vesicant, or caustic, according to the length of time it is applied. Its application requires caution. It is sometimes employed as a substitute for cantharides, when a speedy blister is desired; as, for example, in croup, sorethroat, and other cases of internal inflammation. It may be applied by means of blotting paper or cambric moistened with the acid. It is a good corrosive for destroying warts and corns, and is also a valuable remedy in scaldhead.

ACIDUM ARSENIOSUM. *U. S., Br.*

Arsenious Acid.

Sublimed arsenious acid in masses. *U. S.* An anhydrous acid, obtained by roasting arsenical ores, and purified by sublimation. As_2O_3. *Br.*

Arsenicum album, *Ed.;* White arsenic; Acide arsenieux, Arsenic blanc, *Fr.;* Arsenichte Säure, Weisser Arsenik, *Germ.;* Arsenik, *Dan., Swed., Polish;* Acido arsenioso, Arsenico, *Ital.;* Arsenico blanco, *Span.*

Arsenious acid is prepared chiefly in Bohemia and Saxony, where it is procured on a large scale, as a collateral product, during the smelting of cobalt ores, which are almost invariably accompanied by arsenic. These ores are roasted in reverberatory furnaces, with long horizontal flues. The arsenic is converted by combustion into arsenious acid, which rises in vapour, and condenses on the sides of the flues. In this state it is impure, and requires a second sublimation, which is performed in cast-iron vessels, fitted with conical heads of the same material, having an opening at the summit. The vessels are placed over a furnace, and brought to a red heat, when a portion of the impure arsenious acid is thrown in through the opening, which is immediately stopped. This portion being sublimed, a second portion is introduced in a

similar manner. Finally, the vessels are allowed to cool; and, upon removing the heads, the purified acid is found attached to them in vitreous layers, at first as transparent as glass, but gradually becoming, by contact with the air, opaque at their surface. These are broken into fragments of a convenient size, and thrown into commerce. The arsenious acid which reaches this country is generally packed in casks, containing from two to five hundred pounds, and is shipped principally from the ports of Hamburg and Bremen.

Properties. Arsenious acid is entirely volatilized by heat. As it occurs in commerce, it is in masses, with a vitreous fracture, and of a milk-white colour exteriorly, but, internally, often perfectly transparent. As first sublimed, the whole mass is transparent; but it gradually becomes white and opaque, the change proceeding progressively from the surface inwards. This change has not been well explained; but probably depends upon the absorption of moisture, causing a gradual passage of the acid from the amorphous to the crystalline state. (*Pereira.*) Hence the masses "usually present a stratified appearance, caused by the existence of layers differing in degrees of opacity." *Br.* According to Guibourt, the sp. gr. of the transparent variety is 3·73, of the opaque 3·69. The experiments, however, of Dr. J. K. Mitchell and Mr. Durand make the density of the former variety from 3·208 to 3·333. As it occurs in the shops for medical use, it is often in the form of a white powder, almost as fine as flour. In this state it is sometimes adulterated with powdered lime or chalk, or sulphate or arsenite of lime, a fraud which is easily detected by exposing the powder to a heat sufficient to evaporate the arsenious acid, when these impurities will be left behind. In consequence of the liability of the acid to contain impurities when in powder, it is directed in the U. S. Pharmacopœia to be kept in masses; so that the apothecary may powder it for himself as it is wanted. It has been erroneously stated to have an acrid taste. Dr. Christison asserts that it possesses hardly any taste; inasmuch as it produces merely a faint sweetish impression on the palate. In strong, hot solution, it has an austere taste, most nearly resembling that of sulphate of zinc. (*Mitchell* and *Durand.*) It has no smell, even in the state of vapour; but, when thrown on ignited charcoal, it emits a garlicky odour, in consequence of its deoxidation, and the volatilization of the reduced metal. Its point of sublimation, according to Berzelius, is at an incipient red heat; but, according to Mitchell and Durand, it is lower than that of metallic arsenic, being only 425° F. In the British Pharmacopœia it is said to be entirely volatilized at a temperature not exceeding 400°. Dr. Taylor, in his work on Medical Jurisprudence, gives the subliming point at 370°; and Mr. Wm. A. Guy, who has made careful experiments on the volatility of various substances, states that arsenious acid rises in vapour at about 280°. (*Pharm. Journ. and Trans.*, Feb. 1868, p. 373.) When slowly sublimed, it condenses in regular octohedral crystals, exhibiting a sparkling lustre. It consists of one eq. of arsenic 75, and three of oxygen 24=99. "One hundred grains of this acid, boiled with dilute muriatic acid, and then treated with hydrosulphuric acid, yield a deposit of tersulphuret of arsenic, weighing 124 grains." *U. S.* "Four grains of it, dissolved in boiling water with eight grains of bicarbonate of soda, discharge the colour of 808 grain-measures of *the volumetric solution of iodine.*" *Br.*

Arsenious acid is soluble in water. According to Bussy, at the temperature of 55° a pint of water dissolves 293 grains of the transparent variety, and only about 92 grains of the opaque. Thus the transparent acid, so far from being less, as previously supposed, is much more soluble than the opaque variety. The following particulars are given on the same authority. The transparent acid dissolves much more rapidly than the opaque. By prolonged ebullition with water, the opaque variety attains the same solubility as the transparent, and may be supposed to be converted into the latter. Thus, at the boiling temperature, a pint of water dissolves 807 grains of both varieties. The transparent variety, in cold saturated solution, gradually lessens in solubility, until it reaches the solubility of the opaque, no doubt in consequence of being changed into the

latter. Pulverization lessens the solubility of the transparent variety, without affecting that of the opaque. The mixture of the two varieties of the acid in the same solution serves to explain the anomalies heretofore observed in its solubility. (*Journ. de Pharm.*, Nov. 1847.) In relation to some of these results, Bussy had been anticipated by Taylor. (See *Lond. and Ed. Philos. Mag.*, Nov. 1837.) "The solution of arsenious acid gives with ammonio-nitrate of silver a canary-yellow precipitate, insoluble in water, but readily dissolved by ammonia and by nitric acid." *Br.* Though arsenious acid combines with salifiable bases, yet, when it is heated with muriate of ammonia, instead of evolution of muriatic acid gas, which might have been anticipated, we have an escape of ammonia; the materials reacting so as to produce chloride of arsenic, water, and ammonia. (V. de Luynes, *Comptes Rendus*, Juin 29, 1857, p. 1354.)

Medical Properties. Internally, the action of the preparations of arsenic is alterative and febrifuge; externally, for the most part, violently irritant. They have been considered as peculiary applicable to the treatment of diseases of a periodical character. At the commencement of their exhibition, the dose should be small, and afterwards gradually increased, the operation being carefully watched. When the specific effects of the medicine are produced, it must be immediately laid aside. These are, a general disposition to œdema, especially of the face and eyelids, a feeling of stiffness in these parts, itching of the skin, tenderness of the mouth, loss of appetite, and uneasiness and sickness of the stomach. The peculiar swelling produced is called *œdema arsenicalis.* Sometimes salivation is produced, and occasionally the hair and nails fall off. It is stated by M. Charot that he has seen, in two cases, decided anaphrodisiac effects result from the prolonged use of arsenic, which disappeared several months after the discontinuance of the remedy, and in one instance returned upon its resumption. (*Ann. de Thérap.*, 1865, p. 267.) The principal preparations now in use are the arsenious acid, the substance under consideration, the solution of arsenite of potassa, or *Fowler's solution*, and the solution of iodide of arsenic and mercury, or *Donovan's solution.* The arseniates of potassa, soda, and iron are also occasionally employed; and the British Pharmacopœia has a preparation denominated hydrochloric solution of arsenic.

M. Tschudi has given some strange accounts of the habitual use, by the peasants of Styria and the Tyrol, of arsenious acid as an invigorating remedy, which they are unable to relinquish without suffering. The air in the neighbourhood of Swansea, in South Wales, is impregnated with arsenical vapour, derived from the copper smelting works in that locality, and yet the workmen do not appear to suffer in health. (*Wood's Therapeutics*, ii. 308.) This negative statement is very different from that of M. Tschudi, who would lead us to believe that the habitual use of arsenic may be beneficial in ordinary health. Encouraged by the reports from Styria, M. Decaisne tried a course of arsenious acid in marsh cachexy, but with unfavourable results. Upon the whole, it is not improbable that the accounts received of the habitual use of arsenic by the peasants of Styria, though having a basis of truth, are greatly exaggerated. It is said that horse dealers sometimes fatten horses by giving them small doses of arsenic. If this statement be admitted as reliable, it may, perhaps, be explained upon the ground that arsenic, as would seem to result from the experiments of Schmidt and Stürswage upon animals, lessens the amount of carbonic acid expired and urea excreted, showing a diminished oxidation in the system, and consequently a diminished destruction of its constitutents. (*Philos. Mag.*, March, 1860.)

Arsenious acid has been exhibited in a great variety of diseases, the principal of which are scirrhus and cancer, especially cancer of the lip; anomalous ulcers; various cutaneous diseases; intermittent fever; chorea; chronic rheumatism, particularly those forms of it attended with pains in the bones; rheumatic gout; diseases of the bones, especially nodes, and firm swellings with deformity of the small joints of the hands; chronic syphilitic affections; frontal neuralgia; and different painful affections of the head, known under the names of hemicrania and periodical headache. In intermittent fever it is inferior only

to Peruvian bark and its alkaloids, and probably no remedy surpasses or even equals it in that most obstinate affection of the joints frequently called rheumatic gout. It is asserted by M. Blain that, associated with tannin, arsenious acid has been attended with a success in intermittents greater than could be obtained from sulphate of quinia, or arsenious acid alone. (*Ann. de Thérap.*, 1865, p. 270.) Mr. Henry Hunt, of Dartmouth, England, found it useful in mitigating the pain of ulcerated cancer of the uterus, and in menorrhagia; also in irritable uterus, attended with pain and bearing down in the erect posture. He gave it in pill, in the dose of the twentieth of a grain three times a day. In this dose the remedy seldom produces unpleasant feelings, and may be continued for three or four months, for which period it must sometimes be employed, in order to produce the desired effect on the uterus. In cutaneous affections, especially those of a scaly character, as lepra and psoriasis, it is an invaluable remedy. Dr. Pereira says that he has seen it used in a large number of cases of this kind without a single failure. It is thought highly of by some in the treatment of lupus, and of ill-looking sores of the face, lips, and tongue, and sometimes effects a cure. Dr. Piquot, of Honfleur, employs it in apoplectic congestion, in the belief that there is in that affection a great excess of red corpuscles, and that arsenic has the effect of diminishing this constituent of the blood in a very decided manner. (*Ranking's Abstract*, xxxi. 53, Am. ed.) It is asserted also to have proved useful in piles and passive hemorrhages. (*Ibid.*) Inhalation of the vapour of arsenious acid is said to have proved very beneficial in asthma, the arsenious acid being smoked in a cigarette, in the dose of one-quarter of a grain; but this application of the remedy would require great caution. (*Ibid.*, xxxv. 87.) Arsenic has also been found useful in intermittent mania, where quinia had proved useless. (*Ibid.*, xxv. 50.) M. Cahen was very successful with it in cholera; 20 cases having recovered under it out of 24 in which it was used. (*Ann. de Thérap.*, 1867, p. 140.)

Five cases of snake-bite, occurring in men, are said to have been successfully treated by Mr. Ireland, in the Island of St. Lucia, by grain doses of arsenious acid, in the form of Fowler's solution, given every half hour, until the patient began to revive. The quantity of the solution to form this dose is two fluidrachms. The number of doses taken varied from six to eight, which always produced abundant vomiting and purging, results important to the success of the treatment. (*Braithwaite*, xxviii. 423.)

The external application of arsenic has been principally restricted to cancer, and anomalous and malignant ulcers, especially of the kind denominated *noli me tangere*. Dupuytren used with advantage a powder, composed of one part of arsenious acid and twenty-four parts of calomel, as a topical application to herpes exedens, and to the foul ulcers occurring in those who have undergone repeated courses of mercury.

Arsenic is the chief ingredient in nearly all the empirical remedies for the cure of cancer by external application. *Plunket's caustic*, a remedy of this kind of great celebrity, consisted of the Ranunculus acris and Ranunculus Flammula, each an ounce, bruised, and mixed with a drachm of arsenious acid, and five scruples of sulphur. The whole was beaten into a paste, formed into balls, and dried in the sun. When used, these balls were rubbed up with yolk of egg, and spread on pig's bladder. The use of the vegetable matter is to destroy the cuticle; for, unless this is done, the arsenic will not act. Mr. Samuel Cooper thinks that this caustic was never of any permanent benefit in genuine cancer, but has effected cures in some examples of lupus, and malignant ulcers of the lips and roots of the nails. In onychia maligna, Mr. Luke, of London, regards an ointment composed of two grains of arsenious acid and an ounce of spermaceti ointment as almost a specific. (Pereira, *Mat. Med.*)

At Paris, an *arsenical paste* of the following composition has been used as an application to malignant ulcers:—Red sulphuret of mercury 70 parts; dragon's blood 22 parts; arsenious acid 8 parts. It is applied, made up into a paste with saliva. The pain produced by this composition is very severe, and its applica-

tion dangerous. The *arsenical paste of Frère Côme* has been applied advantageously by M. Biett to the ulcerated surfaces in yaws. The precaution was used of not applying it, at one time, over a surface larger than that of half a dollar. This paste is made by mixing water with a powder, consisting of ten grains of arsenious acid, two scruples of red sulphuret of mercury, and ten grains of powdered animal charcoal. The practice of sprinkling unmixed arsenious acid on ulcers is fraught with the greatest danger. Mr. S. Cooper characterizes it as a murderous practice. The acid may, however, be used either in solution, or reduced by some mild ointment. A lotion may be formed of eight grains of arsenious acid and the same quantity of carbonate of potassa, dissolved in four fluidounces of distilled water; and a cerate, of half a drachm of arsenious acid and six drachms of simple cerate. The cerate is sometimes formed of half this strength. The lotion is in effect a solution of arsenite of potassa.

Febure's remedy for cancer consisted of ten grains of arsenious acid, dissolved in a pint of distilled water, to which were added an ounce of extract of conium, three fluidounces of solution of subacetate of lead, and a fluidrachm of tincture of opium. With this the cancer was washed every morning. Febure's formula for internal exhibition was, arsenious acid two grains, rhubarb half an ounce, syrup of chicory q. s., distilled water a pint. Of this mixture, a tablespoonful, containing about the sixteenth of a grain of the acid, was given every night and morning, with half a fluidrachm of the syrup of poppies. The dose was gradually increased to six tablespoonfuls.

Mr. Lloyd, of London, praises the effects of arsenical injections in cancer of the vagina and uterus. They act favourably by preventing rather than destroying the fetor, and by diminishing the sloughing and discharge. The strength of the solution employed was from two to eight grains of arsenious acid to the pint of water. (See *Am. Journ. of Med. Sci.*, Oct. 1854, p. 541.)

The average dose of arsenious acid is the tenth of a grain, three times a day, given in the form of pill. It is usually combined with opium, which enables the stomach to bear the medicine better. A convenient formula is to mix one grain of the acid with ten grains of sugar, and to beat the mixture thoroughly with crumb of bread, so as to form a pilular mass, to be divided into ten pills. The *Asiatic pills*, so called, consist of arsenious acid and black pepper, in the proportion of 1 part of the former to 80 of the latter. A preparation much used on the continent of Europe is *Boudin's solution*, which is simply an aqueous solution of arsenious acid with the addition of wine, and is made by boiling one gramme (15·4 grains) of the acid with one litre (2·1 pints) of distilled water till entirely dissolved, then cooling, filtering, adding enough distilled water to supply the loss, and finally mixing with one litre of white wine. Of this solution a fluidounce contains about one-quarter of a grain of arsenious acid.

Properties of Arsenious Acid as a Poison. Arsenious acid, in an overdose, administered internally, or applied externally, acts with very great energy, and generally destroys life in a short time; but, in some rare instances, no well-marked symptoms are developed until eight or nine hours after the ingestion of the poison. Dr. Edward Hartshorne relates a case of recovery, in which at least a drachm of arsenious acid had been swallowed, and where the symptoms of poisoning were delayed for sixteen hours. (*Med. Examiner*, Dec. 1855, p. 707.) The symptoms produced by the poison are an austere taste; fetid state of the mouth; frequent ptyalism; continual hawking; constriction of the pharynx and œsophagus; the sensation of the teeth being on edge; hiccough; nausea; anxiety; frequent sinkings; burning pain at the præcordia; inflammation of the lips, tongue, palate, throat, bronchi, and œsophagus; irritable stomach, so as not to be able to support the blandest drinks; vomiting of matters, sometimes brown, at other times bloody; black, horribly fetid stools; small, frequent, concentrated, and irregular pulse, but occasionally slow and unequal; palpitations; syncope; insatiable thirst; burning heat over the whole body, or a sensation of icy coldness; difficult respiration; cold sweats; suppression of urine; scanty, red, bloody, and sometimes albuminous urine;

change in the countenance; a livid circle round the eyelids; swelling and itching of the body; livid spots over the surface, and occasionally a miliary eruption; prostration of strength; loss of feeling, especially in the feet and hands; delirium; convulsions, often accompanied with insupportable priapism; falling off of the hair, detachment of the cuticle, &c. In some cases there is inflammation with burning pain in the urino-genital organs. It is very rare to observe all these symptoms in the same individual. Sometimes, indeed, they are nearly all wanting, death taking place without any pain or prominent symptom. Occasionally the symptoms have a perfect resemblance to those of Asiatic cholera, in the stage of collapse. After death, the morbid appearances are various. In some instances, no vestige of lesion can be discovered. The appearances, however, in the generality of cases, are the following. The mouth, stomach, and intestines are inflamed; the stomach and duodenum exhibit spots resembling eschars, and perforations of all their coats; and the villous coat of the former is in a manner destroyed, and reduced to the consistence of a reddish-brown pulp. In cases of recovery, it has been a question how long it takes for the poison to be eliminated from the system. In a case, reported by Dr. D. Maclagan, in which about two drachms of the poison had been swallowed, and in which magnesia was used successfully as an antidote, arsenic was detected in the urine by Marsh's test as late as the twentieth day.

A milder grade of arsenical poisoning, yet sometimes serious in its consequences, has resulted in many instances from the inhalation of the air of apartments lined with green wall-paper, which owes it colour to arsenite of copper, and from which a fine poisonous dust sometimes escapes when the paper has not been well prepared. (See *Chem. News*, March 24, 1860) Death has also resulted, in more than one instance, from working in the manufacture of artificial leaves, which owe their green colour to the same poison. (*Ibid.*, Nov. 30, 1861)

In view of the numerous accidents and crimes caused by the use of arsenious acid, its sale should be regulated by law in all the States of the Union. In 1851, an act for this purpose was passed by the British Parliament.

Dr. Christison divides the poisonous effects of arsenious acid into three orders of cases, according to the character and violence of the symptoms. In the first order, the poison produces symptoms of irritation and inflammation along the course of the alimentary canal, and commonly kills in from one to three days. In the second, the signs of inflammation are moderate, or even altogether wanting, and death occurs in five or six hours, at a period too early for inflammation to be always fully developed. In the third order of cases, two stages occur; the first stage being characterized by inflammatory symptoms, as in the first order; the second, by symptoms referable to nervous irritation, such as imperfect palsy of the arms or legs, epilepsy, tetanus, hysterical affections, mania, and coma. It is a general character of this poison to induce inflammation of the stomach in almost all instances, provided death does not take place immediately, whatever be the part to which it is applied. Thus the poison, when applied to a fresh wound, will give rise to the same morbid appearances in the stomach and intestines, as when it is swallowed. In some cases, observed by Drs. Mall and Baillie, the rectum was much inflamed, while the colon and small intestines escaped.

The precise rank which should be assigned, in the scale of poisons, to arsenious acid when applied externally, is still undetermined. One set of observers contend that its external application is not attended with great danger; while another party conceives that it acts as a virulent poison. Hunter, Sir Everard Home, Jæger, Brodie, Dr. Campbell of Edinburgh, Smith, and Orfila have all adduced experiments on the inferior animals, which prove that arsenious acid, inserted into a recent wound, causes death after a longer or shorter period. Indeed, some observations go to prove that its poisonous effects are developed by a smaller amount, applied in this way, than when taken into the stomach. Nor are there wanting many well-authenticated facts of its deleterious effects, externally applied, on the human constitution. Roux has put on record the case of

a young woman under his care, whose death was caused, after agonizing sufferings, by the application of an arsenical paste to a cancerous breast. Death has occurred from the application of an arsenical paste to a soft tumour of the temple; the poisonous effects on the system at large being the cause of the fatal result. Sir Astley Cooper bears testimony to the dangerous effects of arsenic, externally applied. On the other hand, some writers assert the safety of the external application of this poison. Mr. Blackadder applied it in large quantities to sores, and never witnessed a single instance in which it acted constitutionally. The late Dr. Randolph, of this city, stated that Dr. Physick frequently and successfully employed arsenic by external application, without its being productive of the injurious consequences which have been attributed to it. (*North Amer. Med. and Surg. Journ.*, v. 257.) In weighing testimony so conflicting, we are constrained to believe that the circumstances of the different experiments and observations must have been different; and we think that the observations of Blackadder and Harles show in what this difference consists. It seems to depend entirely on the circumstances of the application, as being favourable or otherwise to absorption. Blackadder attributes his success to the large quantity of arsenic which he employs, and which, he contends, kills the part without being absorbed; and this is probably the fact. Harles's observations may be explained on the same principle. He contended that the outward application of arsenic is comparatively safe to ulcers, either common or malignant; but is dangerous to parts recently wounded and pouring out blood. Here the difference would seem to consist in the greater liability to absorption in the latter than in the former case. The very dilution caused by the blood may be an efficient promoter of absorption; for the experiments of Dr. Campbell show that arsenic acts with more energy when dissolved in water than when in the solid state. The case in which Dr. Randolph employed arsenious acid, by the advice of Dr. Physick, was one of ulcerated scrotum, in which it acted by producing the death of the diseased part, a state evidently unfavourable to absorption. The formula employed was one part of the acid to five of sublimed sulphur. Arsenious acid proves escharotic, according to some, by acting on the vital properties of the part so as to cause its death; according to others, by producing a chemical decomposition of the structure.

Upon the whole, new facts are wanting to clear up this difficult subject. Judging from the lights we possess, the external application of arsenious acid, in case it is absorbed, is attended with very great danger; and the conditions of a part, and of the system at large, favourable or otherwise to absorption, are too little understood, to make it warrantable to use this poison externally without the greatest caution.

Treatment of Poisoning by Arsenious Acid. Before the antidote, to be mentioned presently, can be obtained, the poison should be dislodged as far as possible by free vomiting, induced by the finger, the feather part of a quill, and the administration of an emetic of sulphate of copper or sulphate of zinc. The same object is promoted by the use of the stomach-pump. Demulcent drinks should be freely given, such as milk, white of eggs and water, or flour and water, which serve to encourage the vomiting and envelope the poison.

The antidote above referred to is the hydrated sesquioxide (peroxide) of iron, in the *moist* or *pulpy* state. As soon as it is ready, it must be given in doses of a tablespoonful to an adult, of a dessertspoonful to children, every five or ten minutes, until the urgent symptoms are relieved. It is calculated that the quantity taken should be at least twelve times the supposed amount of the poison swallowed; but, as the antidote is perfectly innocent, it is prudent to give it in larger quantities According to the experiments of E. Riegel, one part of arsenious acid in solution is so fully precipitated by ten of the dry oxide, that, after its action, not a trace of the poison can be detected, even by Marsh's test. Its efficacy is of course greater, the sooner it is administered after the ingestion of the poison; but, even after delay, its use will prove advantageous, so long as any portion of the poison still remains in the stomach.

The antidote acts by producing with the poison, by a transfer of oxygen, from the oxide to the acid, an insoluble, and therefore inert, subarseniate of protoxide of iron ($2Fe_2O_3$ and $AsO_3 = 4FeO, AsO_5$).* The manner of preparing the antidote will be given elsewhere. (See *Ferri Oxidum Hydratum.*) It should be kept by all apothecaries ready for use.

This antidote for arsenious acid was discovered by Drs. Bunsen and Berthold, of Göttingen, in 1834; and its efficacy has been abundantly confirmed by experiments on inferior animals, and by its successful application to numerous cases of poisoning in the human subject. Among others, the reader is referred to the following.—1. The case of M. Blondel, in which two drachms of arsenic had been swallowed. 2. Two cases treated by Dr. Buzorini. 3. A case reported by Mr. John Robson, in which more than a drachm and a half of the poison had been swallowed, and the antidote was not administered until two hours after the poison had been taken. In the last-mentioned case, about an hour after the ingestion of the poison, the stomach-pump was used, but unsuccessfully, on account of the instrument becoming choked with the remains of food. 4. A case related by Dr. Thomas, of Baltimore, in which twenty grains of the poison had been swallowed. 5. Case of Dr. Macdonald in the *N. Y. Journ. of Med. and Surg.* (ii. 205). 6. Case reported by Dr. Gerhard. (*Med. Exam.*, iii. 250.) 7. Cases related by Drs. Smiley and Wallace, of this city. Eight persons in one family were poisoned, of whom six recovered and two died. In the fatal cases, the patients could not retain the antidote. (*Ibid.*, iii. 679.)

Several valuable observations have been made in relation to the antidotal powers of the different oxides of iron, and the circumstances which influence their efficacy. The forms of oxide experimented with are the anhydrous sesquioxide (colcothar), the dry hydrated sesquioxide (rust of iron, and the subcarbonate of iron of the U. S. Pharmacopœia, which are both essentially hydrated oxides), the hydrated oxide in the state of pulp or magma, and the same oxide kept under a stratum of water. Orfila has shown that *colcothar* is without effect, because it does not combine with the arsenious acid. Dr. Von Specz, of Vienna, has proved that *rust of iron* acts as an antidote to arsenious acid; but, as it is much less powerful than the pulpy hydrate, it should be used only in the absence of the latter, and until it can be procured. Orfila agrees with Von Specz as to the degree of efficacy of the rust, and attributes its inferior power to its inability *completely* to neutralize the arsenious acid. According to the French toxicologist, it forms with the acid a subsalt which is poisonous, though much less so than the free arsenious acid. All the best authorities unite in considering the *hydrated oxide*, in the state of *pulp* or *magma*, to be the best form of the antidote; but opinions have been divided as to the necessity of its being *freshly* prepared as well as moist, and as to the relative advantage of much or little water to maintain it in the moist state. An able paper of Prof. William Procter, jun., of this city, appears to have settled these points. (*Amer. Journ. of Pharmacy*, xiv. 29, April, 1842.) He has proved that the moist oxide gradually decreases in its power of neutralizing arsenious acid, the longer it is kept; and that this decrease in power is more rapid in the

* If the statements made by British writers as to the efficiency of the arseniate of protoxide of iron as a remedy, and the minuteness of the dose necessary, be admitted as correct, it will be necessary to seek some other explanation of the antidotal powers of the hydrated sesquioxide of iron than the one above given by the late Dr. Bache. The probability is that the new compound is the *sesquiarseniate of sesquioxide of iron* ($2F_2O_3$ $3AsO_5$); and the following may be the rationale. Six eqs. of sesquioxide (F_2O_3) may surrender, each one eq. of oxygen, to 3 eqs. of arsenious acid (AsO_3), converting them into 3 eqs. of arsenic acid (AsO_5), which then combines with 2 eqs. of undecomposed sesquioxide, producing the sesquiarseniate of sesquioxide of iron ($2F_2O_3, 3AsO_5$); twelve eqs. of protoxide resulting from the loss of one eq. of oxygen, each, by the six eqs. of sesquioxide first mentioned. If this be the true explanation, it may be determined by a simple calculation, based on the combining numbers, that each grain of arsenious acid will require for saturation 2·64 grains of hydrated sesquioxide of iron; but, in fact, according to the experiments of the Messrs. T. & H. Smith, of Edinburgh, 8 grains are practically necessary. (*Note to the thirteenth edition.*)

oxide, when mixed with much water, than when in the form of a thick magma. The cause of this diminution of neutralizing power, on the part of the moist oxide, by being kept, is explained by the experiments of G. C. Wittstein. This chemist finds that the hydrated oxide of iron, recently precipitated, dissolves readily in acetic and other vegetable acids in the cold, but becomes nearly insoluble when kept for some time under water. This change in solubility is attributed by Wittstein to two causes; the gradual change of the oxide from the amorphous to the crystalline state, and its partial dehydration; for, when kept a long time, the oxide loses half its water. From these considerations, Wittstein prefers the more recent oxide as an antidote for arsenic, and recommends that the preparation should be re-made every six months or year, by dissolving the old oxide in muriatic acid, and re-precipitating with ammonia. (*Buchner's Repert.*, xliii. 366.) In the latter remarks, Wittstein has only confirmed what had been previously observed by Procter.

It follows from the above facts and observations, that the forms of sesquioxide of iron are efficacious as antidotes to arsenic in the following order, beginning with the one having the least power:—1, dry hydrated oxide; 2, hydrated oxide, long kept and mixed with much water; 3, the same, long kept and in the form of a thick magma; 4, the same just precipitated and still pulpy. The form of antidote which can be obtained first must be used first, although not the best, and may be replaced by a better as soon as it can be procured. The apothecary should, therefore, always keep the oxide in the form of thick magma, and be prepared, at a moment's warning, to make the antidote. When applied to for it, he must furnish the magma, or, if unprovided with this, the rust or subcarbonate, and immediately proceed to prepare the antidote, which may be done in ten or fifteen minutes, if the proper solutions are always kept on hand. (See *Ferri Oxidum Hydratum.*)

The antidote having been faithfully applied, the subsequent treatment consists in the administration of mucilaginous drinks. Should the patient survive long enough for inflammatory symptoms to arise, these must be combated on general principles. Accordingly, venesection and leeches may become necessary; and, in the course of the treatment, emollient enemata, antispasmodics, and narcotics will often prove useful in mitigating pain and allaying nervous irritation. Convalescence is generally long and distressing; and hence it is of the greatest importance to attend to the diet, which should consist exclusively of milk, gruel, cream, rice, and similar bland articles.

Bussy has proposed light magnesia, or the kind which has not been too strongly calcined, as well as recently precipitated gelatinous magnesia, as an antidote for arsenious acid; and a case is given by him in which it appeared to prove efficacious. (*Journ. de Pharm.*, x. 81.) The dense kind has very little efficacy. Dr. Christison saw a case in which this antidote seemed very serviceable. A successful case is also reported by Cadet-de-Gassicourt (*Journ. de Pharm.*, Mars, 1848), and another by Dr. E. Bissel, of Norwalk, Conn. (*Am. Journ. of Med. Sci.*, July, 1848.) For the full precipitation of arsenious acid, eighteen times its weight of anhydrous magnesia are required. (*E. Riegel.*) Like the sesquioxide of iron, the magnesian antidote is conveniently kept, in a pulpy state, under water in stopped bottles. M. Schroff has made some experiments on rabbits, to determine the comparative efficacy, as antidotes, of the sesquioxide and magnesia, and gives the preference to the latter. The hydrated magnesia is best prepared extemporaneously by quickly forming a solution of sulphate of magnesia, and precipitating by water of ammonia, which is preferable to potassa, as any portion of the latter, remaining in the preparation, might act injuriously by favouring the solubility of the arsenious acid. Notwithstanding these statements, however, it is asserted by T. & H. Smith of Edinburgh, on the basis of experiment, that magnesia is incapable of neutralizing arsenious acid, and is utterly useless as an antidote. (*Pharm. Journ.*, Oct. 1865, p. 144.) Under these circumstances, it would be unwarrantable to rely on it when the ferruginous antidote is attainable.

For the salts of the acids of arsenic, the subacetate of the sesquioxide of iron has been suggested as an antidote by Duflos. In poisoning by these salts, the sesquioxide is said to be without effect.

A mechanical method of counteracting the effects of arsenic is said to have been employed with complete success in several instances. It consists, after thoroughly washing out the stomach, in administering large quantities, a pound or more, of a mixture of chalk and castor oil, of the consistence of thick cream, which so envelopes the particles of the poison adhering to the mucous membrane as to render them harmless, while carried through the bowels and evacuated. (W. T. Fewtrell, *Chem. News*, Jan. 14, 1860, p. 71.)

Reagents for detecting Arsenious Acid. As arsenic is so frequently employed for criminal purposes, it becomes important to detect its presence in medico-legal investigations. The tests for it may be divided into those which indicate indirectly its presence, and those which demonstrate its presence incontestably, by bringing it to the metallic state. The former embrace all the liquid reagents, so called; the latter, the processes for metallization. It is necessary, however, to be aware of the fact, that many of the substances employed as tests for arsenic are themselves often contaminated with arsenic, and unless great care be exercised to select reagents perfectly free from this impurity, there will be danger that the results may be fallacious.

The most characteristic reagents are *sulphuretted hydrogen, ammoniacal nitrate of silver, and ammoniacal sulphate of copper.* In the opinion of Dr. Christison, the concurrent indications of these three tests are all-sufficient for detecting arsenious acid; but we think that, in questions involving life, the metallization of the poison should never be omitted.

In using sulphuretted hydrogen, the solution must be neutral. An excess of alkali may be neutralized with acetic acid, and an excess of nitric or sulphuric acid by potassa. A slight excess of acetic acid is not hurtful, but rather favours the subsidence of the precipitate, which is the tersulphuret of arsenic. According to Dr. Christison, this test is so exceedingly delicate, that it detects the poison when dissolved in one hundred thousand parts of water. The colour it produces is lemon or sulphur-yellow; but the presence of vegetable or animal matter commonly gives it a whitish or brownish tint. Some medical jurists recommend the use of sulphuretted hydrogen water; but the gas is far preferable. It can be applied with much convenience by using one of Dr. Hare's self-regulating gas generators.

The ammoniacal nitrate of silver gives a yellow precipitate of arsenite of silver.

The ammoniacal sulphate of copper is a test of very great delicacy. The precipitate occasioned by it is the arsenite of copper, of an apple-green or grass-green colour. Its operation is prevented by muriatic, nitric, sulphuric, acetic, citric, and tartaric acids in excess; as also by ammonia.

Of the three tests mentioned, perhaps sulphuretted hydrogen is the most delicate; and it has the advantage of yielding a precipitate eligible for subsequent reduction. But they are all liable to the objection of being obscured in their indications, where the amount of poison is small, by the presence of organic principles; a complication constituting the most difficult problem for the medical jurist. As this case includes all others of more easy solution, we shall suppose it to occur, and shall indicate the steps to be pursued.

Having obtained general indications of the presence of arsenic, the first step will be to separate the organic matters; the second, to throw down the arsenic by means of sulphuretted hydrogen; and the third, to reduce the precipitate obtained to the metallic state. It is proper to state here that, in a communication to the Paris Academy, Dr. Blondlot, of Nancy, asserts, as the result of numerous experiments, that the smallest quantity of oily or fatty matter has the effect of diminishing, even to one-twentieth, the solubility of arsenious acid, and consequently of very much increasing the difficulty of detecting it. (See *Am. Journ. of Pharm.*, May, 1860, p. 220.)

The following are the directions given by Dr. Christison for separating the organic principles. Boil the suspected matter with distilled water for half an hour, and filter, first through gauze to separate the coarser particles, and afterwards through paper. To the transparent solution thus obtained add acetic acid, which will coagulate some animal principles. To ascertain whether the solution has been sufficiently freed from animal matter by this measure, neutralize with ammonia, and test a small portion of it with the ammoniacal nitrate of silver. If this give a characteristic precipitate, the solution is sufficiently deprived of animal matter; if not, another measure must be adopted to separate it. This consists in first rendering the solution neutral or slightly alkaline, next faintly acidulating with muriatic acid, and then adding an excess of nitrate of silver. This salt precipitates the animal matter in combination with oxide of silver. After this step, the excess of silver is thrown down by a slight excess of chloride of sodium, and the solution filtered.

The solution having in this manner been disembarrassed of organic matter, the free nitric acid is neutralized by potassa in slight excess, and the solution acidulated with acetic acid. A stream of sulphuretted hydrogen is then passed through it, which will throw down the arsenic as the tersulphuret. If the proportion of arsenic be very small, a yellowishness only will be produced, owing to the precipitate being soluble in an excess of the precipitant. In this case it is necessary to boil, to drive off the excess of sulphuretted hydrogen. The precipitate is then collected and dried. If it be very minute, it must be allowed to subside; and, the clear liquid having been withdrawn, the remainder is to be poured upon a filter. After filtration, the precipitate is washed down to the bottom of the filter, by means of the *pipette*, an instrument employed for washing scanty precipitates. The filter is then gently pressed between folds of bibulous paper, and the precipitate removed with the point of a knife before it dries, and then dried in little masses on a watch-glass. In this manner, Dr. Christison states that it is easy to collect a portion of the tersulphuret so small as the twenty-fifth part of a grain. When the precipitate is small and not easily separated, Devergie recommends to dissolve it in a small quantity of ammonia, filter the solution, and evaporate it in a watch-glass, when the tersulphuret will be left. The precipitate is then to be reduced by means of a flux, which this author recommends to consist of two parts of ignited carbonate of soda and one of charcoal, as preferable to black flux. The best flux for arsenious acid is freshly ignited charcoal.

In order to facilitate the detection of arsenic in the solid tissues, as the liver, spleen, stomach, &c., it is customary first to destroy the animal matter, and then to dissolve out the poison. Various agencies have been resorted to for this purpose, but heating with somewhat less than one-half the weight of concentrated sulphuric acid is perhaps the most convenient and effectual. The animal matter is thus carbonized, and will now yield a part at least of the arsenic which it may contain to boiling water, in a state proper for the application of tests. But M. Blondlot has ascertained by experiment that all the arsenic is not thus extracted; a considerable portion being left behind in the state of insoluble sulphuret, resulting from a partial decomposition of the sulphuric acid. To remedy this disadvantage, M. Blondlot recommends, after the carbonized tissue has been exhausted as far as possible with water, to treat it with solution of ammonia, which dissolves the sulphuret, and yields it on evaporation. The sulphuret is now to be converted into arsenic acid by boiling with nitric acid; and, having been evaporated to dryness, is to be treated with water. The solution thus obtained is to be added to the first, and the two will yield all the arsenic originally present in the tissue. (*Journ. de Pharm.*, Août, 1857, p. 117.)

Another method of separating arsenic in solution from organic matters is by the process of dialysis, invented by Prof. Graham, of London, of which a particular account will be given in the pharmaceutical preface to the second part of this work. By means of an instrument called the dialyser, watery solutions of saline and other crystallizable substances may be separated from those

not crystallizable, such as gelatinous, albuminous, mucilaginous, and amylaceous liquids; the latter refusing to pass through a diaphragm of some porous substance, which is readily permeable by the former. Thus, a circular piece of parchment paper, folded in the form of a common filter, is placed in a vessel containing distilled water; the suspected liquid, having been heated so as to effect a more complete solution of the arsenic, is poured into the filter, and the vessel set aside for twenty-four hours. At the end of this time, the crystallizable matter, including the arsenic, will have, to a great extent, passed through into the distilled water, leaving the organic matters behind, and a solution will have been obtained in a condition fit for the application of the different tests.

Following up a suggestion of Dr. Clarke, of Aberdeen, that arsenic might be separated by taking advantage of the volatility of its chloride, Dr. Andrew Fyfe, of the same place, applied the principle to the detection of the metal when mixed with organic matter. For this purpose, he heated the arsenical liquid with sulphuric acid, free from arsenious acid, in a flask to which a bent tube and cooled receiver were adapted. When the mixture was brought to the boiling point, a little dried sea-salt was added, the receiver was connected, and the distillation continued for some time. Hydrochloric acid was evolved, which, by reacting with the arsenious acid, produced terchloride of arsenic, which distilled over free from organic matter. The terchloride of arsenic was then precipitated by a stream of sulphuretted hydrogen, to obtain the yellow tersulphuret of arsenic, or subjected to the action of Marsh's test. (*Philos. Mag.*, 4th series, ii. 487.) The distillate of terchloride, as thus obtained, is liable to contain sulphurous acid, from the action of organic matter on the sulphuric acid, with the effect of obscuring the indications of Marsh's test when subsequently applied, by giving rise to a yellow ring instead of a black stain. To prevent the formation of sulphurous acid, L. A. Buchner recommends that the chloride of sodium should be added to the arsenical liquid before the sulphuric acid, and previously mixed with a little chlorate of potassa, the chlorine from which has the effect of promoting the formation of the arsenical terchloride, and of rendering the decomposition of the organic matter more complete. (*Pharm. Journ. and Trans.*, July, 1855, p. 38.) Dr. Penny and Mr. W. Wallace bear testimony to the value of the plan of converting the arsenic into terchloride, as a means of separating the metal from organic matter, but think it will be found in practice more convenient to produce the terchloride by the direct agency of hydrochloric acid, than by sulphuric acid and chloride of sodium, as recommended by Dr. Fyfe.

The general formula for reduction is as follows. The operation is performed in a small glass tube. If the matter to be operated on is small, it is introduced to the bottom of the tube, and then a little of the flux is added to cover it, care being taken that the materials are conducted to the place they are to occupy, by means of a small glass funnel with a slender stem, without soiling the empty part of the tube. The heat is applied by means of a spirit-lamp; the upper part of the material being first heated with a small flame, and afterwards the lower part with a larger flame. A little water, disengaged at first, should be removed by a roll of filtering paper, before sufficient heat has been applied to sublime the metal. When the dark crust begins to form, the tube should be held quite steady, and in the same part of the flame. This crust is the metallic arsenic, having the surface next to the tube resplendent and polished, and the interior surface crystalline. Its characters are quite distinct, even when it does not amount to more than the three-hundredth part of a grain. If any doubt should be felt as to the nature of the crust, it may be driven up and down the tube, so as to convert it into sparkling octohedral crystals of arsenious acid, the triangular facets of which may be seen with a magnifying glass. Finally, the crystals may be dissolved in a drop or two of distilled water, and the solution will react characteristically with the liquid tests.

Another method of testing for arsenic has been proposed by Mr. Marsh. It consists in taking advantage of the power, which nascent hydrogen possesses of decomposing the acids of arsenic, with the result of forming water and arse-

niuretted hydrogen. The liquid from the stomach, or obtained from its contents by boiling water, is added to the materials for generating hydrogen (dilute sulphuric acid and zinc), contained in a self-regulating generator of hydrogen. If the liquid from the stomach contain arsenic, the nascent hydrogen will combine with the metal, and the nature of the compound gas formed may be ascertained by burning a jet of it from a fine jet-pipe connected with the generator. The flame will have a characteristic blue colour; and, by holding a porcelain plate against it, a thin film of metallic arsenic, forming a black stain, will be deposited. Liebig and Mohr bear testimony to the delicacy of this test; but, to remove every source of fallacy, it is necessary to be sure of the purity of the materials for generating the hydrogen, by a preliminary trial of the gas, before the suspected liquid is added; as zinc and sulphuric acid are both liable to contain a minute proportion of arsenic. This trial is made by holding a plate against the burning hydrogen, which, if pure, will produce no stain. The pieces of zinc employed should be changed after every experiment. Magnesium might be advantageously substituted for zinc, as it contains no arsenic. A modification of Marsh's apparatus, which is praised by Berzelius for the certainty and distinctness of its results, is figured in the *Chemical Gazette* (iii. 46).

It has been objected to Marsh's test, that antimony forms a compound with hydrogen, very similar to arseniuretted hydrogen, both in the colour of its flame, and in the metallic spot which it deposits during combustion on cold surfaces. Still, the two metals may be discriminated by acting on the metallic spot with a drop or two of fuming nitric acid, with the aid of heat. Arsenic will thus be converted into soluble arsenic acid, precipitable brick-red by nitrate of silver; antimony, on the other hand, into insoluble antimonic acid. Another way of distinguishing them is to apply to the stain a solution of hypochlorite of soda, which instantly dissolves the arsenical spot, without affecting that of antimony. Another method, dependent on the difference of temperature at which the two metals are sublimed, has been proposed by Dr. D. Maclagan, of Edinburgh. It consists in subjecting the metallic spot to about the temperature of 500°, by means of a bath of olive oil; when it will be totally volatilized if arsenic, but remain unchanged if antimony. (*Ed. Month. Journ.*, Nov. 1848.) Prof. E. Davy recommends a platinum spatula, instead of porcelain, to receive the metallic spot. A platinum surface affords facilities for testing the spot, which, if arsenic, may be removed by the flame of a candle, giving rise to a garlicky odour; but, if antimony, cannot be so removed. (See *Am. Journ. of Pharm.*, March, 1857, p. 172.) Hydrosulphate of ammonia dissolves the arsenical spot with difficulty, leaving on evaporation a yellow stain; it readily dissolves the antimonial, and yields an orange-red.

Professor Reinsch has proposed a method for detecting arsenic in organic liquids, which is extremely delicate, and at the same time has the merits of facility and celerity. It consists in acidulating the suspected liquid with muriatic acid, which converts the arsenious acid into the terchloride, and boiling in it, for ten minutes, a slip of copper foil, on which the arsenic is deposited as a white alloy of arsenic and copper; and then separating it in the state of arsenious acid, by subjecting the copper, cut into small chips, to a low-red heat in the bottom of a small glass tube. The peculiar crystalline appearance of arsenious acid, mentioned in the last page, is conclusive of its presence; and, besides, if collected and dissolved in water, it will answer to the ordinary tests for the poison. The form of copper, preferred by Dr. Maclagan, is that of copper wire, No. 24, made bright by being rubbed with sand-paper, and rolled into a loose spiral, about an inch long, by being twisted round a small pencil. In this form, the copper affords an extensive surface for the deposition of the arsenic. The merit of Reinsch's procedure is not so much that it gives a characteristic deposit on the copper; for bismuth, tin, zinc, and antimony also give deposits; as that the copper collects all the arsenic from the organic liquid, and presents it in a convenient form for applying the liquid and subliming tests. Yet the gray metallic appearance of the arsenical deposit can hardly be confounded with that of any

other metal, except perhaps of antimony, which can be distinguished by the tests already mentioned. But Reinsch's method is not without its fallacies. Thus, it has been ascertained that the presence of a nitrate or chlorate in the suspected material, prevents the characteristic action of the arsenic on the copper, until the whole of these substances have been consumed by reaction with the metal. Besides, both muriatic acid and copper, even such as have been sold in the shops as the purest, are liable to contain arsenic, and therefore to afford fallacious results. This, however, is less true of the muriatic acid prepared in this country than the European, as the sulphuric acid employed in its preparation is obtained generally from native sulphur, instead of pyrites as abroad. Nevertheless no conclusion from Reinsch's test can be certainly relied on, unless the muriatic acid has been ascertained to be free from arsenic. With the copper there is less risk, as the arsenic in it can act only by solution of the copper itself, and this is known by the green colour imparted to the liquid; so that, if the arsenical deposit is produced without discoloration of the liquid, the indication of the presence of the poison may be considered as satisfactory. (*Olding* and *Taylor.*)

If the process of Reinsch be applied to the sulphuret (sulphide) of arsenic, it will be necessary to bring this into the liquid form. For this purpose Prof. J. C. Draper, of New York, makes use of ammonia, which dissolves the sulphuret, and is also capable of attacking copper. The substance supposed to contain the sulphuret having been covered, in a suitable vessel, with water of ammonia, is set aside in a warm place, and permitted to stand for a few hours. The solution of the sulphuret is then separated by filtration, strips of clean, bright copper are introduced into it, and the whole gently heated. The copper gradually becomes coated with a deposit like that which is formed in Reinsch's process. (*N. Y. Med. Journ.*, April, 1865, p. 13.)

A modification of the methods of Marsh and Reinsch has been proposed by Dr. Alfred S. Taylor, which he has found effectual in detecting arsenic whether in liquids or solids, and whether associated with organic or inorganic substances, for an account of which, however, we must be content, from want of space, to refer the reader to the paper of that eminent toxicologist in the *Pharmaceutical Journal and Transactions* (Feb. 1861, p. 411).

Still another method of detecting arsenic is the *electrolytic*, consisting in exposing the suspected liquid, in connection with diluted sulphuric acid, to a voltaic current, through the influence of which, if arsenic be present, even though associated with large quantities of organic matter, arseniuretted hydrogen (*terhydride of arsenic*) is evolved. It is, however, only the arsenious acid that will respond to this test, arsenic acid not being affected; and the presence of mercury interferes materially with the process. For an account of the process, and of the method of rendering arsenic acid sensible to the test, and of counteracting the influence of the mercury, see papers by Mr. C. L. Bloxam in the *Pharm. Journ. and Trans.* (Jan. 1860, p. 376, and April, 1861, p. 528).

It has been shown by MM. Malaguti and Sarzeau that, for the detection of minute quantities of arsenic in exhumed bodies, the best method of proceeding is to distil the viscera with aqua regia, made by mixing one part of nitric with three of hydrochloric acid. The animal matter (the liver for example), cut into small pieces, is dried by a gentle heat, and mixed with a quantity of the aqua regia equal to the weight of the matter before it was dried. The mixture is distilled, and the arsenic, if present, comes over in the form of the volatile terchloride, which may be converted into the tersulphuret in the usual manner.

Arsenic may be detected in exhumed bodies long after death. M. Blondlot found it in the brain of a body that had been buried twenty years. In this case, it was ascertained that no arsenic existed in the earth of the cemetery. (See *Brit. and For. Medico-chir. Rev.*, Jan. 1855, p. 222.) It is necessary also to be guarded against the possible presence, about the body, of metals which may contain arsenic; as, for example, brass and copper. L. A. Buchner has found, in the intestines of persons who had been poisoned with arsenious acid, examined some months after death, the poison in the state of yellow sul-

phuret of arsenic, into which it had been converted by the sulphuretted hydrogen developed by the putrefactive process that had taken place in the bowels, showing that even in poisonous doses arsenic has not always the property of preserving the body from corruption. (*Neues Repertorium*, xvii. 21.)

ACIDUM CARBOLICUM. *Br.*

Carbolic Acid.

An acid obtained from coal-tar oil by fractional distillation and subsequent purification. *Br.*

Syn. Phenic Acid. Phenylic Acid. Phenol. Hydrated Oxide of Phenyl. Phenylic Alcohol. Acide Phénique, *Fr.*

This important medicine is a new officinal of the British Pharmacopœia, not yet introduced into our own, because comparatively little known when the existing edition was prepared. It was discovered, in 1834, in the tar of coal, by Runge, who gave it the name of carbolic acid. In 1841, it was thoroughly investigated by Laurent, by whom it was considered as the hydrated oxide of a peculiar compound radical called *phenyl* (from φαινω, I show), and therefore described by the name of *hydrated oxide of phenyl.* Its acid properties, however, having been subsequently recognised, it received the name of *phenic acid;* but, out of consideration for the original discoverer, chemical writers generally adhere to the title he gave it of carbolic acid. When on the subject of its composition, we shall have occasion to show that it is more closely related chemically with the alcohols, than the acids, and that consequently its proper designation would be *phenylic alcohol.*

Preparation. Carbolic acid exists, in some unknown mode of combination, in that portion of coal-tar which distils over between 300° and 400° F. This, when mixed with a hot concentrated solution of hydrate of potassa, is resolved, on the addition of water, into a light oil and a heavier alkaline liquid. If the latter be separated, and neutralized with muriatic acid, carbolic acid will be disengaged in an impure state, and will float on the surface in the form of a light oil. By distilling this from dried chloride of calcium to separate water, and exposing the distillate to a low temperature, carbolic acid congeals in the form of a colourless crystalline mass, disposed to deliquescence, which is to be separated from the accompanying liquid by pressure in bibulous paper. This remains solid at a higher temperature than that required to congeal it; but at 95° it melts, and constitutes the acid in its liquid form.

But it is much more difficult to obtain the acid in its pure crystalline condition than might be inferred from this simple method of preparation. There are two difficulties especially in the way; one consisting of the presence in coal-tar oil of another principle, closely analogous to carbolic acid, denominated *cresylic acid,* which is apt to accompany the former in all the steps of its preparation, and, through its much lower congealing point, interferes with its crystallization; the second, of the existence in the original oil of a principle which, on exposure to the air, becomes of a brown colour, and if not thoroughly separated in the process, imparts the same property to the carbolic acid. Now cresylic acid has remedial and hygienic influences, equal, and, as some think, even superior in certain respects to the carbolic; so that unless the object be to obtain the carbolic acid in the crystalline state, which is for some purposes highly desirable, no great harm can result from their admixture. The colouring impurity, however, is only injurious, and should be got rid of if possible.

The following observations of M. Muller, condensed from the *Zeitschrift für Chemie* (New ser., vol. i. p. 270), may be useful to the manufacturer. Carbolic acid (phenic acid or phenylic alcohol) is habitually accompanied by its congeners, denominated by M. Muller, from his view of the nature of these bodies, *xylic* and *cresylic alcohols,* which adhere to it tenaciously, and cause

it to become brown on contact with the air. The author procures it pure in the following method. Coal-tar yields to soda a mixture of the substances mentioned with naphthalin, which is soluble in a concentrated solution of the alkaline carbolates. Water is added until it ceases to produce a precipitate; and the liquid is exposed to the air in broad shallow vessels, so as to facilitate the formation and deposition of brown substances. The liquid is then filtered, and the quantity of organic matter held in solution approximatively determined. As the matter consists mainly of carbolic acid and its congeners, combined with the alkali used, it is easily separated by acids. But the carbolic acid is the last to separate; so that it is easy to get rid of the congeners, as well as the brown and resinified products, by adding only so much acid, the quantity being ascertained by calculation, as may be required to precipitate at once the foreign substances. By a few additions cautiously made, the operator will soon reach a point at which the carbolic acid will remain nearly pure. After rectification, the product soon crystallizes. As water, even in minute proportion, hinders this crystallization, a current of dry air is made to pass over the carbolic acid nearly boiling hot, so as to complete the desiccation. The crystallization is promoted by a sudden reduction of temperature, or the introduction of a fragment of the acid already crystallized. M. Muller attaches much importance to the long exposure to the air of the original alkaline solution, so as to favour the resinification and deposition of the brown matters; as the carbolic acid is always impure when coloured. It often also contains a fetid substance, which is probably a sulphuretted compound of phenyl or cresyl. This can be separated by distillation from a little oxide of lead. (*Journ. de Pharm. et de Chim.*, 4e sér., ii. 408.)

Commercial forms. In one of his latest publications in reference to carbolic acid, Dr. F. Crace Calvert, to whom probably, more than any other person, is owing the introduction of this substance into use in Great Britain and the United States, informs us that the carbolic acid obtained by Laurent, melting at 34° C. (93° F.), and boiling at 186° C. (367° F.), was not quite pure. By successive steps of improvement in the process employed by the manufacturing house at Manchester with which he is connected, they had at length succeeded in preparing the pure crystallized acid, without colour or sulphurous odour; but, unfortunately, this statement is not accompanied with an account of the means by which the end had been attained. But, as the products of this factory are those now generally used, a brief notice, derived from the same source, of the forms of the drug prepared by them, and now circulating in the market, is desirable. 1. A pure acid is prepared, crystallizing in white prismatic crystals, but, as usually sold, in a white, hard, fused mass, which differs from Laurent's in being soluble in 20 parts of water instead of 33 parts, fusible at 106° instead of 93°, and boiling at 359° instead of 367°. This should be preferred for internal use. 2. The second form is less pure. Like Laurent's, it is white, solid, and fusible at 93°, and may be employed for external purposes, whether in medicine or surgery; but it is objectionable for internal use on account of its tar-like taste. 3. A third quality is manufactured, in white detached crystals, which melt at 81°. This, when dissolved in from 50 to 100 parts of water, forms a perfectly colourless solution, which can be used for antiseptic and disinfecting purposes. 4. The fourth and last form is that of a nearly colourless liquid, which is a mixture of carbolic and cresylic acids. Diluted with 100 parts of water or more, it may be used for the coarser antiseptic and disinfecting purposes out of doors, as in cess-pools, sewers, &c., and has been extensively employed to prevent the spread of the late very fatal disease among cattle, the famous *rinderpest*. (*Lancet*, Dec. 14, 1867, p. 734.) Besides these forms of carbolic acid, which issue from the manufacturing establishment of the Messrs. Calvert, there are others from different sources, generally in the liquid state, which are usually of a brownish colour, and consist of mixtures of carbolic acid with the cresylic acid, colouring matter, &c., and of which the first often constitutes but a small proportion. These are often imported

from Germany. They should not be used internally; but, for disinfectant and antiseptic purposes, they are probably equal to solutions of the pure acid, as the cresylic acid is said to be quite as powerfully disinfectant as the carbolic, if not more so.

These impure liquors are sold sometimes under the improper name of *coal-tar creasote*. They are of various shades of colour from a light brown to nearly black. Their value depends on the proportion of carbolic and cresylic acids contained in them. Sometimes they consist of these acids almost exclusively, sometimes contain little comparatively, the residue consisting of nearly valueless coal oils, and occasionally in part of sulphuretted compounds of the two acids. In certain cases, an alkali is added to increase the solubility of the acids. They ought to contain from 70 to 90 parts of the acids (*Squibb*), and should yield this percentage of their bulk to warm water when agitated with it in great excess.*

Properties. Carbolic acid, in its pure state, is a solid at ordinary temperatures, crystallizing in minute plates or long rhomboidal needles, white or colourless, of a peculiar odour recalling that of creasote, and an acrid burning taste. Its sp. gr. is 1·065. (*Lemaire.*) If coloured brown under the influence of light and air, it is impure. It deliquesces on exposure, and ultimately becomes liquid; and the presence of water in the smallest proportion causes it to liquefy. When quite pure, it melts at 106°, forming an oily-looking, colourless liquid, and boils at 359° F. (*Calvert*); but as often met with its point of fusion is lower, and that of volatilization higher than those named. The Br. Pharmacopœia gives the former at 95°, the latter at 370°. Carbolic acid is inflammable, burning with a reddish flame. The plane of polarization of a ray of polarized light is not affected by it. It is soluble in 20 parts of water (*Lemaire*); its solution being, if pure, colourless, and remaining so; but if impure, coloured brownish by exposure. It is very soluble in alcohol, ether, acetic acid, glycerin, and the volatile and fixed oils. (*Lemaire.*) Though neutral to test-paper, it combines feebly with salifiable bases; its salts being decomposed by carbonic acid, and those with the alkalies having an alkaline reaction. The carbolate of potassa is said to be decomposed even by water. Heated with ammonia, it yields aniline and water. Nitric acid converts it into picric acid, in the manufacture of which it is largely used. It reduces many metallic salts, especially those of silver and copper, and coagulates collodion. All the soluble carbolates communicate to pine wood, impregnated with their solution, the property of assuming a deep-blue colour half an hour or an hour after having been steeped in muriatic acid. (*Lemaire.*) Carbolic acid in solution coagulates albumen, arrests fermentation, instantly destroys the lower forms of vegetable and animal life, and in very small proportion prevents mouldiness in vegetable juices, and protects animal substances against putrefaction.

The substances with which carbolic acid is most likely to be confounded are cresylic acid and creasote, the former, like it, extracted from coal-tar, the latter from wood-tar exclusively. As cresylic acid is incapable of crystallizing at

* Mr. William Crooks gives the following methods of testing these liquids, with sufficient accuracy for practical use. Commercial carbolic acid fit for disinfecting purposes is soluble in from 20 to 70 parts of water, and in twice its bulk of solution of caustic soda, while the oily impurities are nearly insoluble. 1. Put one fluidrachm of the liquid to be examined in a bottle, add half a pint of warm water, and shake occasionally for half an hour. The amount of oily residue will indicate the measure of adulteration. 2. Mix one part of caustic soda with ten parts of the adulterated liquid, and shake them well together. The residue undissolved is impurity. 3. The presence of the "sulpho-carbolic and sulpho-cresylic acids," as well as the sophistication which consists in dissolving carbolic acid in water by means of an alkali, may be determined through the greater solubility of the adulterated than the unadulterated liquid. Put a wineglassful of the suspected liquid in a bottle, and add half a pint of warm water. If the greater portion dissolves, it is adulterated. If the liquid change litmus decidedly red, the impurity will be shown to consist of the acids mentioned; while, if the alkaline adulteration has been used, the litmus previously reddened will have its blue colour restored. (See *Am. Journ. of Pharm.*, May, 1867, p. 282.)

ordinary temperatures, the two cannot be confounded in the solid state, and, as before observed, its presence in the liquid state is of little consequence; as its virtues are of the same kind, and at least equal. Its boiling point, however, is considerably higher than that of carbolic acid, being about 400°; and it may, therefore, be supposed to be present in any suspected liquid which will not crystallize at any common temperature, nor boil under 395° to 400°. Creasote is distinguished by its less density, its liquid form, and higher boiling point; by not coagulating collodion; and by the different effects on it of strong nitric acid, which with carbolic acid produces pure picric or trinitrophenic acid, and with creasote, oxalic acid, resinous matter, and but a small proportion of picric acid (Calvert, *Lancet*, Oct. 31, 1863, p. 523.) Carbolic acid differs also in having no effect on polarized light. The change of colour in pine wood under the successive action of carbolic and muriatic acids has been mentioned above.

Composition. The view generally taken of the composition of carbolic acid is, that it is the hydrated oxide of a peculiar compound radical denominated by Laurent *phenyl* ($C_{12}H_5$), and therefore, being analogous to the alcohols, should be called *phenylic alcohol*. It may be represented by the formula $C_{12}H_5O+HO$, or empirically $C_{12}H_6O_2$. Indeed, its claims to be considered as an acid are very feeble; as, though it combines with salifiable bases, it is incapable of neutralizing the alkalies, does not affect the colour of litmus, and may be separated from its combinations with great facility, sometimes it is asserted even by water. Shaken in the liquid form with one-fourth of water, and cooled to 40° F., it crystallizes in the form of a hydrate, $C_{12}H_5O+2HO$. (C. H. Wood, *Pharm. Journ. and Trans.*, July, 1867, p. 19.)

Medical Properties and Uses. Carbolic acid, in the liquid form, is locally powerfully irritant, and, applied undiluted to the skin, causes a sharp pain lasting for about an hour, and accompanied with a whiteness of the surface, which has been ascribed to the coagulation of albumen, and is followed by severe inflammation and separation of the epidermis. In contact with mucous surfaces it acts in the same way, and if continued long enough may produce a superficial caustic effect. Taken internally in large quantities, and in a concentrated state, it operates as an irritant or corrosive poison; and a case is recorded of instant death in a man, who, half intoxicated, had swallowed a bottle of it in mistake for rum. (*Med. Times and Gaz.*, Aug. 1866, p. 173.) Several instances, besides, have been known of serious injury from its incautious use. (*Chem. News*, Sept. 7, 1866, p. 119.) Its effects when taken internally in moderate doses do not seem to have been very accurately studied. They are, however, very probably similar to those of creasote. Upon the alimentary mucous membrane the medicine operates as a gentle irritant, and, being absorbed into the circulation, probably escapes through the kidneys, and by exhalation from the bronchial mucous membrane, thus acting as a diuretic and expectorant, and at the same time as an alterative to the urinary and respiratory passages. It is also somewhat stimulant to the circulation; and, though it produces no very observable influence on the brain in the ordinary medicinal doses, it seems to act powerfully on that organ when very largely taken. In experiments made by Dr. W. Kempster, of Utica, New York, on certain small animals, as the cricket, the mouse, and the rat, by confining them in large glass vessels, with a little liquid carbolic acid, either spread over the sides of the vessel, or suspended within it upon a piece of sponge, the animals, at first greatly excited, soon began to show signs of intoxication by their staggering movements, which were followed by a state of anæsthesia, and death preceded by violent convulsions. The brain and its membranes were found, on dissection, greatly congested; while the spinal cord below the cervical vertebra was bloodless, the lungs were collapsed, and the heart tense, though filled with coagulated blood. (*Am. Journ. of Med. Sci.*, July, 1868.)

But by far the most important property of carbolic acid, both as a therapeutic and preventive agent, is its destructive influence over the lower grades of organic life, whether vegetable or animal. In a solution containing only one part of

the acid in 500 of water, it instantly destroys vegetable mould, both plant and spores, and operates with equal destructiveness upon minute or microscopic animalcules. Through this power it checks the different proper fermentations, including the putrefactive, and thus acts powerfully as an antiseptic or disinfecting agent. It operates with wonderful efficiency in correcting or preventing putrefaction in animal substances, produces the same effect in the living human subject, and, through the same influence, corrects or suppresses those fermentative processes in the body which often lead to the most serious results, as purulent infection, poisoned dissecting wounds, carbunculous diseases, and hospital gangrene. Of these applications, as well as of its use in the prevention of infectious diseases, we shall treat more in detail directly.

Carbolic acid has been used internally with advantage in vomiting and diarrhœa, and in cases of dyspepsia accompanied with pain after eating, in all of which it may be supposed to act usefully by its stimulant or alterative influence on the mucous membrane. But there are also gastric and intestinal affections in which its antizymotic powers may sometimes give it great efficiency, as in yeasty vomiting, excessive flatulence, with or without pain, dependent on fermentation in the incompletely digested food, and in those cases of obstinate diarrhœa associated with the action of putrescent miasms on the system. Dr. Kempster speaks of it as being successfully used in the State Lunatic Asylum at Utica, in sluggishness of the bowels with offensive breath; and in all instances of fetid eructation, or extremely offensive flatulent discharges per anum, it would be very apt to afford relief. In cases of foul breath, connected with morbid states of the blood, it is clearly indicated; as also in chronic bronchial inflammation, and disease of the urinary passages attended with offensive purulent discharge; in all which cases it may come by absorption into positive contact with the morbid cause. From its poisonous action on the lower animals, its use in the different verminose diseases of the bowels has been suggested; and it is peculiarly applicable to ascarides in the rectum administered by injection. In various so-called zymotic diseases, as scarlatina, diphtheria, &c, independently of its usefulness as a local application, it may be given in the hope that it may interrupt the fermentative process supposed to be going on in the system, as it interrupts similar processes out of the body.

But it is more as a topical than as an internal and systemic remedy that carbolic acid has been used; and its employment in this way has reference in general to its antiseptic and antizymotic property. As regards the mere correction of offensive odour, by decomposition or neutralization of the effluvia on which the odour depends, there are other medicines much more energetic than carbolic acid, as chlorine, bromine, and especially permanganate of potassa. Indeed, it has been doubted whether carbolic acid acts, in any degree, upon the offensive effluvia; but this, I think, is going too far; and the probability is that, even as regards the odorous matter, it exercises some deodorizing influence beyond that of merely disguising the smell of the offensive exhalations by its own, in other words, that it really acts chemically on them; though much less energetically than several other deodorizers. Its real action, however, is much more upon the cause of the exhalations than upon themselves. Most of these offensive odours depend upon a species of fermentation, the putrefactive for example, and the fermentations themselves are at present generally ascribed to the influence of microscopic organisms. Now carbolic acid, even in very dilute solution, is powerfully destructive of all such organisms, and consequently of the fermentative processes they support. Thus, carbolic acid acts much more by preventing putrefactive exhalations, than by destroying them. A piece of offensive animal matter is less speedily deodorized by carbolic acid than by permanganate of potassa; but the former in a short time entirely suppresses the putrefaction, and the matter consequently ceases to smell because it ceases to putrefy; whereas, under the mere chemical agent, it is only by its constant presence that the odour is prevented, and the putrefaction goes on unchecked.

Through its parasiticidal influence, carbolic acid is highly useful, as a local

application, in all the diseases which are connected with or dependent on the presence of microscopic plants or animals. Hence its use in scabies, in which it destroys the itch insect, in the different forms of porrigo and trichosis, in pityriasis versicolor, in the thrush of infants, and in all cases of minute vermin affecting the human body. In these cases it is applied to the parts affected in weak solution, or in the form of ointment, or, where the affection is widely diffused, in that of bath. Offensive diphtheric exudations, putrid ulcers wherever they can be reached, and suppuration with a similar offensive odour, whether on the outer surface, or from the mucous passages, as of the nose, bronchial tubes, external meatus, urinary outlets, the rectum, and the vagina in females, afford similar indications for its use. Hence, it has been recommended in diphtheria, scarlatina anginosa, malignant or putrid sorethroat, ozæna, chronic bronchitis with copious expectoration of bad-smelling pus, in purulent otitis, in chronic cystirrhœa, hemorrhoids, rectal fistulas, abscesses into which the air has found entrance, and in leucorrhœa, and offensive lochial discharges. In the bronchial affection, the solution has been employed successfully by Dr. Kempster in the form of spray by means of the atomizer. (*Am. Journ. of Med. Sci.*, July, 1868.) It may be used advantageously also in anthrax, malignant erysipelas, hospital gangrene, and in fistulous ulcers, often affecting the bones, into which it may be injected. On the same principle, it has recently been much used as a dressing in compound fractures, and after extensive surgical operations, in which it was introduced by Dr. Jos. Lister, Prof. of Surgery in the University of Glasgow. (*Lancet*, Sept. 21, 1867, p. 353.) In bad cases of this kind, copious suppuration is apt to occur, with offensive discharges from the putrefaction of pus, blood, or other substances in the wound, by which the system often becomes seriously affected, and even purulent infection may take place. By dressing the wounds with carbolic acid in various degrees of strength, these sinister effects are often obviated, the suppurative process itself controlled, and healing greatly promoted. This is easily understood, if it be admitted that the changes originate in the presence of living organisms, giving rise to putrefactive or other hurtful fermentations. Exactly on the same grounds, good may be anticipated in puerperal cases attended with offensive discharges, and in the systemic disturbances from dissecting and other poisoned wounds. It has been highly recommended as a dentifrice in carious teeth with offensive breath, and to keep the teeth and gums clean from tartar or other morbid deposit, consequent upon, or at least connected with the presence of minute parasitic organisms in these parts. Introduced on cotton, in a concentrated liquid state, into the cavity of a carious tooth, it quickly relieves pain; but care must be taken to prevent it from touching the lips, or internal surface of the mouth. In cases, too, of morbidly offensive secretion in the axilla and groin, between the toes, &c., it may be used in the form of solution or ointment with hope of benefit.

Independently of its disinfectant properties, it may be employed locally, in weak solution, as a gentle irritant or alterative, or concentrated, as a mild escharotic, in chronic indolent or flabby ulcers, or in those of a specific character, as the syphilitic, in cutaneous eruptions independent of cryptogamic cause, and in non-suppurative chronic or even acute inflammation of the mucous membranes, as in common angina. In scalds and burns it is said to have proved very useful. Dr. E. R. Squibb has published a statement of extraordinary success from it in two cases, one a scald and the other a burn, in which its application in the early stage produced a prompt relief of the pain, and favoured a speedy cure. (*N. Y. Med. Gaz.*, April 18, 1868, p. 236.) In consequence of its coagulating albumen, it may sometimes be beneficially employed to arrest hemorrhage.

The dose of carbolic acid is one or two grains, or of the acid in its concentrated liquid form one or two drops, which may be given in half a fluidounce or a fluidounce of sweetened water. An excellent menstruum is glycerin, which dissolves it in all proportions; and the Br. Pharmacopœia has a pre-

paration denominated *glycerine of carbolic acid*, made by rubbing an ounce (avoirdupois) of the acid with four fluidounces of the menstruum, of which about four and a half minims represent a grain of the acid. From this solution formulas may be readily prepared, either for internal or external use, by diluting it with water. An emulsion also may be made by mixing one part of the acid with eight parts of water and one or two parts of sugar.

For external use the strength varies greatly according to the object desired. When applied with a view to its superficial escharotic action, as in gangrenous or specific ulcers, it may be used in the solid state properly comminuted, or in the strongest liquid form. In this state it may be readily obtained by placing the bottle containing it in hot water. For the skin affections one part of the acid may be dissolved in one hundred or two hundred parts of water; or the impure liquid acid may be used, diluted in the same proportion. M. Bazin uses a solution of one part in forty parts of acetic acid of 8° B., and 100 of water, in tetter and psora, and states that a single application will destroy the itch insect. A solution containing a grain to the fluidounce of water may be used for application, in the form of *spray*, to the fauces, larynx, and bronchia, by means of the *atomizer;* and the strength may be increased, if thought desirable, up to four or five grains or more to the fluidounce.

Prof. Lister, in his use of the acid in compound fractures, first introduces the liquid acid of its full strength into all accessible parts of the wound, in order completely to destroy all the septic germs which may have entered the wound with the air at the occurrence of the accident; and, for this purpose, a few drops of water added to the crystallized acid are sufficient to render it liquid. The next step is to cover the surface of the wound and a part of the sound skin with lint dipped into the liquid acid, in order to prevent the introduction of the septic agent from the atmosphere, along the stream of blood, &c. oozing from the wounded surfaces, and making its escape. The lint he protects by a tin covering, which is raised daily to admit of a fresh application of the acid. If the wound, however, is extensive, he substitutes for the saturated lint a sort of paste, made by rubbing up common whiting with a solution of one part of carbolic acid in four parts of boiled linseed oil, so as to form a firm putty, which is to be applied of the thickness of one-fourth of an inch, between two pieces of muslin. This does not excoriate the skin. So long as there is any discharge, the paste is renewed daily. The whole is covered with rags dipped in the oleaginous solution of the acid, applied directly to the skin and kept there. When the discharge ceases, the paste is removed; but the original dressing is left till the wound heals. This plan, introduced into hospital practice, has not only acted most favourably on individual cases, but has had an excellent effect in preserving the healthfulness of the wards; the prevalence of pyæmia, hospital gangrene, erysipelas, &c., having been effectually prevented.

For a gargle in diphtheria, the sorethroat of scarlatina, &c., 20 minims of the liquid acid may be mixed with half a drachm of acetic acid (*Br.*), two fluidrachms of tincture of myrrh, and six fluidounces of water. It is asserted that with this early applied there will be few failures in diphtheria. (*M. and S. Reporter*, Aug. 3, 1867, p. 101; from *Med. T. and Gaz.*) For burns and scalds a liniment may be made by rubbing together one part of carbolic acid and 6 parts of olive oil, applied on lint. For the dressing of cancerous and other foul ulcers, an ointment may be used composed of 5 grains of the acid rubbed with an ounce of simple cerate.

The impure liquid acid sold in the shops usually contains from 70 to 90 per cent. of carbolic and cresylic acids jointly (*Squibb*), and, as the latter acid is quite equal to the former in disinfecting power, yields, if dissolved in water in the proportion of one to 80 parts, a solution equivalent on the average to that produced by dissolving one part of the pure acid in 100 parts of water.

M. Bobœuf prefers the salts of carbolic acid to the acid itself. He has found the carbolate of potassa or soda, in a solution of from 5° to 10° B., applied, by means of compresses, to bleeding wounds, to suppress hemorrhage instantly. (*Ann. de Thérap.*, 1862, p. 62.)

The *hygienic application* of carbolic acid is among its most important uses, if not absolutely the most important. By the free use of it in the wards of hospitals, and in the private chambers of the sick, sprinkling it over the contents and through the air of the infected apartments, introducing it into the close stools, and washing with it to a greater or less extent, the persons of the sick when requiring it, much may no doubt be done towards the prevention of infectious and probably even contagious diseases; and there is reason to believe that the spread of certain fatal epidemics, as cholera, yellow-fever, and various malignant typhoid affections, though probably not arrested, may be much limited by bringing this agent to bear upon the morbific causes, and especially by correcting, through its influence, the numerous exhalations from accumulations of filth, which contribute to the support and propagation of these causes. It is believed that the use of carbolic acid proved to a certain extent effectual in limiting the prevalence of the epidemic cattle disease lately so destructive in Europe. For these purposes, as before stated, the impure liquid acid is at least equally effectual; and Dr. Squibb recommends that, for disinfecting purposes, a solution should be kept on hand made, on the large scale, by dissolving two pints of the impure acid in a barrel or forty gallons of water; this being of about the same strength as the acid usually sold for such purposes. (*N. Y. Med. Gaz.*, April 18, 1868, p. 235.)

Off. Prep. Glycerinum Acidi Carbolici, *Br.* W.

ACIDUM CHROMICUM. *U. S.*

Chromic Acid.

This is a new officinal of the U. S. Pharmacopœia, in which it is placed in the Materia Medica Catalogue as an article furnished by commerce. It is readily obtained by mixing 100 measures of a cold saturated solution of bichromate of potassa with 150 measures of sulphuric acid, and allowing the mixture to cool. The sulphuric acid unites with the potassa, and sets free the chromic acid, which is deposited in crystals. The mother-liquor having been poured off, these are placed upon a tile to drain, covered with a glass bell-jar.

Properties. Chromic acid is in the form of anhydrous, acicular crystals, of a brilliant crimson-red colour and an acid metallic taste, deliquescent, and very soluble in water, forming an orange-yellow solution. "At a heat between 356° and 374°, they melt into a reddish-brown liquid, which, on cooling, becomes a red, opaque, and brittle mass." *U. S.* Chromic acid is a teroxide of the metal chromium, having the formula CrO_3. At a heat above the melting point, it gives off half its oxygen, and is converted into the green sesquioxide Cr_2O_3. It is a powerful oxidizing and bleaching material, and gives up its oxygen with great facility to organic matter, which is at the same time dissolved. "If a few drops of alcohol are allowed to fall on a small portion of it, a vigorous action takes place, attended with an increase of bulk, and the liquid formed becomes yellowish-brown." *U. S.*

Medical Uses. Chromic acid is used medically only as an escharotic, in which capacity it acts by rapidly oxidizing and thus decomposing the tissues, while, by the loss of one-half its oxygen, it is itself converted into the inert sesquioxide. It was first employed as a caustic by Prof. Sigmund, of Vienna, on the recommendation of Dr. Heller. Used in substance, made into a paste with water, its action is exceedingly slow and gradual, but deeply penetrating. In saturated solution its action is less penetrating and less gradual. By using a solution more or less dilute, the action may be graduated according to the degree of effect desired. Prof. Sigmund tried the concentrated solution, with advantage, for the destruction of condylomata, occurring in his syphilitic wards. The acid has been used with very good results by Mr. Marshall, of University College Hospital, London, for removing warts and other morbid growths from the genital organs. The solution employed was of the strength of 100 grains

of the acid to a fluidounce of distilled water. It is most conveniently applied by means of a pointed glass rod. Dissolved in an equal weight of distilled water, it has been employed very advantageously by M. Hairion in destroying excrescences in the female generative organs, and in certain obstinate forms of granular conjunctivitis, in which nodules form on the conjunctiva, threatening a destruction of the neighbouring tissues, especially of the cornea. He applies it by means of a pencil, and finds it neither very painful, nor followed by much reaction. Nevertheless great caution is required not to allow the destruction of parts to extend too far; and in ordinary granular disease of the membrane he considers it too hazardous for use. (*Archives Générales*, Mars, 1859, p. 352.) Chromic acid is well suited to the destruction of morbid growths, and gives less pain than other caustics. It acts as a rapid solvent of organic matter. "Smaller animals (mice, birds, &c.) were so completely dissolved by the acid within fifteen or twenty minutes, that no trace of their bones, skin, hair, claws, or teeth could be discovered." (*Dublin Quarterly Journ.*, xiii. 250, from the *Wiener Medizinische Wochenschrift.*) B.

ACIDUM CITRICUM. *U.S., Br.*

Citric Acid.

Acidum limonis, *Lat.;* Acide citrique, *Fr.;* Citronensäure, *Germ.;* Acido citrico, *Ital., Span.*

Citric acid is the peculiar acid to which limes and lemons owe their sourness. It is present also in the juice of other fruits; such as the cranberry, the red whortleberry, the berry of the bittersweet, the red gooseberry, the currant, the strawberry, the raspberry, the tamarind, and the red elderberry (fruit of Sambucus racemosa rubra). The latter berry contains citric acid so abundantly that it has been proposed as a source of the acid by M. Thibierge, of Versailles.

The acid is extracted from lemon or lime juice by a very simple process, for which we are indebted to Scheele. The boiling juice is first completely saturated with carbonate of lime (chalk or whiting) in fine powder, and the citrate of lime formed is allowed to subside. This is then washed repeatedly with water, and decomposed by dilute sulphuric acid. An insoluble sulphate of lime is immediately formed, and the disengaged citric acid remains in the supernatant liquor. This is carefully concentrated in leaden boilers until a pellicle begins to form, when it is transferred to other vessels in order to cool and crystallize.

In the *U. S. Pharmacopœia* citric acid is properly placed in the Materia Medica list as an article purchased from the manufacturing chemist. The *British Pharmacopœia* gives the following process for preparing it.

"Take of Lemon Juice *four pints* [Imperial measure]; Prepared Chalk *four ounces and a half* [avoirdupois]; Sulphuric Acid *two fluidounces and a half;* Distilled Water *a sufficiency.* Heat the Lemon Juice to its boiling point, and add the Chalk by degrees till there is no more effervescence. Collect the deposit on a calico filter, and wash it with hot water till the filtered liquor passes from it colourless. Mix the deposit with a pint [Imp. meas.] of Distilled Water, and gradually add the Sulphuric Acid previously diluted with a pint and a half [Imp. meas.] of Distilled Water. Boil gently for half an hour, keeping the mixture constantly stirred. Separate the acid solution by filtration, wash the insoluble matter with a little Distilled Water, and add the washings to the solution. Concentrate the solution to the density of 1·21, then allow it to cool, and after twenty-four hours decant the liquor from the crystals of sulphate of lime which have formed; further concentrate the liquor until a film forms on its surface, and set it aside to cool and crystallize. Purify the crystals if necessary by a recrystallization." *Br.*

A preliminary fermentation, which was directed in the former British Pharmacopœia, has been abandoned in the present; and properly, as the viscidity which it was intended to remove, is sufficiently got rid of by heating the juice to the boiling point. The Br. Pharmacopœia states, as an evidence

of the purity of the crystals, that "70 grains dissolved in distilled water are neutralized by 1000 grain-measures of the *volumetric solution of soda.*"

Preparation on the Large Scale. The juice is placed in a large vat, closed at top, and is saturated with whiting (carbonate of lime). Carbonic acid gas is evolved, which passes out by an exit-pipe, and may be used in the manufacture of bicarbonate of soda; and citrate of lime precipitates. The supernatant liquor, containing much extractive matter, is drawn off; and the citrate of lime is decomposed by dilute sulphuric acid, liberating the citric acid, and precipitating the lime as a sulphate. The mixture of citric acid and sulphate of lime is run off into a wooden filter back, lined with lead, furnished with a perforated false bottom, and lined throughout with stout twilled flannel. The solution of citric acid passes off through a pipe, leading from the bottom of the back to suitable reservoirs. The sulphate is washed until it becomes tasteless, and the washings are run off into the same reservoirs. The filtered acid solution is then concentrated by evaporation in wooden vessels lined with lead, through which steam is made to pass by means of coiled lead pipes. As citric acid is liable to decomposition, if subjected to too high a temperature, the use of the vacuum pan is highly advantageous in concentrating the solution. When the liquor is sufficiently concentrated, it is transferred to cylindrical sheet-lead vessels, placed in a warm situation, to crystallize. The crystals, at first obtained, are coloured. In order to purify them, they are redissolved in a small quantity of water, with the assistance of heat, and the solution is digested with purified animal charcoal, filtered, and recrystallized. The crystals, after having been washed and drained, are dried on wooden trays lined with sheet-lead, in a room heated by steam. More recently, Dr. Price and Mr. Pontifex, both of England, have made improvements in the manufacture of citric acid, for the details of which the reader is referred to the *Pharm. Journ. and Trans.* (xiii. 313, and xvi. 430).*

The citrate of lime of the above process should be decomposed without delay; for, if kept, it will undergo fermentation, with the effect of destroying the citric acid. According to Personne, the products of this fermentation are acetic and butyric acids; carbonic acid and hydrogen being evolved. It is desirable to have a slight excess of sulphuric acid, as this rather favours than otherwise the

* Some suggestions have recently appeared in the journals, in relation to the preparation of citric acid on the large scale, which may be of use to the manufacturer. In the *Chemical News* (Jan. 20, 1866, p. 40) is a short paper by Mr. Frederick Row, in which it is stated that the lemon or lime juice imported, from which most of the acid is prepared, contains so much colouring matter, mucilage, and other impurities, as very much to impede the process, and to make repeated crystallization and saturation necessary, to render the crystals fit for the market. It seems that the acid imported has undergone concentration, for the obvious purposes of enabling it to keep better, and to lessen the cost of carriage. Mr. Row states that he has found that much of the difficulty may be obviated by diluting the concentrated liquor, so that it shall have the strength of the fresh juice, by which operation much of the mucilage and other impurities will be made to separate in a flocculent form, and the citrate of lime, and consequently the citric acid will be obtained in a state of comparative purity.

Another important point is that the sulphuric acid, in slight excess at first, accumulates largely in proportion with the repeated evaporation and crystallization of the citric acid out of the solutions, and thus exercises a most destructive action on that remaining in the mother-liquors. The most effectual way of removing this difficulty is to pass the mother-liquors, as soon as the sulphuric acid becomes in injurious excess, through a fresh portion of citrate of lime, which not only removes the sulphuric acid, but causes also at the same time the deposition of flocculent matters before held in solution by means of the acid, consisting mainly of sulphate of lime.

Preparation of citric acid with the aid of magnesia. M. Perret proposes to manufacture citric acid by preparing from the juice, in the situations where lemons and limes are produced, first an insoluble tribasic citrate of magnesia, and then from this a soluble bibasic citrate of magnesia, which may be delivered to the manufacturing chemist for the extraction of the citric acid. The advantage of this method is that a material is brought to the manufacturer not liable to the injurious changes to which lemon-juice and mere citrate of lime are liable on exposure. The tribasic citrate is made from the defecated juice by adding an excess of magnesia; and the bibasic from it, by treating it with an additional quantity of juice equal to that first employed. (*Journ. de Pharm. et de Chim.*, 4e sér., iv. 48; also *Chem. News*, March 2, 1866, p. 100.)—*Note to the thirteenth edition*

crystallization of the citric acid. It is found necessary, also, to add occasionally a small proportion of sulphuric acid to the citric acid liquor, during the progress of its concentration.

According to the late Mr. Parkes, a gallon of good juice, if the process be well conducted, will yield eight ounces of white crystals. But the product depends on the proportion of citric acid in the juice, which is very variable. The more recent the juice the better the quality. That which is stale will sometimes be quite sour, without containing any citric acid, in consequence of having undergone the acetous fermentation.

Properties. Citric acid is a white, crystallized solid, often in large crystals, having the form of rhomboidal prisms with dihedral summits. It is permanent in a dry air, but becomes moist in a damp one. Its sp. gr. is 1·6. Its taste is strongly acid, and almost caustic. When heated, it dissolves in its water of crystallization, and, at a higher temperature, undergoes decomposition, becoming yellow or brown, and forming a very sour syrupy liquid, which is uncrystallizable. By destructive distillation it gives rise to water, empyreumatic oil, acetic and carbonic acids, carburetted hydrogen, and a number of pyrogenous acids, among which is the *aconitic.* A voluminous coal is left.

Citric acid dissolves in three-fourths of its weight of cold, and half its weight of boiling water. It is soluble also in alcohol, but is insoluble in pure ether. A weak solution of it has an agreeable taste, but cannot be kept, as it undergoes spontaneous decomposition. It is incompatible with alkaline solutions, whether pure or carbonated, converting them into citrates; also with the earthy and metallic carbonates, most acetates, the alkaline sulphurets, and soaps. It is characterized by its taste, by the shape of its crystals, and by forming an insoluble salt with lime-water when heated, and a deliquescent one with potassa. If sulphuric acid be present, the precipitate by acetate of lead will not be entirely soluble in nitric acid; the insoluble portion being sulphate of lead. Sometimes crystals of tartaric acid are substituted for or mixed with the citric, or the two acids may be mixed in powder, a fraud which is readily detected by adding a solution of carbonate of potassa to one of the suspected acids; when, if tartaric acid be present, a crystalline precipitate of bitartrate of potassa (cream of tartar) will be formed. A still more delicate method of detecting tartaric acid is to digest the suspected acid with hydrated sesquioxide of iron in a test tube, afterwards to raise the heat slowly to the boiling point, and, having allowed the excess of oxide to subside, to decant the clear liquid, and evaporate it to a syrupy consistence. If the acid is pure the liquid remains limpid, and of a fine red colour; if contaminated with the tartaric acid, even to the extent of only one per cent., it becomes cloudy, and deposits tartrate of the sesquioxide. (*Journ. de Pharm.*, Août, 1862, p. 169.) Another test is permanganate of potassa, of which an alkaline solution is without action on citric acid; while, under the action of tartaric acid, the peroxide of manganese is deposited. (*Ibid.*, Sept. 1867, p. 239.) "The aqueous solution of citric acid is not darkened by sulphuretted hydrogen, gives no precipitate when added in excess to solution of acetate of potassa, or of chloride of barium, and, if sparingly added to cold lime-water, does not render it turbid," *Br.;* showing the absence of metals, and of oxalic, tartaric, and sulphuric acids. Lime or other fixed impurity is detected by incinerating the acid, alone or with red oxide of mercury, when the fixed matter will be left. "One hundred grains of citric acid saturate 150 grains of bicarbonate of potassa." *U.S.*

Composition. The formula of this acid, considered dry, as it exists in the citrate of silver, is $C_{12}H_5O_{11}$. When crystallized from its solution by cooling, it contains four eqs. of water, three of which are basic. The British Pharmacopœia gives the formula of the crystallized acid $3HO,C_{12}H_5O_{11}+2HO$, thus giving it two eqs. of water of crystallization.

Medical Properties, &c. Citric acid, when given in concentrated solution to the inferior animals, acts as a poison, producing effects similar to those of oxalic acid. When largely diluted with water, it forms a cooling refreshing drink.

Accordingly, it is much used for making a substitute for lemonade. It is also employed in the composition of effervescing draughts, and for preparing the neutral mixture. (See *Liquor Potassæ Citratis.*) When added in the quantity of nine drachms and a half to a pint of distilled water, it forms a solution of the average strength of lemon-juice. Of this solution, or of lemon-juice, a scruple of bicarbonate of potassa saturates three fluidrachms and a half; a scruple of carbonate of potassa, four fluidrachms; and a scruple of carbonate of ammonia, six fluidrachms. Half a fluidounce of lemon-juice, or of an equivalent solution of citric acid, when saturated, is considered a dose. An agreeable substitute for lemonade may be made by dissolving from two to four parts of the acid, mixed with sugar and a little oil of lemons, in nine hundred parts of water; or a scruple of the acid may be dissolved in a pint of water, and sweetened with sugar which has been rubbed on fresh lemon peel. The dose of the acid may be stated at from five to thirty grains.

The physiological action of a weak solution of citric acid is that of a refrigerant, increasing the fluidity of the blood, and rendering it less coagulable Hence its utility in inflammations and fevers. Dr. C. W. Oleson, of Bloomingdale, Ill., has found it peculiarly useful in a case of metritis, giving a teaspoonful of a solution, containing about four grains of the acid, every two hours. (*Am. Journ. of Med. Sci.*, July, 1867, p. 277.) It is also useful in scurvy, liver disease, and dropsy. In recent times citric acid, in the form of lemon-juice, has come into vogue as a remedy for gout and rheumatism; but the trials made with it in these diseases have not shown that it possesses any peculiar efficacy. Dr. H. Bence Jones has made some interesting observations on citric acid and lemon-juice, and concludes that their action is identical. Experimental trials showed that they always increase the acidity of the urine. In view of this fact, Dr. Jones cautions the practitioner against the use of the juice for three or four weeks continuously in chronic gout or rheumatism, for fear that red gravel, or uric acid calculus should be produced. (See *Am. Journ. of the Med. Sci.*, Jan. 1855, p. 204.) The dose of lemon-juice in inflammatory rheumatism is two fluidounces, repeated from four to six times a day. Citric acid has recently been employed with much supposed advantage, as a local remedy, in diphtheric exudation, and in cancerous ulcers, being applied in the form of lemon-juice, or dissolved in water in the proportion of a drachm to eight fluidounces.

ACIDUM LACTICUM. *U.S.*

Lactic Acid.

This is a new officinal of the U. S. Pharmacopœia, and placed in the Materia Medica list, without a formula for its preparation. Lactic acid was discovered by Scheele. It exists in sour milk, and has been found in a number of the secretions, including the healthy gastric juice, in which its presence has been incontestably proved by Bernard and Barreswil. Liebig has shown that it exists abundantly in the juice of flesh. It has been detected by Prof. Wittstein in the vegetable kingdom, especially in the peduncles of Solanum Dulcamara, and the liquid which oozes from freshly cut vine branches. It is a product of the viscous or lactic fermentation of rice-water, and of the juices of the beet, turnip, and carrot. Indeed, it is formed whenever sugar in solution, of whatever kind, is placed in contact with an alkaline or earthy carbonate, in presence of a special ferment, as, for example, the casein of milk, or cheese which

contains it. Pasteur has demonstrated that the lactic acid fermentation, like the vinous, is accompanied with the growth of a peculiar microscopic plant or mycoderm, which he is disposed to consider as the real agent of the changes produced. This fermentation is attended with the production not only of lactic acid, but of other substances also, and among them, a peculiar *gum-like substance* in abundance, which, first noticed by Kirchof, has been isolated in a pure state by Brüning. Though similar to arabin and dextrin, with the formula $C_{12}H_{10}O_{10}$, it is not identical with either, and yields no mucic acid when treated with the nitric. (See *Chem. Gaz.*, May 15, 1858, p. 197.)

Preparation. Lactic acid may be obtained by the following process, which was recommended by M. Louradour as the first step in preparing lactate of iron. Ferment whey by keeping it at a temperature between 70° and 80°, whereby it becomes charged with a considerable quantity of lactic acid. Evaporate the liquor to one-third of its bulk, decant and filter, and then saturate with milk of lime. This converts the lactic acid into lactate of lime, which remains in solution, and throws down a precipitate, consisting principally of phosphate of lime. The liquor is filtered again, and precipitated by oxalic acid, which throws down the lime as oxalate of lime, and sets free the lactic acid. By a new filtration a solution of lactic acid is obtained, containing lactin (sugar of milk) and certain salts. From these it may be purified by concentrating it to a syrupy consistence, and treating it with alcohol, which dissolves the acid, and precipitates the lactin and foreign salts. The solution is filtered, and the lactic acid is obtained pure by distilling off the alcohol. Wackenroder's method is to mix 10 parts of skimmed milk, 2·5 of sugar of milk, 2 of chalk, and 20 of water, to digest at about 75° for six weeks, or till the chalk is dissolved, then to express, clarify, and evaporate so as to crystallize the *lactate of lime*, and, having recrystallized this salt, to decompose it with sulphuric or oxalic acid in exact saturating proportions.

Lautemann proposes a modification of this plan, consisting in substituting oxide of zinc for chalk. The fermentation is completed in eight or ten days. After boiling, the mixture is filtered, and the liquor, having been evaporated and again filtered, is allowed to stand. Lactate of zinc now separates, from which the acid may be obtained by dissolving the salt in boiling water, throwing down the zinc by sulphuretted hydrogen, filtering, and concentrating. The solution now contains mannite and lactic acid, both the result of the fermentation. By agitating with ether the acid is dissolved, and the mannite left; and by evaporating the ethereal solution the lactic acid is obtained. (See *Philos. Mag.*, May, 1860, p. 385.)

Properties. Lactic acid is a limpid, syrupy liquid, colourless or of a pale-wine colour, of a slight not unpleasant odour, and a very sour taste. Its sp. gr. is 1·212, and its formula $C_6H_6O_6$, or, if considered as hydrated, $C_6H_5O_5+HO$. Some consider it a bi-basic acid, and give as its formula $C_{12}H_{12}O_{12}$, or $C_{12}H_{10}O_{10}+2HO$. It mixes in all proportions with water, alcohol, and ether. Exposed to a heat of 480°, it is for the most part converted into a new body called concrete lactic acid or *lactide*. It coagulates albumen, and dissolves a large quantity of freshly precipitated phosphate of lime; a property which, doubtless, renders it important in the animal economy.

In the U. S. Pharmacopœia it is stated to produce no precipitate with acetate of lead, oxalate of ammonia, or, after saturation by ammonia, with sulphuretted hydrogen; proving the absence of sulphuric acid, lime, and metallic salts. Ninety grains of it are saturated by not less than 75 grains of bicarbonate of potassa. When gently heated it should yield no smell of acetic or butyric acid. Its colour is not changed by an excess of caustic potassa.

Lactic acid, of the kind found in muscle, is said to exist copiously in the urine, both of men and animals, when labouring under the poisonous effects of phosphorus. (Schultzen, *Zeitschrift für Chem.*, 1867, p. 138.)

Medical Properties and Uses. Lactic acid was proposed by Magendie, on theoretical grounds, as a remedy in certain forms of dyspepsia, and for the re-

moval of phosphatic deposits in the urine. It has subsequently been employed with good effects in dyspepsia by Dr. Handfield Jones and Dr. O'Connor, both of London. The remedy should be taken at the time of meals. It is most conveniently given in solution sweetened with sugar, prepared like lemonade. From one to three drachms may be taken in the course of the day.

Lactic acid is a useful addition to medicinal pepsin, increasing the solvent power of that agent upon the food, when taken into the stomach. Some importance has also been attached to it from the supposition that it might be the materies morbi in rheumatism, as uric acid has been supposed to be in gout; but in either case the acid is probably rather the effect than the cause of the disease.

Off. Prep. Ferri Lactas, *U.S.* B.

ACIDUM MURIATICUM. *U.S.*

Muriatic Acid.

An aqueous solution of chlorohydric acid gas, of the sp. gr. 1·16. *U.S.*

Off. Syn. ACIDUM HYDROCHLORICUM. Hydrochloric acid gas, HCl, dissolved in water, and forming 31·8 per cent. by weight of the solution. *Br.*

Spirit of sea-salt, Marine acid, Hydrochloric acid, Chlorohydric acid; Acide hydrochlorique, *Fr.;* Salzsäure, Kochsalzsäure, *Germ.;* Acido muriatico, *Ital., Span.*

The muriatic acid of pharmacy and the arts is a solution of muriatic acid *gas* in water. It is sometimes called *liquid* muriatic acid, but more properly *aqueous* muriatic acid. The acid is placed in the Materia Medica Catalogue of the U.S. Pharmacopœia; but among the Preparations in the *British*, which gives the following process for preparing it.

"Take of Chloride of Sodium, dried, *forty-eight ounces* [avoirdupois]; Sulphuric Acid *forty-four fluidounces;* Water *thirty-six fluidounces;* Distilled Water *fifty fluidounces.* Pour the Sulphuric Acid slowly into thirty-two [fluid]ounces of the Water, and when the mixture has cooled, add it to the Chloride of Sodium previously introduced into a flask having the capacity of at least one gallon [Imp. meas.]. Connect the flask by corks and a bent glass tube with a three-necked wash-bottle, furnished with a safety tube, and containing the remaining four [fluid]ounces of the Water; then, applying heat to the flask, conduct the disengaged gas through the wash-bottle, into a second bottle containing the Distilled Water, by means of a bent tube dipping about half an inch below the surface; and let the process be continued until the product measures sixty-six [fluid]ounces, or the liquid has acquired a sp. gr. of 1·16. The bottle containing the distilled water must be kept cool during the whole operation." *Br.*

Preparation. Muriatic acid is obtained by the action of sulphuric acid on chloride of sodium or common salt. The commercial acid is procured, on a large scale, by distilling the salt with an equal weight of sulphuric acid, somewhat diluted with water, from iron stills, furnished with earthen heads into earthenware receivers containing water. When thus obtained, it is contaminated with iron and other impurities, and is not fit for medicinal purposes.

Commercial muriatic acid is now procured in large quantities in England, during the decomposition of common salt for the purpose of making sulphate of soda, from which soda-ash and carbonate of soda are afterwards manufactured in immense quantities. When the object is to obtain sulphate of soda, the decomposition of the sea-salt is performed in semi-cylindrical vessels, the curved part, next the fire, being made of iron, and the upper or flat surface, of stone. If the acid is to be saved, it is conveyed by a pipe to a double-necked stoneware receiver, half filled with water, and connected with a row of similar receivers, likewise containing water.

The acid, when required to be pure, is generally prepared by saturating distilled water with the gas in a Woulfe's apparatus. A quantity of pure fused common salt is introduced into a retort or matrass, placed on a sand-bath. The

vessel is then furnished with an S tube, and connected with a series of bottles, each two-thirds full of water. A quantity of sulphuric acid is then gradually added, equal in weight to the common salt employed, and diluted with one-third of its weight of water. The materials ought not to occupy more than half the body of the retort. When the extrication of the gas slackens, heat is applied, and gradually increased until the water in the bottles refuses to absorb any more, or until no more gas is found to come over. As soon as the process is completed, boiling water should be added to the contents of the retort or matrass, in order to facilitate the removal of the residue. During the progress of the saturation, the water in the several bottles increases in temperature, which lessens its power of absorption. It is, therefore, expedient, in order to obtain a strong acid, to keep the bottles cool by means of water or ice. The connecting tubes need not plunge deeply into the acid.

The process of the British Pharmacopœia is substantially the same as the one here described, with the exception of the proportion of the acid and salt employed. In the process for muriatic acid, theory calls for a little less than 82 parts of liquid sulphuric acid to 100 of common salt. A moderate excess of the former may be useful to ensure the complete decomposition of the salt; but the quantity of acid, directed in the British process, is sufficient to decompose twice the quantity of common salt taken. The intention obviously is to use enough of the acid to form the bisulphate instead of sulphate of soda; and it is thought that the process is thus facilitated.

The rationale of the process for obtaining this acid is very simple. Common salt is a compound of chlorine and sodium; muriatic acid, of chlorine and hydrogen; and liquid sulphuric acid, of dry sulphuric acid and water. The water is decomposed; its oxygen, combining with the sodium of the common salt, generates soda, which unites with the sulphuric acid to form sulphate of soda; while the hydrogen and chlorine, being both in the nascent state, combine, and escape as muriatic acid gas. The residue of the process is consequently sulphate of soda or Glauber's salt.

As muriatic acid, prepared in the ordinary mode, often contains arsenic, so as to obscure its indications when employed in testing for that poison, it is of interest to the practical toxicologist to know that it may be obtained free from that impurity by distilling chloride of sodium or potassium with oxalic acid in equivalent proportions. (*Chem. News*, Jan. 18, 1862, p. 41.)

Properties of the Pure Acid. Muriatic acid, when pure, is a transparent colourless liquid, of a suffocating odour and corrosive taste. Exposed to the air it emits white fumes, owing to the escape of the acid gas, and its union with the moisture of the atmosphere. When concentrated, it blackens organic substances like sulphuric acid. Its sp. gr. varies with its strength. When as highly concentrated as possible, its density is 1·21. The *U.S. medicinal acid*, as well as that of the present *British* Pharmacopœia, has the sp. gr. 1·16; and "114·8 grains by weight, mixed with half a [fluid]ounce of distilled water, require for neutralization 1000 grain-measures of *the volumetric solution of soda*." *Br.* When of the sp. gr. 1·16 it contains rather more than 33·9 per cent. of muriatic acid gas. (*Phillips.*) It freezes at 60° below zero. When exposed to heat, it continues to give off muriatic acid gas, with the appearance of ebullition, until its sp. gr. falls to 1·094, when it properly boils, and distils over unchanged.

Muriatic acid is characterized by forming, on the addition of nitrate of silver, a white precipitate (chloride of silver), which is insoluble in nitric acid, but readily soluble in ammonia. It is incompatible with alkalies and most earths, with oxides and their carbonates, and with sulphuret of potassium, tartrate of potassa, tartar emetic, tartrate of iron and potassa, nitrate of silver, and solution of subacetate of lead.

As it is desirable to know, on many occasions, in chemical and pharmaceutical operations, the quantity of strong aqueous acid, of acid gas, and of chlorine, contained in samples of acid of different densities, we subjoin a table by Dr. Ure, containing this information.

Table of the quantity of Aqueous Muriatic Acid of sp. gr. 1·2, *of Muriatic Acid Gas, and of Chlorine in* 100 *parts of Aqueous Acid of different densities.*

Sp. Gr.	Aqueous Acid of sp. gr. 1·2.	Acid Gas.	Chlorine.	Sp. Gr.	Aqueous Acid of sp. gr. 1·2.	Acid Gas.	Chlorine.

Impurities. This acid, when pure, will evaporate without residue in a platinum spoon. If sulphuric acid be present, a solution of chloride of barium will cause a precipitate of sulphate of baryta in the acid, previously diluted with distilled water. Iron may be detected by saturating the diluted acid with carbonate of soda, and then adding ferrocyanide of potassium, which will strike a blue colour if that metal be present. The absence of arsenic may be inferred if it do not tarnish bright copper foil when boiled with it, and of this as well as other metallic impregnation, excepting that of iron, by its giving no precipitate with sulphuretted hydrogen. Ammonia in excess shows the absence of iron, if it produces no precipitate. Free chlorine or nitric acid may be discovered by its having the power to dissolve gold-leaf. Any minute portion of the leaf which may be dissolved is detected by adding a solution of protochloride of tin, which will give rise to a purplish tint. The free chlorine is derived from the reaction of nitric or hyponitric acid on a small portion of the muriatic acid, which is thus deprived of its hydrogen. Hence it is that, when free chlorine is present, hyponitric acid or some other oxide of nitrogen is also present as an impurity. The nitric and hyponitric acids are derived from nitrates in the common salt, and from hyponitric acid in the commercial sulphuric acid employed in the preparation of the muriatic acid. The absence of sulphur is indicated by the same test as in the instance of acetic acid. (See *page* 21.)

Muriatic Acid of Commerce. This acid has the general properties of the pure aqueous acid. It has a yellowish colour, owing to the presence of sesquichloride of iron, or of a minute proportion of organic matter, such as cork, wood, &c. It usually contains sulphuric acid, and sometimes free chlorine and nitrous acid. But the most injurious impurity, to those who consume it in the arts, is sulphurous acid. Mr. T. H. Savory analyzed three samples of commercial muriatic acid, each having a sp. gr. of between 1·16 and 1·17, and found them to contain from 7 to nearly 11 per cent. of sulphurous acid. To detect this acid, M. Girardin has proposed a very delicate test, namely, the protochloride of tin. The mode of using the test is to take about half an ounce of the acid to be tested, and to add to it two or three drachms of the protochloride. The mixture having been stirred two or three times, as much distilled water as of the protochloride is to be added. If sulphurous acid is present, the muriatic acid becomes turbid and yellow immediately upon the addition of the protochloride; and, upon the subsequent addition of the water, a slight evolution of sulphuretted hydrogen takes place, perceptible to the smell, and the liquid assumes a brown hue, depositing a powder of the same colour. The manner in which the test acts is as follows. By a transfer of chlorine, the test is converted into bichloride and metallic tin, the latter of which, by reacting

with the sulphurous acid, gives rise to a precipitate of the deutoxide and protosulphuret of tin. In case the sulphurous acid forms but one-half of one per cent. of the commercial acid, the precipitate may not be perceptible. Under these circumstances, a solution of sulphate of copper must be added to the liquid previously warmed, when a brown precipitate of sulphuret of copper will be immediately formed. (*Heintz.*) M. Lembert has proposed the following, which he considers as a more delicate test of sulphurous acid. Saturate the suspected muriatic acid with carbonate of potassa, and add successively a little weak solution of starch, one or two drops of solution of iodate of potassa, and sulphuric acid, drop by drop. Sulphurous acid, if present, will be set free with iodic acid, and these, by reacting on each other, will develope iodine, which will cause a blue colour with the starch.

Another impurity occasionally present in the commercial acid, as shown by Dupasquier, is arsenic. The immediate source of this impurity is the sulphuric acid used to prepare the muriatic acid. The sulphuric acid derives the arsenic from the sulphur used in its manufacture, and this last from pyrites containing a little of the poisonous metal. The arsenic, when present, is in the form of a terchloride, and, from its volatility in this state of combination, is transferred to the muriatic acid, distilled from the commercial acid. This impurity is separated by diluting the acid with an equal volume of water, and passing through it sulphuretted hydrogen, which throws down the arsenic as a tersulphuret. According to Wittstein muriatic acid is freed from arsenic by mercury, according to Reinsch by copper, and in either case it may be deprived of metallic impregnation by distillation. (See *Am. Journ. of Pharm.*, Sept. 1851, p. 408.) M. Auguste Houzeau asserts that it is sufficient to deprive commercial arseniferous muriatic acid of arsenic simply to boil it, in a flat-bottomed vessel, to two-thirds of its original volume; all the arsenic escaping in the form of the terchloride. (*Journ. de Pharm. et de Chim.*, 4e sér., i. 97.) When leaden vessels are used in preparing muriatic acid, it is apt to contain chloride of lead, which falls as a white precipitate on neutralizing the acid. The nature of the precipitate is verified by dissolving it in nitric acid and adding iodide of potassium, when the yellow iodide of lead will fall. (*Hainault*) This impurity, being fixed, may be got rid of by distilling the acid. A small proportion of thallium has been detected in commercial muriatic acid by Mr. Wm. Crookes, being derived from sulphuric acid, in the manufacture of which pyrites were employed. (*Chem. News*, April 25, 1863, p. 194.)

Properties of Muriatic Acid Gas. Muriatic acid gas is a colourless elastic fluid, possessing a pungent odour, and the property of irritating the organs of respiration. It destroys life and extinguishes flame. It reddens litmus powerfully, and has the other properties of a strong acid. Its sp. gr. is 1·269. Subjected to a pressure of 40 atmospheres, at the temperature of 50°, it is condensed into a transparent liquid, to which alone the name of *liquid muriatic acid* properly belongs. It is absorbed by water with the greatest avidity, and, according to the temperature and pressure, unites with a greater or less quantity of that liquid. Water, at the temperature of 69°, takes up 464 times its volume of the gas, increasing one-third in bulk, and about three-fourths in weight. Water thus saturated constitutes the strong aqueous acid already described.

Composition. Muriatic acid gas consists of one eq. of chlorine 35·5, and one of hydrogen 1 = 36·5; or of one volume of chlorine and one of hydrogen, united without condensation.

Medical Properties. Muriatic acid is tonic, refrigerant, and antiseptic. It is exhibited, largely diluted with water, in low fevers, phthisis, chronic dyspepsia, some forms of syphilis, and to counteract phosphatic deposits in the urine. Dr. Paris has given it with success in malignant cases of typhus and scarlatina, administered in a strong infusion of quassia. It may also be added with advantage to infusions of columbo, gentian, and cinchona. It proves a good adjunct to gargles in ulcerated sorethroat and scarlatina maligna. The dose

for internal exhibition is from ten to twenty minims, in a sufficient quantity of some bland fluid, as barley-water or gruel. In the composition of gargles, it may be used in the proportion of from half a fluidrachm to two fluidrachms, mixed with six fluidounces of the vehicle. (See *Acidum Muriaticum Dilutum.*) It has been found useful, as a topical application, in various affections of the skin, particularly in follicular acne. It may be used diluted with glycerin, or concentrated. If applied in an undiluted form, it should be removed in less than thirty seconds by washing with pure water and afterwards with soap.

Toxicological Properties. Muriatic acid, when swallowed, is highly irritating and corrosive, but less so than sulphuric or nitric acid. It produces blackness of the lips, fiery redness of the tongue, hiccough, violent efforts to vomit, and agonizing pain in the stomach. There is much thirst, with great restlessness, a dry and burning skin, and a small concentrated pulse. If the acid has been recently swallowed, white vapours of a pungent smell are emitted from the mouth. The best antidote is magnesia, which acts by saturating the acid. Soap is also useful for the same reason. In the course of the treatment, bland and mucilaginous drinks must be freely given. When inflammation supervenes, it must be treated on general principles.

ACIDUM NITRICUM. *U.S., Br.*

Nitric Acid.

Nitric acid, of the specific gravity 1·42. *U.S.* An acid containing 70 per cent. by weight of the nitric acid HO,NO_5, corresponding to 60 per cent. of anhydrous nitric acid NO_5. *Br.*

Spirit of nitre; Aqua fortis; Acide nitrique, Acide azotique, *Fr.;* Saltpetersäure, *Germ.;* Zaltpeterzuur, Sterkwater, *Dutch;* Shedwater, *Swed.;* Acido nitrico, *Ital., Span.*

Nitric acid is one of the five compounds formed between nitrogen and oxygen. These are nitrous oxide (exhilarating gas), NO; nitric oxide, NO_2; nitrous acid (formerly hyponitrous acid), NO_3; hyponitric acid (formerly nitrous acid), NO_4; and nitric acid, NO_5.

Nitric acid is now officinal in two forms; the pure acid of the sp. gr. 1·42, and the diluted. The strong acid, of the sp. gr. 1·5, which was recognised in the former Br. Pharmacopœia, has been abandoned in the present. The two stronger will be noticed here, and the diluted under the preparations. (See *Acidum Nitricum Dilutum.*)

The usual practice, adopted in the laboratory for obtaining nitric acid, is to add to nitrate of potassa in coarse powder, contained in a retort, an equal weight of strong sulphuric acid, poured in by means of a tube or funnel, so as not to soil the neck. The materials should not occupy more than two-thirds of the capacity of the retort. A receiver being adapted, heat is applied by means of a spirit-lamp, the naked fire, or a sand-bath, moderately at first, but afterwards more strongly when the materials begin to thicken, in order to bring the whole into a state of perfect fusion. Red vapours will at first arise, and afterwards disappear in the course of the distillation. Towards its close they will be reproduced, and their reappearance will indicate that the process is completed

The proportion of equal weights, as above given, corresponding nearly to one eq. of nitrate of potassa and two of monohydrated sulphuric acid, is the best for operations on a small scale in the laboratory. This proportion is preferred by Thenard. In operations on a large scale, where an iron vessel is used, a strong heat applied, and water placed in the receivers to condense the acid, less sulphuric acid may be advantageously employed.

Monohydrated Nitric Acid. Nitrate of Water. This is the strongest liquid nitric acid that can be procured, and may be supposed to be obtained by distilling one eq. of pure and dry nitre with two eqs. of monohydrated sulphuric acid. One eq. of monohydrated nitric acid distils over, and one eq. of monohydrated bisulphate of potassa remains behind, KO,NO_5 and $2(HO,SO_3)=HO$, NO_5 and $KO,2SO_3+HO$. Acid of this strength is very difficult to get, and requires for its preparation the most elaborate attention to separate the superabundant water. According to Mr. Arthur Smith, of London, acid, dehydrated as far as possible, is perfectly colourless, boils at 184°, has the sp. gr. 1·517 at 60°, and nearly approaches, in composition, to a monohydrate. Acid of this strength, even at the boiling temperature, has not the slightest action on tin or iron. (*Phil. Mag.*, Dec. 1847.) According to Millon, the true monohydrate has a sp. gr. as high as 1·521.

The acid of the late Br. Pharmacopœia, having the sp. gr. 1·5, is of a yellowish colour, and strongly corrosive It is considered to be a sesquihydrate, consisting of one eq. of dry acid 54, and one and a half eqs. of water 13·5=67·5. Strictly speaking, it is a nitrate of water, diluted with half an eq. of water ($HO, NO_5+\frac{1}{2}HO$). An acid of this strength is inconveniently strong, is constantly undergoing decomposition under the influence of light, and has consequently been replaced by a pure acid of the density 1·42. This substitution was made in the U. S. Pharmacopœia of 1850, and in the British of 1867.

Nitric Acid (sp. gr. 1·42). *Quadrihydrated Nitric Acid.* This is the acid now officinal in both the U. S. and Br. Pharmacopœias. Acid of the density 1·5 was not found in any of the shops, and much pains were required to get it of that strength. Besides, acid of this density was not necessary for any process of the Pharmacopœia. Considerations of this kind induced the revisers of our national standard of 1850 to lower the strength of officinal nitric acid to 1·42, its purity in other respects remaining the same. To satisfy the tests given in the U. S. Pharmacopœia, it must be colourless, entirely volatilizable by heat, and, when diluted with distilled water, not precipitated by hydrosulphuric acid, nitrate of silver, or chloride of barium. Acid of the density 1·42 is the most stable of the hydrated compounds of nitric acid, and boils at 250°. When either stronger or weaker than this, it distils over at a lower temperature; and, by losing more acid than water in the first case, and more water than acid in the second, constantly approaches to the sp. gr. 1·42, when its boiling point becomes stationary. These facts in relation to quadrihydrated nitric acid were first observed by Dalton, and have since been confirmed by Mr. Arthur Smith, of London. This acid consists of one eq. of dry acid and four of water ($4HO, NO_5$); but as only one of the eqs. of water is *basic*, the other three being *constitutional*, the true formula is HO,NO_5+3HO. "Ninety grains by weight of it, mixed with half an ounce of distilled water, require, for neutralization, 1000 grain-measures of the *volumetric solution of soda.*" *Br.*

Nitric Acid of the Arts. Two strengths of this acid occur in the arts; *double aqua fortis* (sp. gr. 1·36), which is half the strength of concentrated nitric acid, and *single aqua fortis* (sp. gr. 1·22), which is half as strong as the double. Aqua fortis is sometimes obtained by distilling a mixture of nitre and calcined sulphate of iron. By an interchange of ingredients, sulphate of potassa and nitrate of iron are formed, the latter of which, at the distilling heat, readily abandons its nitric acid. The sulphate of potassa is washed out of the residue, and the sesquioxide of iron which is left is sold, under the name of *colcothar*, to the polishers of metals. The distillation is performed in large cast-iron retorts, lined on the inside with a thick layer of red oxide of iron, to protect them from

the action of the acid. The acid is received in large glass vessels containing water. A considerable portion of the acid is decomposed by the heat into reddish vapours, which subsequently dissolve in the water, and absorb the oxygen which had been disengaged. The acid thus obtained is red and tolerably strong, but is diluted with water before being thrown into commerce.

The reddish acid, called *nitrous acid of the shops*, is nitric acid containing more or less hyponitric acid (NO_4). The same acid may be formed by impregnating, to a limited extent, colourless nitric acid with nitric oxide (NO_2). If the saturation be complete, every two eqs. of nitric acid become three eqs. of hyponitric acid, by the aid of one eq. of nitric oxide ($2NO_5$ and $NO_2 = 3NO_4$). The nitrous acid of the shops may be converted into colourless nitric acid by exposing it to a gentle heat. As hyponitric acid (NO_4) forms, in contact with bases, a nitrate and nitrite, there being no hyponitrates, some chemists consider it as a compound of nitric and nitrous acids ($2NO_4 = NO_5 + NO_3$).

In France, nitric acid is manufactured on the large scale from nitre and sulphuric acid in cast-iron cylinders. The cylinders are disposed horizontally across a furnace, and are strewed internally throughout their length with nitre. Two circular cast-iron plates, each pierced with a hole, serve to close the ends. At one end the sulphuric acid is poured in, and, by means of a stoneware tube connected with the other end, the nitric acid is conducted to receivers. The sulphate of potassa is removed after each operation. The iron cylinders are acted upon by the acid; but this disadvantage is counterbalanced by a great saving of expense, when the process is conducted in such vessels.

In England, nitric acid is generally procured, for the purposes of the arts, by distilling the materials in earthenware retorts, or cast-iron pots with earthen heads, connected with a series of glass or stoneware receivers containing water. The proportion of sulphuric acid, employed by the manufacturer, is between one and two equivalents to one of the salt; and hence the product has an orange-red colour, which is removed by heating the acid.

In the United States, nitric acid is made, on the large scale, in a distillatory apparatus having the same general arrangement as in France and England. Sometimes a cast-iron cylinder is used, as in France, and sometimes a thick cast-iron pot with an earthenware head. The pot is set in brick-work over a fire-place, and, the materials having been placed in it, the head is luted on with a fat lute, and made to communicate with two receivers, either of stoneware or glass, connected together by means of a tube. Large demijohns of glass answer the purpose of receivers very well. The incondensible products are made to pass, by means of a tube, into a portion of water. The quantity of sulphuric acid, employed in different establishments, varies from one-half to two thirds of the weight of the nitre. Nitrate of soda (cubic nitre), imported into the United States from Peru, is used by some manufacturing chemists to obtain nitric acid. One objection to this salt is that it often contains much common salt. If pure, it yields 10 per cent. more acid for a given weight than nitrate of potassa; but the residuum, sulphate of soda, is less valuable than sulphate of potassa. The latter salt, under the name of *sal enixum*, is sold to the alum makers.

M. Mallet, of Paris, has proposed to obtain nitric acid from nitrate of soda, by distilling it with dried boracic acid. In this case, biborate of soda or borax is the residue. Another method, employed by Kuhlman, is to expose a mixture of nitrate of soda and chloride of manganese to a heat of about 450° F., and to pass the mixed gases which escape through water. Hyponitric acid and oxygen are disengaged, which become nitric acid when they enter the water. (See *Pharm. Journ. and Trans*, Oct. 1862, p. 155.)

General Properties of Nitric Acid. Nitric acid, so called from nitre, is a liquid, extremely sour and corrosive. It was discovered by Raymond Lully, in the 13th century, and its constituents by Cavendish, in 1784. When perfectly pure it is colourless; but, as usually obtained, it has a straw colour, owing to the presence of hyponitric acid. The concentrated acid, when exposed to the air, emits white fumes, possessing a disagreeable odour. By the action

of light it undergoes a slight decomposition, and becomes yellow. It acts powerfully on animal matter, causing its decomposition. On the living fibre it operates as a strong caustic. It stains the skin and most animal substances of an indelible yellow colour. On vegetable fibre it acts peculiarly, abstracting hydrogen or water, and combining with its remaining elements. When diluted, nitric acid converts most animal and vegetable substances into oxalic, malic, and carbonic acids. The general character of its action is to impart oxygen to other bodies, which it is enabled to do in consequence of the large quantity of this element which it contains in a state of loose combination. It acidifies sulphur and phosphorus, and oxidizes all the metals, except chromium, tungsten, columbium, cerium, titanium, osmium, rhodium, gold, platinum, and iridium. In the liquid state it always contains water, which is essential to its existence in that state It combines with salifiable bases and forms nitrates. When mixed with muriatic acid, mutual decomposition takes place, and a liquid is formed, capable of dissolving gold, called nitromuriatic acid or aqua regia.

A trace of nitric acid has been detected in atmospheric air. It is said to be always present in the air in summer. (*Kletzinsky.*)

Tests. Nitric acid, when uncombined, is recognised by its dissolving copper with the production of red vapours, and by its forming nitre when saturated with potassa. When in the form of a nitrate, it is detected by its action on gold-leaf, after the addition of muriatic acid, in consequence of the evolution of chlorine; or it may be discovered, according to Dr. O'Shaughnessy, by heating the supposed nitrate in a test tube with a drop of sulphuric acid, and then adding a crystal of morphia. If nitric acid be present, it will be set free by the sulphuric acid, and reddened by the morphia. The same effect is produced by brucia, by commercial strychnia, on account of its containing brucia, and still more strongly, according to M. Braun, by sulphate of aniline, which is an exceedingly delicate test. (*Journ. de Pharm. et de Chim.*, Août, 1867, p. 157.) To prevent all ambiguity, arising from the accidental presence of nitric acid in the sulphuric acid employed, the operator should satisfy himself, by a separate experiment, that the latter acid has no power to produce the characteristic colour with morphia. Another test for nitric acid is to add *pure* sulphuric acid to the concentrated liquid, suspected to contain it, together with a little concentrated solution of the sulphate of protoxide of iron. The smallest trace of nitric acid affords, when the mixture is warmed, a pink-red colour; and, if it be present in considerable amount, the liquid becomes almost black.

The most common impurities in nitric acid are sulphuric acid and chlorine; the former derived from the acid used in the process, the latter from common salt, which is not an unfrequent impurity in nitre. They may be detected by adding a few drops of the solution of chloride of barium and of nitrate of silver to separate portions of the nitric acid, diluted with three or four parts of distilled water. If these reagents should produce a precipitate, the chloride will indicate sulphuric acid, and the nitrate, chlorine. These impurities may be separated by adding nitrate of silver in slight excess, which will precipitate them as sulphate and chloride of silver, and then distilling nearly to dryness in very clean vessels. The sulphuric acid may also be got rid of by distilling from a fresh portion of nitre. The chlorine may be separated, without the use of nitrate of silver, by distilling the commercial acid, and rejecting the first eighth or fourth which comes over, according to the quality of the acid, and reserving that which passes subsequently, which is absolutely pure. (*Ch. Barreswil.*) According to M. Lembert, the nitric acid of commerce sometimes contains iodine, probably derived from the native nitrate of soda, in which he found that element. It may be detected by saturating the suspected acid with a carbonated alkali, pouring in a little clear solution of starch, and then adding a few drops of sulphuric acid. If iodine be present, the sulphuric acid will set it free, and the starch solution will become blue. Another test, proposed by Mr. Stein, is to introduce a stick of tin into the suspected acid, and, after red vapours have begun to escape, to withdraw the metal, add a few drops of sul-

phuret of carbon, and agitate. If iodine be present, drops of sulphur will soon separate, coloured more or less deeply red according to the amount of impurity. These impurities, however, do not affect the medical properties of the acid.

As a nitric acid below the standard strength is necessarily employed in many chemical and pharmaceutical operations, it often becomes important to know the proportion of dry acid, and of acid of the strength of 1·5, contained in an acid of any given specific gravity. The following table, drawn up from experiments by Dr. Ure, gives information on these points.

Table showing the Quantity of Hydrated Nitric Acid (sp. gr. 1·5), *and of Dry Nitric Acid, contained in* 100 *parts of the Acid at different Densities.*

Sp. Gr.	Hyd. Acid in 100.	Dry Acid in 100.	Sp. Gr.	Hyd. Acid in 100.	Dry Acid in 100.	Sp. Gr.	Hyd. Acid in 100.	Dry Acid in 100.	Sp. Gr.	Hyd. Acid in 100.	Dry Acid in 100.

Composition. The composition of the officinal acid of the density 1·42 has already been given. It contains about 75 per cent. of nitric acid, of the sp. gr. 1·5. Anhydrous nitric acid consists of one eq. of nitrogen 14, and five eqs. of oxygen 40 = 54; or, in volumes, of one volume of nitrogen and two and a half volumes of oxygen, supposed to be condensed, to form nitric acid vapour, into one volume. In 1849, the interesting discovery was made by M. Deville, of Besançon, of the means of isolating *anhydrous nitric acid.* The method pursued was to pass perfectly dry chlorine over nitrate of silver. The anhydrous acid is in the form of colourless, brilliant, limpid crystals, which melt at 85° and boil at 113°. In contact with water, they form a colourless solution with evolution of heat, without the disengagement of gas. (*Journ. de Pharm.*, Mars, 1849, p. 207.)

Medical Properties. Nitric acid is tonic and antiseptic. Largely diluted with water, it forms a good acid drink in low forms of fever. It is praised as an antiperiodic in intermittent fever by Dr. Geo. Mendenhall and Dr. E. T. Bailey, of Indiana, given in doses of from five to eight drops once in six hours, without regard to intermissions or exacerbations. (See *Am. Journ. of the Med. Sci.*, Oct. 1854, p 581.) According to Dr. Arnoldi, of Montreal, nitric acid, added to water so as to give it the acidity of lemon-juice, and sweetened, is an efficacious remedy in hooping-cough; and his report of its value was confirmed by Dr. Geo. D. Gibbs, in his treatise on hooping-cough, published in London in 1854. The dose for a child one year old is a dessertspoonful every hour; for an

adult, a tumblerful during the day. To save the teeth, the mouth should be washed after each dose In syphilis, and in the chronic hepatitis of India, this acid was highly extolled by Dr. Scott, formerly of Bombay. It has occasionally excited ptyalism. It cannot be depended upon as a remedy in syphilis, but, in worn-out constitutions, is often an excellent adjuvant, either to prepare the system for the use of mercury, or to lessen the effects of that metal on the economy. As nitric acid dissolves both uric acid and the phosphates, it was supposed to be applicable to cases of gravel in which the uric acid and the phosphates are mixed; but experience has not confirmed the opinion. Nevertheless, when the sabulous deposit depends upon certain states of disordered digestion, this acid may prove serviceable by restoring the tone of the stomach. The dose is from five to twenty minims in three fluidounces or more of water, given three or four times a day. The diluted acid is more convenient for prescribing.

Externally, nitric acid has been used with advantage as a lotion to ulcers, in the strength of about twelve minims to the pint of water. This practice originated with Sir Everard Home, and is particularly applicable to those ulcers which are superficial and not disposed to cicatrize. It is also useful in ulceration of the mouth and gums as a gargle, made by adding about sixty drops of the acid to a pint of water. In sloughing phagedæna, *strong* nitric acid is one of the best remedies, applied by means of a piece of lint tied round a small stick, or by the use of a glass brush. Sometimes a piece of lint is soaked with the strong acid, and pressed into the sore, being allowed to remain for several hours. In cancrum oris concentrated nitric acid, freely applied, is one of the best local remedies that can be employed for arresting the phagedenic ulceration, and disposing the sore to heal. The *strong* acid has also been found very useful as an escharotic, in the local treatment of hemorrhoids and of prolapsus ani, by Dr. W. Cooke, of London, and others. For information as to the mode of applying the acid, the instruments employed, and the precautions to be observed, the reader is referred to *Ranking's Abstract* (Am ed., xx. 143, and xxiii. 158).

Nitric acid, in the state of vapour, is considered useful for destroying contagion, and hence has been employed for purifying jails, hospitals, ships, and other infected places. It is prepared for use by the extemporaneous decomposition of nitre by sulphuric acid. Half an ounce of powdered nitre is put into a saucer, which is placed in an earthen dish containing heated sand. On the nitre two drachms of sulphuric acid are then poured, and the nitric acid fumes are immediately disengaged. The quantities just indicated are considered sufficient for disinfecting a cubic space of ten feet. Fumigation in this manner was first introduced by an English physician, Dr. Carmichael Smyth, who received from the British Parliament, for its discovery, a reward of five thousand pounds. But nitric acid, as a disinfectant, is not comparable to chlorine; and, since the introduction of chlorinated lime and the solution of chlorinated soda as disinfecting agents, this gas has been brought into so manageable a form, that its use has entirely superseded that of nitric acid vapour.

Properties as a Poison. Nitric acid, in its concentrated state, is one of the mineral poisons most frequently taken for the purpose of self-destruction. Immediately after swallowing it, there are produced burning heat in the mouth, œsophagus, and stomach, acute pain, disengagement of gas, abundant eructations, nausea, and hiccough. These effects are soon followed by repeated and excessive vomiting of matter having a peculiar odour and taste, tumefaction of the abdomen with exquisite tenderness, a feeling of coldness on the surface, horripilations, icy coldness of the extremities, small depressed pulse, horrible anxieties, continual tossings and contortions, and extreme thirst. The breath becomes extremely fetid, and the countenance exhibits a complete picture of suffering. The cases are almost always fatal. The best remedies are repeated doses of magnesia as an antidote, mucilaginous drinks in large quantities, olive or almond oil in very large doses, emollient fomentations, and clysters. Until magnesia can be obtained, an immediate resort to a solution of soap in large amount will be proper.

ACIDUM PHOSPHORICUM GLACIALE. *U. S.*

Glacial Phosphoric Acid.

Phosphoric acid, in the anhydrous state, consists of one eq. of phosphorus and five eqs. of oxygen, PO_5, and can be obtained only by the direct union of its constituents, which takes place when phosphorus is burned in perfectly dry oxygen gas. Thus procured, it is in the form of a white amorphous powder, extremely deliquescent, volatilizable at a red heat, and assuming, when it cools after fusion, a vitreous appearance. It has been shown by Prof. Graham that this acid is capable of assuming three isomeric conditions, each characterized by peculiar properties, and essentially distinguished by their relations to bases, water being considered as acting the part of a base. These are most conveniently designated as *monobasic*, *bibasic*, and *tribasic phosphoric acids*, the first uniting with one eq. of base, the second with two eqs., and the third with three. Obtained in any other way than as above stated, they are always combined with water, the *monobasic* consisting of one eq. of acid and one of water, HO,PO_5, the *bibasic* of one of the former and two of the latter, $2HO,PO_5$, the *tribasic* of one to three, $3HO,PO_5$. When uniting with other bases than water, the same relation of equivalents is observed, the monobasic combining with only one eq., giving up its eq. of water, the bibasic with one or two eqs. according as it retains one or gives up both its eqs. of water, the tribasic with one, two, or three eqs., according to the number of eqs. of water it abandons; in other words, the eqs. of water being replaced by as many eqs. of base; so that the acid always has its characteristic complement of basic eqs., water being counted among them. Other names had been given to these acids before their peculiar character was developed; the common and best known form of the acid being called simply *phosphoric acid*, which is the tribasic; another, from heat being used in its production, *pyrophosphoric*, which is the bibasic; and the third *metaphosphoric acid*, which is *monobasic*. An aqueous solution of either of the three acids, heated so long as water escapes, yields the monobasic or metaphosphoric acid; and as, upon cooling, it becomes a transparent ice-like solid, it has received in this state the name of glacial phosphoric acid. Conversely, this monobasic acid is slowly transformed, in aqueous solution, and more rapidly if the solution is heated, into the bibasic and tribasic forms. Mr. Maisch has ascertained that nitric acid, added to the solution of the monobasic acid, with the aid of heat, causes the change from the monobasic to the tribasic form, or that of common phosphoric acid, without undergoing any observable change itself, and without the intermediate production of the bibasic.

The three forms of acid are distinguishable by peculiar reactions. Thus, the *monobasic* is characterized by coagulating albumen, and giving white gelatinous uncrystallizable precipitates with the soluble salts of baryta, lime, and silver; the *bibasic* does not coagulate albumen, and, though it causes a *white* precipitate with nitrate of silver, must first be neutralized; the tribasic does not coagulate albumen, and until neutralized does not precipitate nitrate of silver; but after neutralization throws down a *yellow* precipitate of phosphate of silver. The two latter forms of the acid will be considered in the second part of this

work under appropriate heads. Our attention will at present be confined to the monobasic acid, which is the glacial acid of the U. S. Pharmacopœia.

Glacial Phosphoric Acid. *U. S. Metaphosphoric Acid. Monobasic Phosphoric Acid. Monohydrated Phosphoric Acid. Phosphate of Water.* This is most advantageously obtained from calcined bones, by first treating them with sulphuric acid, which produces an insoluble sulphate and soluble superphosphate of lime; then dissolving out the latter salt, and saturating it with carbonate of ammonia, which generates phosphate of ammonia in solution; and, finally, obtaining the phosphate of ammonia by evaporation to dryness, and then igniting it in a platinum crucible. The ammonia and all the water except one eq. for each eq. of the acid are driven off, and the glacial acid remains.

Properties. Thus procured, glacial phosphoric acid is in the form of a white, transparent, fusible solid, inodorous and sour to the taste, slowly deliquescent, slowly soluble in water, and soluble also in alcohol. Its formula is HO,PO_5, and it contains 11·2 per cent. of water. As already stated, it is characterized by producing white gelatinous precipitates with albumen, and with the soluble salts of lime, baryta, and silver; and the precipitate produced with the chloride of barium is readily redissolved by an excess of the acid. This is the form of the acid which results when the anhydrous acid, produced by burning phosphorus in dry oxygen gas, is introduced into water.

Impurities. Glacial phosphoric acid is seldom prepared in this country. That found in our shops is almost all imported, and chiefly from Germany. It is often more or less impure, containing most frequently, as shown by the experiments of Mr. Maisch, silica, and the phosphates of lime and magnesia, which are precipitated from a neutralized solution of the acid by ammonia. In one instance 8 per cent. of these impurities was found; but in some others little or none. Mr. Maisch never found nitric or muriatic acid, and sulphuric acid rarely; and, though the presence of ammonia might be suspected from the source whence the acid is obtained, he did not detect it. (*Am. Journ. of Pharm.*, May, 1860, p. 194.) In consequence of its deliquescence upon exposure to the air, a portion of the monobasic acid passes into the state of the tribasic. This is detected, if in considerable quantity, by giving a yellowish colour to the precipitate with nitrate of silver. The U. S. Pharmacopœia directs that the acid, in aqueous solution, should yield no precipitate with sulphuretted hydrogen, showing the absence of metals; should cause a white precipitate with chloride of barium soluble in an excess of acid; and, with an excess of ammonia, should cause only a slight turbidness, proving the almost total absence of earthy salts. Should the presence of arsenic be ascertained by the tests for that metal, it may be separated by boiling with muriatic acid, so as to convert the arsenic into its very volatile chloride, which would escape with the vapours of the muriatic acid.

Medical Uses. Glacial phosphoric acid is seldom if ever used medicinally in reference to its influence on the system, though probably capable of producing all the effects for which the officinal diluted acid is employed. It was introduced into the Materia Medica of our Pharmacopœia as affording a convenient method of preparing the medicinal acid. It may also be used in prescriptions with the insoluble phosphates to render them soluble in the liquors of the stomach, and thereby favour their entrance into the circulation. Thirty-eight and a half grains, dissolved in a fluidounce of water, form a solution about equal in strength to the officinal U. S. diluted acid.

Off. Prep. Acidum Phosphoricum Dilutum, *U. S.* B.

ACIDUM SULPHURICUM. *U. S., Br.*

Sulphuric Acid.

Sulphuric acid, of the specific gravity 1·843. *U. S.* It contains 96·8 per cent. by weight of the Sulphuric Acid, HO,SO_3, and corresponds to 79 per cent. of anhydrous sulphuric acid, SO_3. *Br.*

Oil of vitriol, Vitriolic acid; Acide sulfurique, *Fr.;* Vitriolöl, Schwefelsäure, *Germ.;* Acido solforico, *Ital.;* Acido sulfurico, *Span.*

Sulphuric acid is placed in the Materia Medica list of the U. S. Pharmacopœia, as an article to be obtained from the wholesale manufacturer; and the same is now the case with the British Pharmacopœia. Provision, however, is made that it shall be free from all odorous substances, and all metallic and other non-volatile impurities.

Preparation. Sulphuric acid is obtained by burning sulphur, mixed with one-eighth of its weight of nitre, over a stratum of water contained in a chamber lined with sheet-lead. If the sulphur were burned by itself, the product would be sulphurous acid, which contains only two-thirds as much oxygen as sulphuric acid. The object of the nitre is to furnish, by its decomposition, the requisite additional quantity of oxygen. To understand the process, it is necessary to bear in mind that nitric acid contains five, sulphuric acid three, sulphurous acid two, nitric oxide two, nitrous acid three, and hyponitric acid four equivalents of oxygen, combined with one eq. of their several radicals. One eq. of sulphur decomposes one eq. of nitric acid of the nitre, and becomes one eq. of sulphuric acid, which combines with the potassa of the nitre to form sulphate of potassa. In the mean time, the nitric acid, by furnishing three eqs. of oxygen to form the sulphuric acid, is converted into one eq. of nitric oxide, which is evolved. This gas, by combining with two eqs. of the oxygen of the air, immediately becomes hyponitric acid vapour, which diffuses itself throughout the leaden chamber. While these changes are taking place, the remainder of the sulphur is undergoing combustion, and filling the chamber with sulphurous acid gas. One eq. of hyponitric acid vapour, and one eq. of sulphurous acid gas, being thus intermingled in the chamber, react on each other, with the aid of moisture, so as to form a crystalline compound, consisting of one eq. of sulphuric acid and one eq. of nitrous acid, united with a portion of water. This compound falls into the water of the chamber, and is instantly decomposed. The sulphuric acid dissolves in the water, and the nitrous acid, resolved, at the moment of its extrication, into hyponitric acid and nitric oxide, escapes with effervescence. The hyponitric acid thus set free, and that reproduced by the nitric oxide uniting with the oxygen of the air, again react with sulphurous acid and humidity, and give rise to a second portion of the crystalline compound, which undergoes the same changes as the first. Thus, the nitric oxide performs the part of a carrier of oxygen from the air of the chamber to the sulphurous acid, converting the latter into sulphuric acid. The residue of the combustion of the sulphur and nitre, consisting of sulphate of potassa, is sold to the alum makers.

Preparation on the Large Scale. The leaden chambers vary in size, but are generally from thirty to thirty-two feet square, and from sixteen to twenty high. The floor is slightly inclined to facilitate the drawing off of the acid, and covered to the depth of several inches with water. There are several modes of burning the mixture of sulphur and nitre, and otherwise conducting the process. That pursued in France is as follows. Near one of the sides of the chamber, and about a foot from its bottom, a cast-iron tray is placed over a furnace, resting on the ground, its mouth opening externally, and its chimney having no communication with the chamber. On this tray the mixture is placed, being introduced by a square opening, which may be shut by means of a sliding door, and the lower side of which is level with the surface of the tray. The door being shut, the fire is gradually raised in the furnace, whereby the sulphur is inflamed, and the products already spoken of are generated. When the combustion is over, the door is opened, and the sulphate of potassa removed. A fresh portion of the mixture is then placed on the tray, and the air of the chamber is renewed by opening a door and valve situated at its opposite side. Next, the several openings are closed, and the fire is renewed. These operations are repeated, with fresh portions of the mixture, every three or four hours, until the water at the bottom of the chamber has the sp. gr. of about 1·5. It is then drawn off and transferred to leaden boilers, where it is boiled down to the sp. gr. 1·7. At this density it begins to act on lead, and its further concentration must be

conducted in large glass or platinum retorts, where it is evaporated as long as water distils over. This water is slightly acid, and is thrown back into the chamber. When the acid is fully concentrated, grayish-white vapours arise, which indicate the completion of the process. The acid is allowed to cool, and is then transferred to demijohns of green glass, called carboys, which, for greater security, are surrounded with straw or wicker-work, and packed in square boxes, enclosing all the carboy except the neck.

As, in the manufacture of sulphuric acid, nitre is the most expensive material, many plans have been resorted to for obtaining the necessary hyponitric acid at a cheaper rate. One plan is to procure it by treating molasses or starch with common nitric acid. In this case, the manufacturer obtains oxalic acid as a collateral product, which serves to diminish the expense. Sometimes nitrate of soda is substituted for nitre. The advantages of the former salt are its greater cheapness, and its larger proportional amount of nitric acid. Another method, sometimes practised, consists in filling the leaden chamber with sulphurous acid by the combustion of sulphur, and afterwards admitting into it hyponitric acid and steam. The acid is generated from a mixture of sulphuric acid with nitre or nitrate of soda, placed in an iron pan over the burning sulphur in the sulphur furnace, where the draught conducts the hyponitric acid fumes into the chamber. As, under these circumstances, sulphurous and hyponitric acids and aqueous vapour are mingled in the chamber, all the conditions necessary for generating the crystalline compound, already alluded to, are present. Mr. Thomas Bell, of England, obtained a patent in Dec. 1852 for the use of ozonized air, produced either by electricity, or by the slow combustion of phosphorus, in order to cause the union of sulphurous acid with the requisite oxygen, in the leaden chamber, without the use of nitre. (*Pharm. Journ. and Trans.*, March, 1853.)*

The process for making sulphuric acid by the combustion of sulphur with nitre was first mentioned by Lemery, and afterwards put in practice by an English physician, of the name of Ward. As practised by him, the combustion was conducted in very large glass vessels. About the year 1746, the great improvement of leaden chambers was introduced by Dr. Roebuck, of Birmingham, where the first apparatus of this kind was erected. In consequence of this improvement, the acid immediately fell to one-fourth of its former price.

The only way to obtain pure sulphuric acid is by distillation. Owing to the high boiling point of this acid, the operation is rather precarious, in consequence of the danger of the fracture of the retort from the sudden concussions to which the boiling acid gives rise. Dr. Ure recommends that a retort of the capacity of from two to four quarts be used in distilling a pint of acid. This is connected, by means of a wide glass tube three or four feet long, with a receiver surrounded with cold water. All the vessels must be perfectly clean, and no luting employed. The retort is then gradually heated by a small furnace of charcoal, or, what is better, by means of a sand-bath, the retort being buried in the sand up to the neck. It is useful to put into the retort a few sharp-pointed pieces of glass, or slips of platinum foil, with the view of diminishing the shocks produced by the acid vapour. The distilled product ought not to be collected until a dense grayish white vapour is generated, the appearance of which is a sign that the pure concentrated acid is coming over. If this vapour should not immediately appear, it shows that the acid subjected to distillation is not of full strength; and the distilled product, until this point is attained, will be an acid water. In the distillation of sulphuric acid, M. Lembert uses fragments of the mineral called

* We are told by R. Weber that, in the presence of much water, sulphurous acid reduces binoxide of nitrogen (nitric oxide) to the protoxide (nitrous oxide); and thus considerable loss of nitric acid may be incurred in the manufacture. But sulphuric acid of a certain strength prevents this reaction, which should therefore diminish with the increase of sulphuric acid, and perhaps cease when the acid on the floor of the chamber becomes sufficiently concentrated. The inference is that the sulphuric acid in the chamber should always be kept of the necessary strength, which in the beginning of the process can be accomplished by the addition of a certain quantity of the acid. (*Chem. News*, July 5, 1867, p. 12; from *Pogg. Ann.*, cxxx. 277.)—*Note to the thirteenth edition.*

quartzite, instead of pieces of glass or platinum foil. After a time the fragments get worn, and must be changed.

What is said above relates to the mode of preparing common sulphuric acid; but there is another kind, known on the continent of Europe by the name of the *fuming sulphuric acid of Nordhausen*, so called from its properties, and a place in Saxony where it is largely manufactured. This acid is obtained by distilling dried sulphate of iron in large stoneware retorts, heated to redness, and connected with receivers of glass or stoneware. The fuming acid distils over, and sesquioxide of iron is left in the form of *colcothar* or *polishing rouge*, a material used for polishing metals, particularly gold and silver. According to A. Vogel, jun., a better polishing rouge for fine work is made by calcining oxalate of protoxide of iron. (*Chem. Gaz.*, Nov 1, 1854, p. 410.)

Properties. Sulphuric acid (*sulphate of water*), commonly called *oil of vitriol*, is a dense, colourless, inodorous liquid, of an oleaginous appearance, and strongly corrosive. On living tissues it acts as a powerful caustic. In the liquid form, it contains water, which is essential to its existence in that form. It unites with water in all proportions, and much heat is evolved on the mixture of the two fluids. When pure, and as highly concentrated as possible, as manufactured in leaden chambers, its sp. gr. is 1·845 (1·8485, Ure), a fluidounce weighing a small fraction over 14 drachms. When of this sp. gr., it contains about 18 per cent. of water. If its density exceed this, the presence of sulphate of lead, or other impurity may be inferred. The commercial acid is seldom of full strength. According to Mr. Phillips, it has generally the sp. gr. 1·8433, and contains 22 per cent. of water; and this is about the strength of the Br. acid, of which the sp. gr. is stated to be 1·843. The strong acid boils at 620°, and freezes at 15° below zero. When diluted, its boiling point is lowered. When of the sp. gr. 1·78, it deposits crystals of the bihydrated acid at about 28°, and hence it is hazardous for manufacturers to keep an acid of that strength in glass vessels in cold weather, as they are liable to burst. With salifiable bases it forms a numerous class of salts, called sulphates. It acts powerfully on organic bodies, whether vegetable or animal, depriving them of the elements of water, developing charcoal, and turning them black. A small piece of cork or wood, dropped into the acid, will on this principle render it of a dark colour. It absorbs water with avidity, and is used as a desiccating agent. It has been ascertained by Professors W. B. and R. E. Rogers to be capable of absorbing 94 per cent. of carbonic acid gas, a fact having an important bearing on analytic operations. When diluted with distilled water, it ought to remain limpid; and, when heated sufficiently in a platinum spoon, the fixed residue should not exceed one part in 400 of the acid employed. When present in small quantity in solution, it is detected unerringly by chloride of barium, which causes a precipitate of sulphate of baryta. The most usual impurities in it are the sulphates of potassa and lead; the former derived from the residue of the process, the latter from the leaden boilers in which the acid is concentrated. Occasionally nitre is added to render dark samples of acid colourless. This addition gives rise to the impurity of sulphate of potassa. These impurities often amount to 3 or 4 per cent. The commercial acid cannot be expected to be absolutely pure; but, when properly manufactured, it should not contain more than one-fourth of 1 per cent. of impurity. The fixed impurities are discoverable by evaporating a portion of the acid, when they will remain. If sulphate of lead be present, the acid will become turbid on dilution with an equal bulk of water. This impurity is not detected by sulphuretted hydrogen, unless the sulphuric acid be saturated with an alkali. If only a scanty muddiness arises, the acid is of good commercial quality.

Other impurities occur in the commercial sulphuric acid. Hyponitric acid is always present in greater or less amount. It may be detected by gently pouring a solution of green vitriol over the commercial acid in a tube, when the solution, at the line of contact, will acquire a deep-red colour, due to the liberation of deutoxide of nitrogen. Another method is to pass into tincture of guaiac

the gases proceeding from the suspected acid heated with iron filings. If hyponitric acid is present the tincture becomes blue. The commercial acid, however, is not to be rejected, unless the test shows the presence of hyponitric acid in unusual quantity. Hyponitric acid is an injurious impurity when the sulphuric acid is employed in the manufacture of muriatic acid, which is decomposed by the hyponitric acid with evolution of chlorine. To remove this impurity it was recommended by Wackenroder, before distilling it, to heat the acid with a little sugar. This and the hyponitric acid mutually decompose each other, and the products are dissipated by heat. For the removal of the nitrogen acids generally, Dr. J. Löwe recommends the addition, to the heated sulphuric acid, of small portions of dry oxalic acid, so long as it exhibits a yellow tinge. The oxalic acid is decomposed into carbonic acid and oxide, the latter of which, in becoming carbonic acid, deoxidizes and destroys the nitrogen acids. A slight excess of oxalic acid produces no harm; as it is immediately decomposed. Perhaps a better method of getting rid of these acids is to distil with a little sulphate of ammonia. When sulphate of potassa is fraudulently introduced into the acid to increase its density, it may be detected by saturating the acid with ammonia, and heating to redness in a crucible; when sulphate of ammonia will be expelled, and the sulphate of potassa left.

Arsenic is sometimes present in sulphuric acid. In consequence of the high price of Sicilian sulphur, some English manufacturers have employed iron pyrites for the purpose of furnishing the necessary sulphurous acid in the manufacture of oil of vitriol. As the pyrites usually contains arsenic, it happens that the sulphurous acid fumes are accompanied by this metal, and thus the sulphuric acid becomes contaminated. From 22 to 35 grains of arsenious acid have been found in 20 fluidounces of oil of vitriol, of English manufacture, by Dr. G. O. Rees and Mr. Watson, and a still larger proportion by Mr. J. Cameron, of South Wales. To detect this impurity, the acid, previously diluted with five or six measures of distilled water, must be examined by Marsh's test. (See *Acidum Arseniosum.*) To separate the arsenious acid, Dr. J. Löwe recommends that the concentrated sulphuric acid should be gently heated in a flat dish, in a place where the fumes may be carried off, and then treated with small quantities of finely powdered chloride of sodium, constantly stirred in with a glass rod. By the reaction between the arsenious acid and disengaged muriatic acid, terchloride of arsenic is formed, which, being volatile, is separated by the heat. The heat is afterwards continued, to expel the excess of muriatic acid. This mode of purification introduces into the oil of vitriol a little sulphate of soda. Buchner proposes a similar process; instead of chloride of sodium, employing muriatic acid, or a stream of the acid gas. This plan does not introduce sulphate of soda into the acid; but is less convenient than that of Löwe, and, when the aqueous muriatic acid is used, tends to weaken the oil of vitriol by introducing water. Experience, however, has shown that neither plan can be entirely relied on. An excess of sulphuric acid is said to prevent the formation of the chloride of arsenic. (See *Am. Journ. of Pharm.*, Jan. 1860, p. 85.) The sulphuric acid manufactured in the U. States, being usually made from Sicilian sulphur, seldom contains arsenic. Dupasquier states that tin is sometimes present in commercial sulphuric acid, derived from the solderings of the leaden chambers. It may be discovered by sulphuretted hydrogen, which precipitates sulphuret of tin, convertible by nitric acid into the white insoluble deutoxide of tin. Should the precipitate be the mixed sulphurets of arsenic and tin, the former would be converted by nitric acid into arsenic acid and dissolved, and the latter into insoluble deutoxide and left. As ordered by the Br. Pharmacopœia, "50·6 grains by weight, mixed with distilled water, require for neutralization 1000 grain-measures of *the volumetric solution of soda.*" *Br.*

As sulphuric acid is often under the standard strength, it becomes important to know how much hydrated sulphuric acid of the standard specific gravity and of dry acid is contained in an acid of any given density. The following table, drawn up by Dr. Ure, gives this information.

Table of the Quantity of Hydrated Sulphuric Acid of Sp. Gr. 1·8485, *and of Dry Acid, in* 100 *parts of Dilute Acid at Different Densities.*

Sp. Gr.	Hyd. Acid in 100.	Dry Acid in 100.	Sp. Gr.	Hyd. Acid in 100.	Dry Acid in 100.	Sp. Gr.	Hyd. Acid in 100.	Dry Acid in 100.	Sp. Gr.	Hyd. Acid in 100.	Dry Acid in 100.

Composition. The hydrated acid of the sp. gr. 1·845 (1·8485, Ure) consists of one eq. of dry acid 40, and one eq. of water 9=49. As the water acts the part of a base, the proper name of it is sulphate of water, its formula being HO,SO_3. The dry acid consists of one eq. of sulphur 16, and 3 eqs. of oxygen 24=40. The ordinary commercial acid (sp. gr. 1·8433) consists, according to Phillips, of one eq. of dry acid, and one and a quarter eqs. of water. The hydrated acid of Nordhausen has a density as high as 1·89 or 1·9, and consists of two eqs. of dry acid, and one eq. of water ($HO,2SO_3$). This acid is particularly adapted to the purpose of dissolving indigo for dyeing the Saxon blue. When heated gently in a retort, connected with a dry and refrigerated receiver, dry or anhydrous sulphuric acid distils over, and the common monohydrated acid remains behind. In performing this operation, much difficulty from concussion is avoided, and the product of dry acid increased, by introducing a coil of platinum wire into the retort. The dry acid may also be obtained by the action of dry phosphoric acid on concentrated sulphuric acid, according to the method of Ch. Barreswil. The mixture must be made in a refrigerated retort, and afterwards distilled by a gentle heat into a refrigerated receiver. *Anhydrous sulphuric* acid under 64° is in small colourless crystals, resembling asbestos. It is tenacious, difficult to cut, and may be moulded in the fingers like wax, without acting on them. Exposed to the air, it emits a thick opaque vapour of an acid smell. Above 64° it is a liquid, very nearly of the density 2

Medical Properties. Sulphuric acid is tonic, antiseptic, and refrigerant. Internally it is always administered in a dilute state. For its medical properties in this state, the reader is referred to the title, *Acidum Sulphuricum Dilutum.* Externally it is sometimes employed as a caustic; but, from its liquid form, it is very inconvenient for that purpose. A plan, however, has been proposed by Prof. Simpson by which it becomes very manageable. This consists in mixing it with dried and powdered sulphate of zinc sufficient to give it a pasty consistence. When mixed with saffron to the consistence of a ductile paste, Velpeau found it

a convenient caustic, not liable to spread or be absorbed, and producing an eschar which is promptly detached. It is used also as an ointment, mixed with lard, in the proportion of a drachm to an ounce, in swellings of the knee-joint and other affections. Charpie, corroded by it, is a good application to gangrene.

Toxicological Properties. The symptoms of poisoning by this acid are the following:—Burning heat in the throat and stomach, extreme fetidness of the breath, nausea and excessive vomitings of black or reddish matter, excruciating pains in the bowels, difficulty of breathing, extreme anguish, a feeling of cold on the skin, great prostration, constant tossing, convulsions, and death. Sometimes there is no pain whatever in the stomach; sensibility being apparently destroyed by the violence of the caustic action. The intellectual faculties remain unimpaired. Frequently the uvula, palate, tonsils, and other parts of the fauces are covered with black or white sloughs. The treatment consists in the administration of large quantities of magnesia, or, if this be not at hand, of solution of soap. The safety of the patient depends upon the greatest promptitude in the application of the antidotes. After the poison has been neutralized, mucilaginous and other bland drinks must be taken freely. According to Dr. Geoghegan, the acid may be detected, after death, in the blood and the parenchymatous viscera, especially the liver. It is found, not as a sulphate, but combined severally with the colouring matter and tissues.

The holes burnt in linen by sulphuric acid, so long as the texture is undisturbed, are distinguished from those produced by red-hot coals, by the paste-like characters of the edges of the former. (*Masclika*, of Prague.)

Uses in the Arts. Sulphuric acid is more used in the arts than any other acid. It is employed to obtain many of the other acids; to extract soda from common salt; to make alum and sulphate of iron, when these salts command a good price, and the acid is cheap; to dissolve indigo; to prepare skins for tanning; to prepare phosphorus, chlorinated lime, sulphate of magnesia, &c. The arts of bleaching and dyeing cause its principal consumption.

ACIDUM TARTARICUM. *U.S., Br.*

Tartaric Acid.

"An acid, $2HO,C_8H_4O_{10}$, a crystalline acid prepared from the Acid Tartrate of Potash." *Br.*

Acide tartrique, *Fr.;* Weinsteinsäure, *Germ.;* Acido tartarico, *Ital., Span.*

Tartaric acid is placed, in the U.S. Pharmacopœia, in the Materia Medica list, as an article to be purchased from the manufacturing chemist. In the Br. Pharmacopœia a process is given for its preparation. It is extracted from *tartar*, a peculiar substance which concretes on the inside of wine casks, being deposited there during the fermentation of the wine. Tartar, when purified and reduced to powder, is the cream of tartar of the shops, and consists of two eqs. of tartaric acid united to one of potassa. (See *Potassæ Bitartras.*) The following is the British process.

"Take of Acid Tartrate of Potash *forty-five ounces* [avoirdupois]; Distilled Water *a sufficiency;* Prepared Chalk *twelve ounces and a half* [avoird.]; Chloride of Calcium *thirteen ounces and a half* [avoird.]; Sulphuric Acid *thirteen fluidounces.* Boil the Acid Tartrate of Potash with two gallons [Imperial measure] of the Water, and add gradually the Chalk, constantly stirring. When the effervescence has ceased, add the Chloride of Calcium dissolved in two pints [Imp. meas.] of the Water. When the tartrate of lime has subsided pour off the liquid, and wash the tartrate with Distilled Water until it is rendered tasteless. Pour the Sulphuric Acid, first diluted with three pints [Imp. meas.] of the Water, on the tartrate of lime, mix thoroughly, boil for half an hour with repeated stirring, and filter through calico. Evaporate the filtrate at a gentle heat until it acquires the sp. gr. of 1·21, allow it to cool, and then separate and reject the crystals of sulphate of lime which have formed. Again evaporate the clear liquor till a film forms on its surface, and allow it to cool and crystallize. Lastly purify the crystals by solution, filtration (if necessary), and recrystallization " *Br.*

Tartaric acid was first obtained in a separate state by Scheele in 1770. The process consists in saturating the excess of acid in bitartrate of potassa or cream of tartar with carbonate of lime, and decomposing the resulting insoluble tartrate of lime by sulphuric acid, which precipitates in combination with the lime, and liberates the tartaric acid. The equivalent quantities are one eq. of bitartrate, and one of carbonate of lime. The process, when thus conducted, furnishes the second equivalent, or excess of acid only of the bitartrate. The other equivalent may be procured, as in the British process, by decomposing the neutral tartrate of potassa, remaining in the solution after the precipitation of the tartrate of lime, by chloride of calcium in excess. By double decomposition, chloride of potassium will be formed in solution, and a second portion of tartrate of lime will precipitate, which may be decomposed by sulphuric acid together with the first portion. The process, when thus conducted, will, of course, furnish twice as much tartaric acid as when the excess of acid only is saturated and set free.

Preparation on the Large Scale. The process pursued on the large scale is different from that above given. The decompositions are effected in a wooden vessel, closed at the top, called a generator, of the capacity of about 2000 gallons, and furnished with an exit-pipe for carbonic acid, and with pipes, entering the sides of the generator, for the admission of steam and of cold water respectively. Into the generator, about one-fourth filled with water, 1500 pounds of washed chalk (carbonate of lime) are introduced, and the whole is heated by a jet of steam, and thoroughly mixed by an agitator, until a uniform mass is obtained. About two tons of tartar are now introduced by degrees, and thoroughly mixed. The carbonate of lime is decomposed, the carbonic acid escapes by the exit-pipe, and the lime unites with the excess of tartaric acid to form tartrate of lime, which precipitates; while the neutral tartrate of potassa remains in solution. The next step is to decompose the tartrate of potassa, so as to convert its tartaric acid into tartrate of lime. This is effected by the addition of sulphate of lime in the state of paste, which, by double decomposition, forms a fresh portion of tartrate of lime, while sulphate of potassa remains in solution. The solution of sulphate of potassa, when clear, is drawn off into suitable reservoirs, and the remaining tartrate of lime is washed with several charges of cold water, the washings being preserved. The tartrate of lime, mixed with sufficient water, is now decomposed by the requisite quantity of sulphuric acid, with the effect of forming sulphate of lime, and liberating the tartaric acid, which remains in solution. The whole is now run off into a wooden back, lined with lead, furnished with a perforated false bottom, and covered throughout with stout twilled flannel. Through this the solution of tartaric acid filters, and the filtered liquor passes through a pipe, leading from the bottom of the back, to suitable reservoirs. The sulphate of lime is then washed until it is tasteless, and the whole acid liquor is evaporated, in order to crystallize. The evaporation is effected in wooden vessels, lined with lead, by means of steam circulating in coils of lead-pipe, care being taken that the heat does

not exceed 165°. The vacuum-pan is used with advantage in evaporating the acid solution; as it furnishes the means of concentration at a lower temperature. When the acid liquor has attained the sp. gr. of about 1·5, it is drawn off into sheet-lead, cylindrical, crystallizing vessels, capable of holding 500 pounds of the solution. These crystallizers are placed in a warm situation, and, in the course of three or four days, a crop of crystals is produced in each, averaging 200 pounds. These crystals being somewhat coloured, are purified by redissolving them in hot water The solution is then digested with purified animal charcoal, filtered, again concentrated, and crystallized. The crystals, having been washed and drained, are finally dried on wooden trays, lined with thin sheet-lead, placed in a room heated by steam. The mother-liquors of the first crystallization are again concentrated, and the crystals obtained, purified by animal charcoal as before. When the residuary liquors are no longer crystallizable, they are saturated with chalk, and converted into tartrate of lime, to be added to the product of a new operation. In order to obtain fine crystals of tartaric acid, it is necessary to use a slight excess of sulphuric acid in decomposing the tartrate of lime. (*Pharm. Journ. and Trans.*, Feb. 1851.) The merit of this process consists in the greater economy of sulphate of lime over chloride of calcium for decomposing the tartrate of potassa.

Dr. Price, of England, has made some improvements in the above process, which are described, in detail, in the London *Pharmaceutical Journal and Transactions* (Jan. 1854, p. 315). The main point in his improvements is to convert the crude tartar into tartrate of potassa and ammonia by means of ammoniacal liquor, which gives a soluble double salt, comparatively free from organic colouring matter and other impurities, and, therefore, favourable for conversion into tartrate of lime by the usual methods. Mr. Pontifex, of England, has obtained a patent for an improvement in manufacturing tartaric acid, which consists in evaporating in vacuo. (*Ibid.*, Feb. 1857, p. 430.)

Liebig has succeeded in preparing tartaric acid artificially by the oxidation of sugar of milk, and other substances, by nitric acid; and the resulting product has been found to be identical in all respects, even in its influence on polarized light, with the acid derived from grapes.

Properties. Tartaric acid is a white crystallized solid, in the form of irregular six-sided prisms. Sometimes two opposite sides of the prism become very much enlarged, so as to cause the crystals to present the appearance of tables. The Br. Pharmacopœia states that the primary form is the oblique rhombic prism. As found in the shops, it is in the form of a fine white powder, prepared by pulverizing the crystals. It is unalterable in the air, and possesses a strong acid taste, which becomes agreeable when the acid is sufficiently diluted with water. It is soluble in a little less than its weight of cold water, and in half its weight of boiling water. It is also soluble in alcohol. A weak solution undergoes spontaneous decomposition by keeping, becoming covered with a mouldy pellicle. In the form of crystals it always contains combined water, from which it cannot be separated without the substitution of a base. In uniting with bases, it has a remarkable tendency to form double salts, several of which constitute important medicines. It combines with several of the vegetable organic alkalies, so as to form salts. It is distinguished from all other acids by forming a crystalline precipitate, consisting of bitartrate of potassa, when added to a neutral salt of that alkali. When associated with an excess of boracic acid, it is detected with difficulty; potassa not precipitating it, even with the addition of acetic or muriatic acid. Its separation, however, may be effected, according to Barfoed, by means of fluoride of potassium, which detaches the boracic acid, to form the fluoborate of potassa, and renders free the tartaric acid, which then responds to the ordinary test. (*Journ. de Pharm. et de Chim.*, 4e sér., ii. 70.) Its most usual impurity is sulphuric acid, which may be detected by the solution affording, with acetate of lead, a precipitate only partially soluble in nitric acid. When incinerated with red oxide of mercury, it leaves no residuum, or a mere trace. The British Pharmacopœia

directs that it should give no precipitate with solution of sulphate of lime, showing the absence of racemic and oxalic acids, or with solution of oxalate of ammonia, which would detect lime, sometimes present in minute proportion. Its solution should not be affected by sulphuretted hydrogen. "One hundred grains saturate 133·5 grains of bicarbonate of potassa." *U.S.* "Seventy-five grains dissolved in water require for neutralization 1000 grain-measures of *the volumetric solution of soda.*" *Br.*

Tartaric acid is incompatible with salifiable bases and their carbonates; with salts of potassa, with which it produces a crystalline precipitate of bitartrate; and with the salts of lime and lead, with which it also forms precipitates. It consists, when dry, of four eqs. of carbon 24, two of hydrogen 2, and five of oxygen 40 = 66; and, when crystallized, of one eq. of dry acid 66, and one of water 9 = 75. But, if we agree with the chemists who regard it as bibasic, these numbers must be doubled, and its formula given, as in the British Pharmacopœia, $C_8H_4O_{10}$, or, in its crystallized state, $2HO,C_8H_4O_{10}$. In this view, its ordinary salts, whether with one or two bases, consist of one eq. of acid and two of base; and in the acid or bitartrates, one eq. of base is replaced by one of water, as in the bitartrate of potassa or cream of tartar, the constitution of which would be expressed by the formula $KO,HO+C_8H_4O_{10}$.

Racemic acid, otherwise called *paratartaric* or *uvic acid*, is isomeric with tartaric acid. It exists, naturally, in small proportion, in the juice of grapes, growing in particular localities, and was obtained artificially, in 1853, by M. Pasteur. By combination with certain organic alkalies, M. Pasteur has resolved racemic acid into two acids which form distinct salts with the alkali. The acids in these salts have the power of turning the plane of polarization of polarized light in contrary directions, one to the right, the other to the left, which has caused them to be distinguished as *dextro-* and *lævo-tartaric acids*. Ordinary tartaric acid is dextro-tartaric acid, which may be converted into racemic acid, by exposing it, in the form of tartrate of cinchonia, to a heat of 338° for several hours. At the same time, a portion of tartaric acid is formed, which has no action on polarized light, and which is, therefore, called *inactive tartaric acid*. This acid, like racemic acid, is resolvable into dextro- and lævo-tartaric acids. Accordingly, we have four isomeric tartaric acids—dextro-tartaric (ordinary tartaric acid); lævo-tartaric; racemic, consisting of dextro- and lævo-tartaric acids; and inactive tartaric acid. Racemic acid differs from ordinary tartaric acid in being much less soluble in water, in precipitating the neutral salts of lime, and in want of action on polarized light. When crystallized it contains one eq. more of water than tartaric acid. The *racemates* differ from the tartrates in their crystalline form, and in their less solubility in water.

Medical Properties. Tartaric acid, being cheaper than citric acid, forms, when dissolved in water and sweetened, a good substitute for lemonade. It is much used in medicine to form acid refrigerant drinks and effervescing draughts. It is also employed in making *soda powders* and *Seidlitz powders*, preparations now officinal in the U. S. Pharmacopœia. (See *Pulveres Effervescentes* and *Pulveres Effervescentes Aperientes*, Part II.) Tartaric acid, dried by a gentle heat, and then mixed with bicarbonate of soda, in the proportion of thirty-five grains of the acid to forty of the bicarbonate, forms a good effervescing powder, the dose of which is a teaspoonful, stirred in a tumbler of water. The powder is generally directed to be kept in well-stopped vials; but Prof. Otto has shown that this direction tends to spoil rather than to preserve it, by preventing the evaporation of some water of crystallization which is set free by a commencing chemical reaction. A better plan is to keep the powder in ordinary boxes. On this subject see remarks by Mr. J. M. Maisch, published in the *Proceedings of the American Pharmaceutical Association* (A. D. 1856, p. 52). The neutralizing power of tartaric acid is about the same as that of citric acid. Tartaric acid, in an overdose, acts as a poison. After death, it may be detected in the blood and liver, from which it should be extracted by absolute alcohol, to avoid the error of mistaking the tartrates for it.

Aconite Root.

The root of Aconitum Napellus. *U. S.* The dried root; collected in the winter or early spring before the leaves have appeared. *Br.*

Aconit, *Fr.;* Eisenhut, Mönchskappe, *Germ.;* Aconito Napello, *Ital.;* Aconito, *Span.*

ACONITUM. *Sex. Syst.* Polyandria Trigynia.—*Nat. Ord.* Ranunculaceæ.

Gen. Ch. Calyx none. *Petals* five, the highest arched. *Nectaries* two, peduncled, recurved. *Pods* three or five. *Willd.*

The plants belonging to this genus are herbaceous, with divided leaves, and violet, yellow, or white flowers, in spikes, racemes, or panicles. In the Paris Codex three species were recognised as officinal, *A. Anthora, A. Cammarum,* and *A. Napellus;* but the French authorities unite at present with our own and the British in acknowledging only A. Napellus. There has been much difference of opinion as to the plant originally employed by Störck. Formerly thought to be *A. Napellus,* it was afterwards generally believed to be *A. neomontanum* of Willdenow, and by De Candolle was determined to be a variety of his *A. paniculatum,* designated as *Störckianum.* But, according to Geiger, *A. neomontanum* is possessed of little acrimony; and Dr. Christison states that *A. paniculatum,* raised at Edinburgh from seeds sent by De Candolle himself, was quite destitute of that property. Neither of these, therefore, could have been Störck's plant, which is represented as extraordinarily acrid. It is, however, of little consequence which was used by Störck; as many of the species possess similar virtues, and one is frequently substituted for another in the shops. Those are probably the best which are most acrid. Among these certainly is *A. Lycoctonum.** Dr. Christison found *A. Napellus, A. Sinense, A. Tauricum, A. uncinatum,* and *A. ferox* to have intense acrimony; and Geiger states that he has found none equal, in this respect, to A. Napellus. This species is said to yield aconitia most largely. (*Répert. de Pharm.*, Nov. 1859.) *A. uncinatum* and *A. reclinatum* (Gray) are our only indigenous species. Most of the others are natives of the Alpine regions of Europe and Siberia. Those used in medicine appear to be indiscriminately called by English writers *wolfsbane* or *monkshood.* The root of *A. heterophyllum* is said to be used as an antiperiodic in Upper India (*Pharm. Journ. and Trans.*, xvi. 312), and that of *A. Japonicum* as a local anæsthetic in China, as also for poisoning arrows (*Ibid.*, Nov. 1861, p. 263).

Aconitum Napellus. Linn., *Flor. Suec.*, ed. 1755, p. 168.—*A. neubergense.* De Candolle, *Prodrom.* i. 62.—*A variabile neubergense.* Hayne, *Darstel. und Beschreib. &c.*, xii. 14. This is a perennial herbaceous plant, with a spindle-shaped, tapering root, seldom exceeding at top the thickness of the finger, three or four inches or more in length, brownish externally, whitish and fleshy within, and sending forth numerous long, thick, fleshy fibres. When the plant is in full

* M. Hubschmann is said to have extracted two alkaloids from A. Lycoctonum; one in the form of a white powder, insoluble in ether, but soluble in water and alcohol, which he names *acolytin;* the other crystallizable, very soluble in alcohol, and but slightly so in ether or water, and named by him *lycoctonin.* (*Am. Journ. of Pharm.*, July, 1866, p. 376.)—*Note to thirteenth edition.*

growth, there are usually two roots joined together, of which the older is dark-brown and supports the stem, while the younger is of a light yellowish-brown, and is destined to furnish the stem of the following year, the old root decaying. The stem is erect, round, smooth, leafy, usually simple, and from two to six or even eight feet high. The leaves are alternate, petiolate, divided almost to the base, from two to four inches in diameter, deep-green upon their upper surface, light-green beneath, somewhat rigid, and more or less smooth and shining on both sides. Those on the lower part of the stem have long footstalks and five or seven divisions; the upper, short footstalks and three or five divisions. The divisions are wedge-form, with two or three lobes, which extend nearly or quite to the middle. The lobes are cleft or toothed, and the laciniæ or teeth are linear or linear-lanceolate and pointed. The flowers are of a dark violet-blue colour, large and beautiful, and are borne at the summit of the stem upon a thick, simple, straight, erect, spike-like raceme, beneath which, in the cultivated plant, several smaller racemes arise from the axils of the upper leaves. Though without calyx, they have two small calycinal stipules, situated on the peduncle within a few lines of the flower. The petals are five, the upper helmet-shaped and beaked, nearly hemispherical, open or closed, the two lateral roundish and internally hairy, the two lower oblong-oval. They enclose two pediceled nectaries, of which the spur is capitate, and the lip bifid and revolute. The fruit consists of three, four, or five pod-like capsules.

The plant is abundant in the mountain forests of France, Switzerland, and Germany. It is also cultivated in the gardens of Europe, and has been introduced into this country as an ornamental flower. All parts of it are acrid and poisonous. The leaves and root are used. The leaves should be collected when the flowers begin to appear, or shortly before. After the fruit has formed, they are less efficacious. The root is much more active than the leaves; and an extract from the latter is said to have only one-twentieth of the strength of one made from the former. It should be gathered in autumn or winter after the leaves have fallen, and is not perfect until the second year. It has been mistakenly substituted for horseradish root, as a condiment, with fatal effect; but the possibility of such an event has only to be known to be avoided. The seeds also are acrid. The wild plant is said to be more active than the cultivated. (*Schroff.*) Prof. Wm. Procter has found the roots of the plant cultivated in this country richer in the active alkaline principle than the imported roots; having obtained as much as 0·85 per cent. from the former. (*Proceed. of the Am. Pharm. Association*, A. D. 1860.)

Properties. The *fresh leaves* have a faint narcotic odour, most sensible when they are rubbed. Their taste is at first bitterish and herbaceous, afterwards burning and acrid, with a feeling of numbness and tingling on the inside of the lips, tongue, and fauces, which is very durable, lasting sometimes many hours. When long chewed, they inflame the tongue. The *dried leaves* have a similar taste, but the acrid impression commences later. Their sensible properties and medicinal activity are impaired by long keeping. They should be of a green colour, and free from mustiness. The *root* has a feeble, earthy smell. Though sweetish at first, it has afterwards the same effect as the leaves upon the mouth and fauces. It shrinks much in drying, and becomes darker, but does not lose its acrimony. Those parcels, whether of leaves or roots, should always be rejected, which are destitute of this property. The analysis of aconite, though attempted by several chemists, has not been satisfactorily accomplished. Bucholz obtained from the fresh herb of A. neomontanum, resin, wax, gum, albumen, extractive, lignin, malate and citrate of lime and other saline matters, besides 83·33 per cent. of water. During the bruising of the herb, he experienced headache, vertigo, &c., though water distilled from it produced no poisonous effect. It has been rendered probable by Geiger and Hesse, that there are two active principles in aconite; one easily destructible, upon which the acrimony depends, the other less acrid, alkaline, and capable of exerting a powerful narcotic influence. For the latter the name of *aconitin* or *aconitia* has

been proposed. Mr. Thos. B. Groves was unable to obtain any peculiar acrid principle from either the leaves or root by distillation with water; and though, when lime was added, an alkaline distillate was obtained, he found this to owe its alkalinity to ammonia. Mr. Groves, therefore, concluded that aconite contains no peculiar volatile acrid substance, and is disposed to ascribe any loss of acrimony which may take place on drying to the easy destructibility of aconitia; and that any greater acrimony that the root may possess over aconitia is ascribable to an acrid resin with which the root may be said to abound. (*Pharm. Journ. and Trans.*, Sept. 1866, p. 118.) Hesse obtained aconitia from the dried leaves by a process similar to that employed in procuring atropia. (See *Atropia*, Part II.) The U. S. and Br. Pharmacopœias give a process for its preparation. (See *Aconitia*, Part II.) Hubschmann has found in impure commercial aconitia a small proportion of another alkaloid which he names *napellina*.* Messrs. T. and H. Smith, of Edinburgh, have announced the discovery of a new alkaloid in the root, which they propose to name *aconella*, and which bears so close a resemblance to narcotina as to suggest the identity of the two.† Peschier discovered a peculiar acid in aconite, which he called *aconitic acid*. The root contains also mannite and a fatty matter soluble in alcohol.

Medical Properties and Uses. Aconite was well known to the ancients as a powerful poison, but was first employed as a medicine by Baron Störck, of Vienna, whose experiments with it were published in the year 1762. In moderate doses, it has been said to excite the circulation, and to increase the perspiratory

* *Napellina.* To obtain this principle, Hubschmann treats the impure aconitia with the least quantity of ether necessary to dissolve the pure alkaloid, dissolves the residue in alcohol, filters the solution, adds acetate of lead so long as it produces a precipitate, again filters, and, having separated the lead by sulphuretted hydrogen and subsequent filtration, evaporates the alcohol, adds an excess of carbonate of potassa, evaporates to dryness, treats the residue with alcohol, passes the solution through animal charcoal, and again evaporates to dryness. The resulting napellina is in the form of a white powder, of a bitter and afterwards burning taste, of decided alkaline properties, but slightly soluble in ether, and not, like aconitia, precipitated from its aqueous solution by ammonia. It contains nitrogen. (See *Am. Journ. of Pharm.*, xxx. 399.)—*Note to the twelfth edition.*

† *Aconella.* The Messrs. Smith obtained this alkaloid in the following manner. The juice of the fresh root is evaporated to a soft extract, which is exhausted by officinal alcohol. The alcoholic liquid is treated with lime in the proportion of 1·5 per cent. of the root employed. To the liquid, previously filtered, sulphuric acid is gradually added till a precipitate ceases to be produced. After filtration, the alcohol is distilled off, and the watery residue, after separation of a copious dark-green fatty matter, is again filtered. The liquid is now very acid; and it is through this acidity that it retains the aconella; so that all that is required to separate the alkaloid is to neutralize the acid. For this purpose carbonate of soda is added, at first freely while there is brisk effervescence, but at last gradually, with constant stirring, till the liquid is nearly, but not quite neutralized, when it is to be set aside for a time. The aconitia, which has hitherto accompanied the aconella, remains in the solution provided it be not alkaline, while the latter alkaloid is deposited partially crystallized. After a day or two, it is to be removed, and may be purified by repeated solution in hot alcohol, with the addition of animal charcoal. It is deposited from the alcoholic solution on cooling.

Aconella is thus obtained in snow-white tufts of acicular crystals, which are without taste, though bitter in solution, nearly insoluble in pure water, but very soluble in water acidulated by any acid, soluble in 300 parts of cold and 11·4 parts of boiling alcohol of 0·840, moderately soluble in ether, much more so in acetic ether, and remarkably so in chloroform. It is distinguished by an extraordinary facility of crystallization. It forms salts with the acids, of which only the muriate is crystallizable. It is precipitated from its acidulated solution by tincture of iodine. Tannic acid precipitates its oxalate but not its muriate. Its solution in acids, even in contact with an excess of the base, reddens litmus, though the alkaloid itself restores the blue of litmus paper feebly reddened by acids. It is not poisonous; the Messrs. Smith gave 15 grains to a cat without apparent inconvenience. In all these points it resembles *narcotina*, and its combining number was found virtually to be the same. Hence the Messrs. Smith, as stated in the text, are disposed to consider it identical with that alkaloid.

An important practical consideration is that aconella probably often constitutes an unintentional impurity of aconitia, being precipitated along with it in its preparation. Hence in some degree may be accounted for the frequent relative weakness of the aconitia of the shops. (*Pharm. Journ. and Trans.* Jan. 1864, p. 317.)—*Note to the twelfth edition.*

and urinary discharges; but these effects are doubtful, and certainly not constant. Schroff, however, states that it generally increases the secretion of urine. According to Dr. Fleming, it is a powerful sedative to the nervous system, reducing also the force of the circulation. In moderate doses, it produces warmth in the stomach and sometimes nausea, general warmth of the body, numbness and tingling in the lips and fingers, muscular weakness, diminished force and frequency of the pulse, and diminished frequency of respiration. From larger doses all these effects are experienced in an increased degree. The stomach is more nauseated; the numbness and tingling extend over the body; headache, vertigo, and dimness of vision occur; the patient complains occasionally of severe neuralgic pains; the pulse, respiration, and muscular strength are greatly reduced; and a state of general prostration may be induced, from which the patient may not quite recover in less than two or three days. The effects of remedial doses begin to be felt in twenty or thirty minutes, are at their height in an hour or two, and continue with little abatement from three to five hours.

In poisonous doses, besides the characteristic tingling in the mouth and elsewhere, aconite occasions burning heat of the œsophagus and stomach, thirst, violent nausea, vomiting, purging, severe gastric and intestinal spasms, headache, dimness of vision with contracted or expanded pupils, numbness or paralysis of the limbs, diminished sensibility in general, stiffness or spasm of the muscles, great prostration, pallid countenance, cold extremities, an extremely feeble pulse, and death in a few hours, sometimes preceded by delirium, stupor, or convulsions. All these effects are not experienced in every case; but there is no one of them which has not been recorded as having occurred in one or more instances. Dissection reveals inflammation of the stomach and bowels, and engorgement of the brain and lungs. Pereira states that, when dogs are opened immediately after death from aconite, no pulsations of the heart are visible. Life may usually be saved by a timely and thorough evacuation of the stomach, and the use of stimulant remedies internally and externally; and it is wonderful how rapidly the patient passes from a state of imminent danger to perfect health. Experiments upon inferior animals appear to have demonstrated a physiological antagonism between aconite and nux vomica, or of their two alkaloids respectively, of which advantage may be taken in treating the poisonous effects of these substances. In a case of extreme poisoning from tincture of aconite in a child, the tincture of nux vomica was administered with the apparent effect of saving life. (Hanson, *Boston Med. and Surg. Journ.*, Sept. 26, 1861.) But reliance should not be placed on this antidote to the exclusion of emetic and stimulant measures. Applied to the skin, aconite occasions heat and prickling or tingling, followed by numbness, and, if in contact with a wound, produces its peculiar constitutional effects. Applied to the eye, it causes contraction of the pupil. In relation to its mode of action, it appears to be locally irritant, and, at the same time, entering the system, to operate powerfully on the brain, spinal marrow, and nerves, directly diminishing their power, and thus producing, to a greater or less extent, paralysis both of sensation and motion. The heart also feels this paralyzing influence, and hence proceeds the great depression of the pulse under the full action of the medicine.

Aconite has been employed in rheumatism, neuralgia, gout, anginose and catarrhal affections, scrofula, phthisis, metastatic abscess and other cases of purulent infection, secondary syphilis, carcinoma, certain cutaneous diseases, hooping-cough, amaurosis, deafness, paralysis, epilepsy, intermittent fever, dropsies, and hypertrophy of the heart. It has long enjoyed, in Germany, a high reputation as a remedy in rheumatism; and has recently come into great vogue elsewhere in the treatment of that disease, especially in its chronic and neuralgic forms. By some practitioners it is considered as one of the most effectual remedies in neuralgia, in which it is used both internally and as a local application. Dr. Fleming considers it highly useful as an antiphlogistic remedy, and especially applicable to cases of active cerebral congestion or inflammation; while it is contraindicated in the headache of anæmia, and in all

cases attended with a torpid or paralytic condition of the muscular system. Cazenave has found it very useful in cutaneous eruptions with extreme sensibility of the skin; and it is said sometimes to check excessive sweating. It may be administered in powder, extract, or tincture. The dose of the powdered leaves is one or two grains, of the extract from half a grain to a grain, of the tincture of the leaves twenty or thirty drops, to be repeated twice or three times a day, and gradually increased till the effects of the medicine are experienced. The preparation now most employed is probably the strong tincture of the root, *Tinctura Aconiti Radicis, U. S.* Of this, from five to ten drops may be given three times a day, and gradually increased till its effects become obvious. It is very important to distinguish between the tincture of the leaves and the strong tincture of the root just referred to.* Few patients will bear at first more than ten minims of the latter. Aconite may be used externally in the form of the saturated tincture of the root, of extract mixed with lard, of a plaster or liniment, or of *aconitia*. The tincture may be applied by means of a soft piece of sponge, fastened to the end of a stick.

ADEPS. *U.S.*

Lard.

The prepared fat of Sus Scrofa. Lard should be free from saline matter. Below the temperature of 90°, it has the consistence of a soft solid. *U.S.*

Off. Syn. ADEPS PRÆPARATUS. The purified fat of the hog, Sus scrofa. *Br.*

Axungia *Lat.;* Axonge, Graisse, Saindoux, *Fr.;* Schweineschmalz, *Germ.;* Grasso di porco, Lardo, *Ital.;* Manteca de puerco, Lardo, *Span.*

Lard is the prepared fat of the hog. The Br. Pharmacopœia gives a process for its preparation; but in this country it is purchased by the druggists already prepared. The adipose matter of the omentum and mesentery, and that around the kidneys, are usually employed; though the subcutaneous fat is said to afford lard of a firmer consistence. In the crude state it contains membranes and vessels, and is more or less contaminated with blood, from all which it must be freed before it can be fit for use. For this purpose, the fat, having been deprived as far as possible by the hand of membranous matter, is cut into pieces, washed with water till the liquor ceases to be coloured, and then melted, usually with a small portion of water, in a copper or iron vessel, over a slow fire.† The heat is continued till all the moisture is evaporated, which may be known by the transparency of the melted fat, and the absence of crepitation when a small portion of it is thrown into the fire. Care should be taken that the heat is not too great; as otherwise the lard might be partially decomposed, acquire a yellow colour, and become acrid. This may be guarded against by using a water-bath in melting the lard. The process is completed by straining the liquid through linen, and pouring it into suitable vessels, in which it concretes upon cooling.

* Physicians should be very careful, when prescribing, to designate by name which of these tinctures they intend, whether that of the root, or that of the leaves; as serious mistakes may otherwise occur; and apothecaries should be scrupulous in putting up the prepartion of the U. S. Pharmacopœia when the tincture of the root is prescribed, and not that of Dr. Fleming, which is stronger than the officinal. (*Note to the tenth edition.*)

† Prof. Procter recommends the following method of operating. After careful removal of the membranes and adhering flesh, the crude lard is to be cut into small pieces, malaxated with successive portions of cold water until this remains clear, and then heated moderately, in a tinned vessel, until the melted fat becomes perfectly clear and anhydrous. Lastly, it is to be strained into earthen pots, being occasionally stirred as it cools; and the pots should be securely covered with waxed or varnished paper, and kept in a cool, dry cellar. (*Am. Journ. of Pharm.*, xxxv. 114.)—*Note to the twelfth edition.*

Lard may be rendered quite inodorous by melting it, when fresh, by means of a salt-water bath, adding a little alum or common salt, continuing the heat till a scum rises, which is to be skimmed off, and, after the lard has concreted, separating the saline matter by washing it thoroughly with water. For a particular account of the process, see the *Am. Journ. of Pharm.* (xxviii. 176).

The following is the process of the British Pharmacopœia for preparing lard. "Take of the internal fat of the abdomen of the hog, perfectly fresh, *fourteen pounds*. Remove as much of the membranes as possible, cut the fat into small pieces, put it into a suitable vessel with about four gallons of cold water, and, while a current of water is running through the vessel, break up the masses of fat with the hands, exposing every part to the water, so that whatever is soluble may thus be dissolved and carried away. Afterwards collect the washed fat on a sieve or in a cloth, drain away as much as possible of the water, liquify the fat at a heat not exceeding 212°, and strain through flannel, pressing the residue while hot; then put it into a pan heated by steam, and keep it at a temperature a little but not much above 212°, stirring it continually, until it becomes clear and entirely free from water; finally strain it through flannel." *Br.*

Lard, as offered for sale, often contains common salt, which renders it unfit for pharmaceutic purposes. This may be detected, when the quantity is insufficient to be sensible to the taste, by means of nitrate of silver, which will produce a precipitate of chloride of silver with water in which the salted lard has been boiled, after cooling and filtration. To free it from this impurity, it may be melted with twice its weight of boiling water, the mixture well agitated and set aside to cool, and the fat then separated. American lard is said to be adulterated, in England, with water, starch, and a small proportion of alum and quicklime, which render it whiter, but unfit for medical use. The Br. Pharmacopœia provides against the admixture of starch by directing that distilled water, in which it has been boiled, should not be rendered blue by the addition of solution of iodine. Considerable quantities of lard have been imported into France from the United States, adulterated with 25 per cent. of a jelly-like substance supposed to be extracted from Irish moss. This was separated by treating the lard with boiling water. (*Journ. de Pharm.*, 1855, p. 455.)

Properties. Lard is white, inodorous, with little taste, of a soft consistence at ordinary temperatures, fusible at about 100° F., insoluble in water, partially soluble in alcohol, entirely so in ether and the volatile oils, dissolved and decomposed by the stronger acids, and converted into soap by reaction with the alkalies. When melted, it readily unites with wax and resins. According to Braconnot, it contains, in 100 parts, 62 of *olëin* or the liquid principle of oils, and 38 of *stearin* or the concrete principle. But M. Le Canu ascertained that the stearin of Braconnot consists of two distinct substances, differing in fusibility and solubility. For the least fusible of these he retained the name of stearin, and to the other applied that of *margarin*, from its resemblance to the principle of the same name in vegetable oils. Most fats and oils of animal origin are composed of these ingredients, upon the relative proportion of which their consistence respectively depends. The liquid and concrete principles may be obtained separate by the action of boiling alcohol, which deposits the latter on cooling, and yields the former upon evaporation. Another method is to compress fat, or oil congealed by cold, between the folds of bibulous paper. The olein is absorbed by the paper, and may be separated by compression under water; the stearin and margarin remain.

Olein, stearin, and margarin are now generally considered as compounds respectively of oleic, stearic, and margaric acids with glycerin. For an account of these principles, see *Olea Fixa*. Very good candles are made out of the concrete constituents of lard; and the liquid principle or olein is extensively employed for burning in lamps, and other purposes in the arts. Vast quantities of it are prepared in Cincinnati, Ohio, and much is exported. In France it is said to be largely used for adulterating olive oil.

Exposed to the air, lard absorbs oxygen and becomes rancid. It should,

therefore, be kept in well-closed vessels, or procured fresh when wanted for use. In the rancid state, it irritates the skin, and sometimes exercises an injurious reaction on substances mixed with it. Thus, the ointment of iodide of potassium, which is white when prepared with fresh lard, is said to be more or less yellow when the lard employed is rancid. Rancidity in lard and other fats is prevented by digesting them with benzoin, or poplar buds. (See *Unguenta.*)

Medical Properties and Uses. Lard is emollient, and is occasionally employed by itself in frictions, or in connection with poultices to preserve their soft consistence; but its chief use is in pharmacy as an ingredient of ointments and cerates. It is frequently added to laxative enemata.

ALCOHOL. *U.S.*

Alcohol.

Spirit of the specific gravity 0·835. *U.S.*

Off. Syn. SPIRITUS RECTIFICATUS. *Rectified Spirit.* Alcohol, $C_4H_6O_2$, with 16 per cent. of water, of the sp. gr. 0·838. *Br.*

Rectified spirit, Spirit of wine; Alcohol, Esprit de vin, *Fr.;* Rectificirter Weingeist, *Germ.;* Alcoole, Acquavite rectificata, *Ital.;* Alcohol, Espiritu rectificado de vino, *Span.*

ALCOHOL DILUTUM. *U.S.*

Diluted Alcohol.

Alcohol mixed with an equal measure of Distilled Water. The specific gravity is 0·941. *U.S.*

Off. Syn. SPIRITUS TENUIOR. *Proof Spirit.* Made by mixing five pints of Rectified Spirit with three pints of Distilled Water. Sp. gr. 0·920. *Br.*

ALCOHOL FORTIUS. *U.S.*

Stronger Alcohol.

Spirit of the specific gravity 0·817. *U.S.*

From the titles and definitions above given, which include all the forms of alcohol recognised by the U. S. and Br. Pharmacopœias, it will be perceived that there are three officinal strengths of Alcohol, those being considered the same which approach nearly in specific gravity, and are employed for similar purposes. Of these, two are common to both Pharmacopœias; Alcohol, U. S. (sp. gr. 0·835), corresponding with Spiritus Rectificatus, Br. (sp. gr. 0·838), and Diluted Alcohol, U.S. (sp. gr. 0·941), corresponding with Spiritus Tenuior or Proof Spirit, Br. (sp. gr. 0·920). The third, Alcohol Fortius or Stronger Alcohol (sp. gr. 0·817), is peculiar to our own officinal standard. As they are all placed in the Materia Medica Catalogue of the U. S. Pharmacopœia, they will all be considered here.

Alcohol, in the chemical sense, is a peculiar liquid, generated for the most part in vegetable juices and infusions by a *fermentation*, called the *vinous* or *alcoholic*. The liquids which have undergone it are called vinous liquors, and are of various kinds. Thus, the fermented juice of the grape is called wine; of the apple, cider; and the fermented infusion of malt, beer.

With regard to the nature of the liquids susceptible of the vinous fermentation, however various they may be in other respects, one general character prevails; that, namely, of containing sugar in some form or other. It is found, further, that, after they have undergone the vinous fermentation, the sugar they contained has either wholly or in part disappeared; and it was long believed that the only new products are alcohol which remains in the liquid, and carbonic acid which escapes during the process; and that these, when taken together.

are equal in weight to the sugar lost. It was hence inferred that sugar is the subject-matter of the changes that occur during the vinous fermentation, and that it is resolved into alcohol and carbonic acid. More recently, however, it has been shown by M. Pasteur that, along with alcohol and carbonic acid, glycerin and succinic acid are also generated, and that the process is not so simple as at one time supposed.

Sugar will not undergo the vinous fermentation by itself; but requires to be dissolved in water, subjected to the influence of a ferment, and kept at a certain temperature. Accordingly, sugar, water, the presence of a ferment, and the maintenance of an adequate temperature may be deemed the prerequisites of the vinous fermentation. The water acts by giving fluidity, and the ferment and temperature by commencing and maintaining the chemical changes. The precise manner in which the ferment operates in causing the reaction has not been positively determined; but the fermentative change seems to be intimately connected with the multiplication of a microscopic vegetable, in the form of diaphanous globules, contained in the ferment, and called *torula cerevisiæ*. Pasteur has rendered it highly probable that the yeast plant lives and grows at the expense of the sugar, which is converted partly into the tissue of the plant, partly into alcohol and those other products which have been proved to result from vinous fermentation. The proper temperature for conducting the vinous fermentation ranges from 60° to 90°.

Certain vegetable infusions, as those of potatoes and rice, though consisting almost entirely of starch, are, nevertheless, capable of undergoing the vinous fermentation, and form seeming exceptions to the rule, that sugar is the only substance susceptible of this fermentation. The apparent exception is explained by the circumstance, that starch is susceptible of a spontaneous change which converts it into sugar. How this change takes place is not well known, but it is designated by some authors as the *saccharine fermentation*. Thus, Kirchoff proved that, if a mixture of gluten from flour, and starch from potatoes be put into hot water, the starch will be converted into sugar. When, therefore, starch is apparently converted into alcohol by fermentation, it is supposed that it passes through the intermediate state of sugar. According to Berthelot, mannite, glycerin, and similar substances may be made to ferment by contact, for several weeks, with chalk and cheese at 104°; and the change takes place without the production of sugar, provided chalk is present. M. Arnoult has succeeded in obtaining alcohol by fermenting sugar (glucose), formed by the action of sulphuric acid on poplar wood sawdust, which yielded from 70 to 80 per cent. of this kind of sugar.

Alcohol, being the product of the vinous fermentation, necessarily exists in all vinous liquors, and may be obtained from them by distillation. Formerly it was supposed that these liquors did not contain alcohol, but were merely capable of furnishing it, in consequence of a new arrangement of their ultimate constituents, the result of the heat applied. Brande, however, disproved this idea, by showing that alcohol may be obtained from all vinous liquors without the application of heat, and therefore must pre-exist in them. His method of separating it consists in precipitating the acid and colouring matter from each vinous liquor by subacetate of lead, and removing the water by carbonate of potassa. According to Gay-Lussac, litharge, in fine powder, is the best agent for precipitating the colouring matter.

In vinous liquors, the alcohol is diluted with abundance of water, and associated with colouring matter, volatile oil, extractive, and various acids and salts. In purifying it, we take advantage of its volatility, which enables us to separate it by distillation, combined with some of the principles of the vinous liquor employed, and more or less water. The distilled product of vinous liquors forms the different *ardent spirits of commerce*. When obtained from wine, it is called brandy; from fermented molasses, rum; from cider, malted barley, or rye, whisky; from malted barley and rye-meal with hops, and rectified from juniper berries, Holland gin; from malted barley, rye, or potatoes, and rectified from

turpentine, common gin; and from fermented rice, arrack. These spirits are of different strengths, that is, contain different proportions of alcohol, and have various peculiarities by which they are distinguished by the taste. Their strength is accurately judged of by the specific gravity, which is always less in proportion as their concentration is greater. When they have the sp. gr. 0·920 (0·91984, *Drinkwater*), they are designated in commerce by the term *proof spirit*. If lighter than this, they are said to be above proof; if heavier, below proof; and the percentage of water, or of spirit of 0·825, necessary to be added to any sample of spirit to bring it to the standard of proof spirit, indicates the number of degrees the given sample is above or below proof. Thus, if 100 volumes of a spirit require 10 volumes of water to reduce it to proof spirit, it is said to be "10 over proof." On the other hand, if 100 volumes of a spirit require 10 volumes of spirit, of 0·825, to raise it to proof, it is said to be "10 under proof."

Proof spirit is still very far from being pure; being a dilute alcohol, containing about half its weight of water, together with a peculiar oil and other foreign matters. It may be further purified and strengthened by redistillation, or *rectification* as it is called. Whisky is the spirit usually employed for this purpose; and from every hundred gallons, between fifty-seven and fifty-eight may be obtained, of the average strength of rectified spirit (sp. gr. 0·835), corresponding with the *Alcohol* of the U. S. Pharmacopœia, and very nearly with the *Spiritus Rectificatus* of the British. When this is once more cautiously distilled, it will be further purified from water, and the sp. gr. attained will be about 0·825, which is the lightest spirit that can be obtained by ordinary distillation, and is the pure spirit of the British system of excise. It still, however, contains 11 per cent. of water. In the mean while, the spirit, by these repeated distillations, becomes more and more freed from the contaminating oil, called *grain oil* or *fusel oil*. (See *Alcohol Amylicum*.) We shall first consider the general properties of alcohol, and afterwards the different officinal forms.

Properties. Alcohol, using this term in a generic sense, is a colourless, transparent, volatile liquid, of a penetrating, agreeable odour, and burning taste. It should be free from foreign odour, which, when present, is owing to fusel oil. When free from water, it is called *anhydrous* or *absolute alcohol*. It is inflammable, and burns without smoke or residue, forming water and carbonic acid. Its flame is bluish when strong, but yellowish when weak. It combines in all proportions with water and ether; and, when diluted with distilled water, preserves its transparency. Its density varies with the proportion of water it contains. When of the sp. gr. 0·820, its boiling point is at 176°. Its value depends upon the quantity of absolute alcohol contained in it; and, as this is greater in proportion as the sp. gr. is less, it is found convenient to take the density of a sample in estimating its strength. This is done by instruments called hydrometers, which, when allowed to float in the spirit, sink deeper into it in proportion as it is lighter. Each hydrometer strength has a corresponding specific gravity; and, by referring to tables constructed for the purpose, the percentage of absolute alcohol is at once shown. Dr. W. H. Pile, maker of hydrometers, of this city, graduates instruments showing specific gravity at once, which are exceedingly convenient.

Alcohol is capable of dissolving a great number of substances; as, for example, sulphur and phosphorus in small quantity, iodine and ammonia freely, and potassa, soda, and lithia in the caustic state, but not as carbonates. Among organic substances, it is a solvent of the organic vegetable alkalies, urea, tannic acid, sugar, mannite, camphor, resins, balsams, volatile oils, and soap. It dissolves the fixed oils sparingly, except castor oil, which is abundantly soluble. It acts on most acids, forming ethers with some, and effecting the solution of others. All deliquescent salts are soluble in alcohol, except carbonate of potassa; while the efflorescent salts, and those either insoluble or sparingly soluble in water are mostly insoluble in it. It dissolves muriate of ammonia, and most of the chlorides that are readily soluble in water; also some nitrates, but none of the metallic sulphates.

A method of detecting alcohol in small proportions has been proposed by M. Carstanjin. The liquid supposed to contain it, having been mixed with platinum black in a small flask, is heated to 124° F., well shaken, and filtered. To the filtrate a few drops of solution of potassa is added, and the liquor evaporated to dryness on a water-bath. The residue is then heated with a little arsenious acid; when, if alcohol is present, a garlic odour will be perceived, owing to the production of cacodyl. According to M. Nickles, however, propylic alcohol would produce the same result. (*Am. J. of Pharm.*, Sept. 1865, p. 334.)

The following table, constructed by Lowitz and improved by Thomson, gives the sp. gr. of different mixtures by weight of absolute alcohol and water.

Table of the Specific Gravity of different Mixtures by Weight of Absolute Alcohol and Distilled Water, at the Temperature of 60°.

H. von Baumhauer has inferred from his experiments that the results in the above table are not entirely correct. The inaccuracies, however, admitting the results of Baumhauer, are not so great as to be of much importance in a pharmaceutic point of view. (See *Am. Journ. of Pharm.*, July, 1860, p. 1.)

1. Absolute Alcohol. *Anhydrous Alcohol.* This, though formerly directed by the Edinburgh and Dublin Colleges, is not now officinal. By the term is implied pure alcohol, entirely free from water. In this state it cannot be obtained by ordinary distillation alone; the purest alcohol thus procured still containing 11 per cent. of water. To separate this it is customary to have recourse to substances having a very strong affinity for water, sufficient not only to abstract it from the alcohol, but to retain it at a temperature at which alcohol will distil over. Soubeiran recommends the following as an easy method for obtaining it, free from water, abundantly and economically. 1st. Rectify alcohol, marking 86° of the centesimal alcoholmeter of Gay-Lussac (rectified spirit), by distilling it

* Absolute Alcohol.
† Alcohol Fortius, Stronger Alcohol, *U. S.*

¶ Spiritus Tenuior, Proof Spirit, *Br.*
†† Alcohol Dilutum, *U. S.*

from carbonate of potassa. This operation raises its strength to 94° or 95°. 2d. Raise this alcohol to 97° by distilling it with fused chloride of calcium, or by digesting it with quicklime (from which it must be afterwards poured off), in the proportion of a pint of the alcohol to 1½ ounces of the chloride, or 2¼ ounces of the lime. 3d. Distil the product of this operation slowly with quicklime, in the proportion of 3¾ ounces to the pint. The product will be absolute alcohol. The operation may be shortened to two steps, by distilling the alcohol of 94° or 95° with an excess of quicklime (7¼ ounces to the pint). In all cases, before decanting or distilling, the alcohol must be digested for two or three days with the lime, at a temperature between 95° and 100° F. Lime will not answer as a substance to be distilled from, unless it be in sufficient excess; for otherwise, towards the end of the distillation, the hydrate of lime formed will yield up its water to the alcohol, and weaken the distilled product.

Properties. Absolute alcohol is a colourless, volatile liquid, of an agreeable odour and burning taste. It boils at 172°, and is not congealed by a cold of 166° below zero. Its sp. gr. is 0·7978 at 68°, according to Regnault; 0·79381 at 60°, according to Drinkwater. The sp. gr. of its vapour is 1·59. Its freedom from water may be ascertained by dropping into it a piece of anhydrous baryta, which will remain unchanged if the alcohol be free from water; but otherwise will fall to powder. Another method for determining the same point is to allow alcohol to stand for some time, in a stoppered bottle, on anhydrous sulphate of copper. If the alcohol be anhydrous, the salt will remain white; otherwise it will become blue. (*Casoria.*) Absolute alcohol should be free from fusel oil.

Absolute alcohol burns with a pale flame without residue, the products being carbonic acid and water. Its vapour, passed through a porcelain tube filled with pumice-stone and heated to redness, yields carbon, gaseous carbohydrogens, aldehyd, naphthalin, benzin, phenic acid, and various other substances. (*Berthelot.*) It unites in all proportions with ether and water. Its union with water is attended by condensation and a rise of temperature. When 51·9 volumes of alcohol are mixed with 48·1 of water, corresponding with one eq. of the former to six of the latter, the decrease of volume is at the maximum, amounting to 3·4 per cent. Berthelot has announced the formation of alcohol synthetically, by uniting olefiant gas with water. In this discovery he was anticipated by the late Mr. Hennel, who published it in 1828.

Composition. Absolute alcohol consists of four eqs. of carbon 24, six of hydrogen 6, and two of oxygen 16 = 46; or, in volumes, of four volumes of the vapour of carbon, six of hydrogen, and one of oxygen, condensed into two volumes. Its empirical formula is, therefore, $C_4H_6O_2$. Viewed as a hydrated oxide of ethyl, its formula is $C_4H_5,O+HO$.

It has been stated, at *page* 77, that during the vinous fermentation sugar disappears, and that the sole products had been supposed to be alcohol and carbonic acid, which, taken together, were equal in weight to the sugar lost. Now, the comparative composition of the substances concerned supports the opinion that these are the sole derivatives of a portion of the sugar lost. Preparatory to the fermentation, the cane sugar is changed into *grape sugar*, or, according to Mitscherlich and Soubeiran, into *uncrystallizable sugar*. These two sugars, dried at 212°, consist of $C_{12}H_{12}O_{12}$. Supposing one eq. of this fermentable sugar to be the subject-matter of the change, it will be found to have a composition which admits of its being broken up into two eqs. of alcohol and four of carbonic acid; for $C_{12}H_{12}O_{12}=2(C_4H_6O_2)$ and $4(CO_2)$. But it does not follow that all the sugar has been converted into alcohol and carbonic acid; and Pasteur, as before stated, has shown that a portion lost has not been thus converted, but has been partly appropriated to the growth of the yeast plant of the ferment, and partly changed into glycerin and succinic acid.

2. Alcohol Fortius. *U. S. Stronger Alcohol*, sp. gr. 0·817. This was an officinal of the Dublin College, which gave a formula for its preparation, and stated its sp. gr. at 0·818. The Stronger Alcohol introduced into the Materia Medica of the U. S. Pharmacopœia, at the late revision, though of the sp. gr. 0·817, and

therefore a little stronger than the Dublin preparation, may for all practical purposes be considered as identical with it. To prepare it on a small scale, carbonate of potassa, previously ignited in a heated mortar, may be mixed with officinal alcohol (sp. gr. 0·835) in a bottle, and shaken occasionally for about four hours; the mixture being, in the mean time, maintained at the temperature of about 100°. Upon resting, the liquid divides into two strata, the lower consisting of a watery solution of carbonate of potassa, the upper of the stronger alcohol, which is to be separated, and distilled so as to obtain the measure of about nine-tenths of the original alcohol employed.

On a large scale, we are informed that alcohol of this strength is now prepared in the U. States, very abundantly, by simple distillation by means of a modified distillatory apparatus. The modification consists in substituting, for a single refrigerated receiver, a series of receivers, kept at such temperatures that, in the first of them, the watery vapour shall condense with comparatively little of the alcoholic, which, as it passes through the successive recipients, is more and more deprived of water, until, when condensed in the last, it yields a spirit at least as strong as the officinal Stronger Alcohol of the sp. gr. 0·817. At the same time that the spirit is thus strengthened, it becomes, on the same principle, more and more freed from fusel oil, until at length almost wholly deprived of it.

The properties of this form of spirit do not materially differ from those of officinal alcohol, except in its exemption from fusel oil. The test of the absence of this impurity, or of its presence in only very minute proportion, is that, when "treated with a few drops of solution of nitrate of silver, and exposed to a bright light, the alcohol either remains unchanged, or lets fall a very scanty dark precipitate." *U. S.* Stronger alcohol is used exclusively in the preparation of other officinals, as ether, purified chloroform, ethereal oil, spirit of nitrous ether, &c., for which purpose it was introduced into the Pharmacopœia.

3. Alcohol *U. S.* Spiritus Rectificatus. *Br. Officinal Alcohol. Rectified Spirit.* This is the form of spirit resulting from the ordinary distillation of ardent spirit, though not the strongest which can be obtained by a repetition of that process; having the sp. gr. 0·835, U. S., or 0·838, Br., while that of the strongest is 0·825. The British preparation contains 16, the U.S. only 15 per cent. of water. Officinal alcohol, though of standard strength, may still be impregnated with an essential oil, called *fusel oil*. This is usually removed by digesting the alcohol with charcoal. It may also be removed, as well as other impurities, by passing the impure spirit through a filtering bed, composed of sand, wood-charcoal, boiled wheat, and broken oyster-shells, arranged in layers, according to the method of Mr. W. Schaeffer. (*Am. Journ. of Pharm.*, Nov. 1854, p. 536.) Another method, proposed by M. Breton, is to add a few drops of olive oil to the spirit in a bottle, which is then to be shaken, allowed to settle, and decanted. The olive oil dissolves and retains the fusel oil. (*Chem. Gaz.*, April 15, 1859, p. 160.) It may be detected by adding a little of the solution of nitrate of silver to the alcohol, and then exposing it to a bright light. If fusel oil be present, it will be converted into a black powder. Officinal alcohol will not withstand this test; as the best contains a little of the foreign oil. According to Mr. E. N. Kent, of New York, nitrate of silver will not detect fusel oil, but affords its indications by reacting with other organic substances. For detecting fusel oil Mr. Kent finds pure sulphuric acid the best test. To apply it he half fills a test tube with the spirit to be tested, and then fills it up very slowly with pure concentrated sulphuric acid. If the spirit be pure, it will remain colourless; otherwise it will become coloured, the tint being deeper in proportion to the amount of the impurity. (*New York Journ. of Pharm.*, Aug. 1854.) "Four fluidounces, with thirty grain-measures of *the volumetric solution of nitrate of silver*, exposed for 24 hours to bright light, and then decanted from the black powder which has formed, undergoes no further change when again exposed to light with more of the test." *Br.* This admits the presence of a small but limited proportion of fusel oil. The U. S. Pharmacopœia directs that officinal alcohol, when diluted with 20 parts of distilled water, should have little or no foreign odour; the Br. Pharmacopœia that its odour and taste should be purely alcoholic.

The best alcohol, made in Philadelphia, is that manufactured by Z. Locke & Co., under Atwood's patent process, in which manganic acid is used to destroy the fusel oil and other foreign substances. This alcohol withstands the tests of nitrate of silver and sulphuric acid remarkably well.

4. Alcohol Dilutum. *U. S.* Spiritus Tenuior. *Br. Diluted Alcohol. Proof Spirit.* The U. S. preparation, which is placed in the Materia Medica, consists of equal measures of officinal alcohol and water, and has the sp gr. 0·941; the British, for which a process is given, is made by mixing five pints of Rectified Spirit with three pints of Distilled Water, and has the sp. gr. 0·920. The latter is much the stronger of the two, containing only 51 per cent. of water, while the U. S. preparation contains 61 per cent. Considering the purpose to which it is chiefly applied, that of making tinctures, our officinal diluted alcohol is preferable to the British proof spirit; as it has enough alcohol both for solvent effect and preservative influence; and the less there is, when these objects are answered, the better.

Medical Properties, &c. Alcohol is a very powerful diffusible stimulant. It is the intoxicating ingredient in all spirituous liquors, including under this term wines, porter, ale, cider, and every other liquid which has undergone the vinous fermentation. In a diluted state, it excites the system, renders the pulse full, and gives additional energy to the muscles, and temporary exaltation to the mental faculties. It is found to lessen the amount of the excretions, from which fact some physiologists have inferred that it diminishes the disintegration of the tissues. But this is not likely; since the effect of stimulation is to increase function in the tissues, and consequently to cause their waste. On this subject Dr. Wood holds the more probable opinion, that alcoholic liquors, besides furnishing some nutriment, act by promoting digestion and sanguification, thus causing a more thorough appropriation of food to nutrition; and that the saving, thus effected, more than counterbalances the waste of the tissues, implied by increased vital action. (See his *Therapeutics*, 3d ed., i. 655.)

In some states of acute disease, characterized by excessive debility, alcohol is a valuable remedy. In chronic diseases, physicians should be cautious in prescribing liquids containing it, for fear of begetting intemperate habits. Externally, alcohol is sometimes applied to produce cold by evaporation; but, when this is repressed, it acts as a stimulant. A mixture of equal parts of rectified spirit and white of egg forms an excellent application to excoriations from pressure, in their early stage, occurring in protracted diseases. It is to be applied frequently by a fine brush or feather, and renewed as it dries, until an albuminous coating is formed over the excoriated surface.

As an article of daily use, alcoholic liquors produce the most deplorable consequences. Besides the moral degradation which they cause, their habitual use gives rise to dyspepsia, hypochondriasis, visceral obstructions, dropsy, paralysis, and not unfrequently mania.

Effects as a Poison. When taken in large quantities, alcohol, in the various forms of ardent spirit, produces a true apoplectic state, and occasionally speedy death. The face becomes livid or pale, the respiration stertorous, and the mouth frothy; and sense and feeling are more or less completely lost. Where the danger is imminent, an emetic may be administered, or the stomach-pump used. The affusion of cold water is often useful. An enema of two tablespoonfuls of common salt in a pint of warm water is said to dissipate rapidly the more serious symptoms. As a counter-poison, acetate of ammonia has been found to act with advantage. After death, abundant evidence is furnished of the absorption of the alcohol. By Dr. Percy it has been detected in the brain, by others in the ventricles, and by Dr. Wright in the urine. According to Dr. Ducheck, alcohol undergoes, in the system, continued combustion, producing intermediate products, among which is aldehyd, to the presence of which in the blood he attributes intoxication. Mr. R. D. Thomson has proposed the following test for detecting alcohol in medico-legal investigations. Distil one third of the suspected liquid, and to the distillate add a crystal or two of chromic acid, and stir. If the smaller

quantity of alcohol be present, green oxide of chromium, and aldehyd perceptible to the smell, will be developed. Instead of chromic acid, a few grains of powdered bichromate of potassa, acted on by a few drops of sulphuric acid, may be used. Dr. Ed. Strauch objects to this test as liable to some ambiguity, and proposes platinum-black as preferable. For a description of the mode in which he uses it, the reader is referred to the *Chemical Gazette* for Aug. 1, 1854.

It is, however, very rarely that any of the forms of alcohol here described are used internally in their ordinary state; the various forms of ardent spirit and fermented liquors being preferred for this purpose, and these are described elsewhere. The purer forms of alcohol, whether strong or diluted, are employed almost exclusively in pharmacy; as in the preparation of medicines, such as ether, into the composition of which they enter; for the preservation of organic substances; in the extraction of the active principles of vegetables, as in the tinctures; for dissolving bodies soluble in alcohol much more readily than in water, or insoluble in the latter fluid; and for various other pharmaceutic purposes. Nélaton, however, uses rectified spirit as a local application to wounds which are to be healed by the first intention, washing the surfaces with the liquid, before bringing them together, until the flowing of blood ceases.

Diluted alcohol is employed as an addition to the compound infusion of gentian, and to some of the distilled waters and preparations of vinegar, in order to preserve them from decomposition; as a menstruum for extracting the virtues of plants, preparatory to the formation of extracts and syrups; and in preparing many of the spirits, and a few of the medicated wines. But it is in forming the tinctures that diluted alcohol is chiefly used. Some of these are made with officinal alcohol (rectified spirit), but the majority with diluted alcohol (proof spirit) as the menstruum. As the latter contains more than half its weight of water, it is well fitted for acting on those vegetables, the virtues of which are partly soluble in water and partly in alcohol. The apothecary, however, should never substitute the commercial proof spirit for diluted alcohol, even though it may be of the same strength, on account of the impurities in the former; but, when it is recollected how variable the so-called proof spirits are in strength, the objection to their use in pharmacy becomes still stronger. Thus, according to Mr. Brande, gin contains 51·6 per cent. of alcohol of 0 825; and the percentage of the same alcohol is 53·39 in brandy, 53·68 in rum, 53·90 in Irish whisky, and 54·32 in Scotch whisky. The alcohol on which these results are based already contains 11 per cent. of water.

ALCOHOL AMYLICUM. *U.S., Br.*

Amylic Alcohol. Fusel Oil.

"A peculiar alcohol, obtained by distillation from fermented grain or potatoes by continuing the process after the ordinary spirit has ceased to come over. Its sp. gr. is 0·818." *U. S.* Amylic alcohol, $C_{10}H_{12}O_2$, with a small proportion of other spirituous substances. An oily liquid contained in the crude spirit produced by the fermentation of saccharine solutions with yeast, and separated in the rectification of such crude spirit. *Br.*

Syn. Hydrated Oxide of Amyl. Grain Oil. Potato Spirit Oil.

This was an officinal of the late Dublin Pharmacopœia, which directed it to be prepared in the following manner. "Take of the light liquid, which may be obtained at any large distillery by continuing the distillation for some time after the pure spirit has been drawn off, *any convenient quantity*. Introduce it into a small still or retort connected with a condenser, and apply heat so as to cause distillation. As soon as the oil begins to come over unmixed with water, the receiver should be changed, and, the distillation being resumed and carried nearly to dryness, the desired product will be obtained. The liquid drawn over during the first part of the distillation will consist of an aqueous fluid, surmounted by a stratum of the Fusel Oil. This latter, though impregnated with a minute quantity of water, should be separated and preserved, as being sufficiently pure for use."

This oil is always present in the products of alcoholic fermentation. It is an ingredient in the ardent spirit obtained from various grains, but is most abundant in that procured from fermented potatoes. In grain spirit it is present in the proportion of about one part in five hundred by measure. When grain or potato whisky is distilled for the purpose of obtaining alcohol, the pure spirit will continue to come over for a certain time, after which, if the distillation be continued, a milky liquid will be obtained, which, upon standing, will be covered with a stratum of this peculiar oil. Subjected to distillation, the milky liquid will at first boil at a comparatively low temperature, and yield water and a little of the oil; but after a time the boiling point will rise to 269°, when the oil will come over pure. By changing the receiver when the oil begins to distil free from water, the oil is collected separate from the watery part.

Properties. Amylic alcohol is an oily, colourless liquid, of a strong, offensive odour, and acrid, burning taste. As usually prepared it has a pale-yellow colour. Its sp. gr. is 0·813; that of its vapour 3·15. It boils at 269° (270° *Br.*), and congeals at 4° below zero, in the form of crystalline leaves. It is very sparingly soluble in water, but unites in all proportions with alcohol, ether, and essential oils. It dissolves iodine, sulphur, and phosphorus, and is a good solvent for fats, resins, and camphor. When dropped upon paper it does not leave a greasy stain. It does not take fire like alcohol by the contact of flame, but requires to be heated to a temperature of about 130° before it begins to burn. According to M. Pasteur, there are two amylic alcohols, chemically the same, but optically distinct. Amylic alcohol consists of ten eqs. of carbon 60, twelve of hydrogen 12, and two of oxygen 16=88. It is generally considered to be a hydrated oxide of the compound radical *amyl* ($C_{10}H_{11}$); and on this view its formula will be $C_{10}H_{11}O+HO$. Heated with anhydrous phosphoric acid, it loses the elements of two eqs. of water, and forms a carbohydrogen, $C_{10}H_{10}$, homologous with ethylen, called amylen or valeren, which has been proposed as an anæsthetic. (See *Amylen* in Part III.) When subjected to oxidizing agents,

it loses two eqs. of hydrogen and gains two of oxygen, and becomes $C_{10}H_9O_3 + HO$, or *amylic acid*, which is identical with *valerianic acid*, the acid found in valerian. Hence the test given in the Br. Pharmacopœia; "exposed to the air in contact with platinum-black, it is slowly oxidized, yielding valerianic acid." *Br.* This acid bears the same relation to amylic alcohol that acetic acid does to ethylic alcohol, and formic acid to methylic alcohol. Amyl has been isolated by Dr. E. Frankland. It is a colourless pellucid liquid, of the sp. gr. 0·7704. (*Chem. Gaz.*, March 15, 1850.) Its hydruret (hydride), $C_{10}H_{11}H$, has been discovered to be an energetic anæsthetic by Dr. Simpson, of Edinburgh.

Crude fusel oil may be obtained from the alcohol distillers. Mr. Kent, of New York, found in it, as impurities, water, alcohol, acetic and amylic acids, oxide of iron, and an amyl compound, analogous to œnanthic ether. According to Messrs. T. and H. Smith, the crude oil is a mixture of propylic, butylic, and amylic alcohols, and of other alcohols much higher in the series.

Fusel oil was made officinal by the Dublin College, in its Pharmacopœia of 1850, as an artificial source of valerianic acid, to be used in forming valerianate of soda, from which, by double decomposition, three other valerianates, namely, those of iron, zinc, and quinia, were directed by the College to be prepared. It was introduced into the U. S. Pharmacopœia for a similar purpose.

Amylic alcohol is an active irritant poison.

ALETRIS. *U. S. Secondary.*

Star Grass.

The root of Aletris farinosa. *U. S.*

Aletris. *Sex. Syst.* Hexandria Monogynia. — *Nat. Ord.* Liliaceæ.

Gen. Ch. Corolla tubular, six-cleft, wrinkled, persistent. *Stamens* inserted into the base of the segments. *Style* triangular, separable into three. *Capsule* opening at the top, three-celled, many-seeded. *Bigelow.*

Aletris farinosa. Willd. *Sp. Plant.* ii. 183; Bigelow, *Am. Med. Bot.* iii. 92. This is an indigenous perennial plant, the leaves of which spring immediately from the root, and spread on the ground in the form of a star. Hence have originated the popular names of *star grass*, *blazing star*, and *mealy starwort*, by which it is known in different parts of the country. The leaves are sessile, lanceolate, entire, pointed, very smooth, longitudinally veined, and of unequal size, the largest being about four inches in length. From the midst of them a flower-stem rises, one or two feet in height, nearly naked, with remote scales, which sometimes become leaves. It terminates in a slender scattered spike, the flowers of which stand on very short pedicles, and have minute bractes at the base. The calyx is wanting. The corolla is tubular, oblong, divided at the summit into six spreading segments, of a white colour, and when old, of a mealy or rugose appearance on the outside. The plant is found in almost all parts of the United States, growing in fields and about the borders of woods, and flowering in June and July.

Properties. The root, which is the officinal portion, is small, crooked, branched, blackish externally, brown within, and intensely bitter. The bitterness is extracted by alcohol, and the tincture becomes turbid upon the addition of water. The decoction is moderately bitter; but much less so than the tincture. It affords no precipitate with the salts of iron. (*Bigelow.*)

Medical Properties. In small doses the root appears to be simply tonic, and may be employed advantageously for similar purposes with other bitters of the same class. When freely given, it is apt to occasion nausea. In very large doses, it is said to be cathartic and emetic, and to produce some narcotic effect. It has been employed, with asserted benefit, in colic, dropsy, and chronic rheumatism. The powder may be administered as a tonic in the dose of ten grains. W

ALLIUM. *U. S.*

Garlic.

The bulb of Allium sativum. *U. S.*

Ail, *Fr.;* Knoblauch, *Germ.;* Aglio, *Ital.;* Ajo, *Span.*

Allium. *Sex. Syst.* Hexandria Monogynia. — *Nat. Ord.* Liliaceæ.

Gen. Ch. Corolla six-parted, spreading. *Spathe* many-flowered. *Umbel* crowded. *Capsule* superior. *Willd.*

This is a very extensive genus, including more than sixty species, most of which are European. Of the nine or ten indigenous in this country, none are officinal. Dr. Griffith states that the bulb of *A. Canadense* has been substituted for the cultivated garlic, and found equally efficient. (*Med. Bot.* p. 653.) Of the European species several have been used from a very early period, both as food and medicine. *A. sativum*, or garlic, is the only one now officinal; and to this we shall here confine our observations, simply stating that there are few genera, of which the several species resemble one another more closely in sensible and medical properties than the present. For an account of *A. Cepa*, or onion, and *A. Porrum*, or leek, see *Part III.* of this work.

Allium sativum. Willd. *Sp. Plant.* ii. 68; Woodv. *Med. Bot.* p. 749, t. 256. This is a perennial plant, and, like all its congeners, bulbous. The bulbs are numerous, and enclosed in a common membranous covering, from the base of which the fibres that constitute the proper root descend. The stem is simple, and rises about two feet. The leaves are long, flat, and grass-like, and sheathe the lower half of the stem. At the termination of the stem is a cluster of flowers and bulbs mingled together, and enclosed in a pointed spathe, which opens on one side and withers. The flowers are small and white, and make their appearance in July. This species of garlic grows wild in Sicily, Italy, and the south of France; and is cultivated in all civilized countries.

The part employed, as well for culinary purposes as in medicine, is the bulb. The bulbs are dug up with a portion of the stem attached, and, having been dried in the sun, are tied together in bunches, and thus brought to market. They are said to lose, by drying, nine parts of their weight out of fifteen, with little diminution of their sensible properties. This species of Allium is commonly called *English garlic*, to distinguish it from those which grow wild in our fields and meadows. Garlic bulbs are apt to germinate and thus to undergo serious injury. Mr. A. P. Sharp preserves them by placing them in a bottle, pouring on them a little alcohol, about two fluidounces to a quart, and securely closing the bottle by a stopper of glass or cork. All tendency to germinate is thus destroyed, and the bulbs will retain their peculiar smell and taste unchanged for years. (*Proceed. of the Amer. Pharm. Assoc.* for 1864.)

Properties. Garlic, as found in the shops, is somewhat spherical, flattened at the bottom, and drawn towards a point at the summit, where a portion of the stem several inches in length projects. It is covered with a white, dry, membranous envelope, consisting of several delicate laminæ, within which the small bulbs are arranged around the stem, having each a distinct coat. These small bulbs, commonly called *cloves* of garlic, are usually five or six in number, of an oblong shape, somewhat curved, and in their interior are whitish, moist, and fleshy.* They have a disagreeable pungent odour, so peculiar as to have received the name of *alliaceous*. Their taste is bitter and acrid. The peculiar smell and taste, though strongest in the bulb, are found to a greater or less

* In a note, in the preceding edition of the Dispensatory, it was stated that a variety of garlic had been introduced into this market, having larger and fewer cloves or small bulbs than the officinal, and supposed to be the product of a hybrid between the common garlic and the leek. It was also said to be much inferior to the genuine drug. In the *Proceedings of the American Pharmaceutical Association* for 1860, is a paper by Prof. Robert P. Thomas, which satisfactorily shows that this is really, as supposed, the product of a hybrid, probably between *A. sativum* and *A. Porrum*. (*Note to the twelfth edition.*)

extent in all parts of the plant. They depend on an *essential oil*, which is very volatile, and may be obtained by distillation, passing over with the first portions of water. As first obtained, the oil is of a dark brownish-yellow colour, heavier than water, and decomposed at its boiling temperature. It may be purified by repeated distillation in a salt-water bath, and is then lighter than water, of a pale-yellow colour, and not decomposed by boiling. According to Wertheim, it consists of a peculiar organic radical, called *allyl* (C_6H_5), combined with one equivalent of sulphur, and is therefore *sulphuret of allyl*. From one hundred weight of garlic Wertheim obtained from three to four ounces of the impure oil, and about two-thirds as much of the rectified. (*Chem. Gaz.*, iii. 177.) The impure oil has an exceedingly pungent odour, and strong acrid taste; and, when applied to the skin, produces much irritation, and sometimes even blisters. The pure oil combines with nitrate of silver, forming a precipitate, soluble in heated alcohol and afterwards separating in crystals. This compound consists of one eq. of the oil and two eqs. of the salt, and on the addition of ammonia gives up the oil unchanged. (*Journ. de Pharm. et de Chim.*, 4e sér., v. 237, A. D. 1867.) Besides this oil, fresh garlic, according to Cadet-Gassicourt, contains, in 1406 parts, 520 of mucilage, 37 of albumen, 48 of fibrous matter, and 801 of water. Bouillon-Lagrange mentions, among its constituents, sulphur, a saccharine matter, and a small quantity of fecula. The fresh bulbs yield upon pressure nearly a fourth part of juice, which is highly viscid, and so tenacious as to require dilution with water before it can be easily filtered. When dried, it serves as a lute for porcelain. It has the medical properties of the bulbs. Water, alcohol, and vinegar extract the virtues of garlic. Boiling, however, if continued for some time, renders it inert.

Medical Properties and Uses. The use of garlic as a medicine and condiment, ascends to the highest antiquity. When it is taken internally, the oil is speedily absorbed, and, pervading the system, becomes sensible in the breath and various secretions. Even externally applied, as to the soles of the feet, it imparts its odour to the breath, urine, and perspiration, and, according to some writers, may be tasted in the mouth. Its effects on the system are those of a general stimulant. It quickens the circulation, excites the nervous system, promotes expectoration in debility of the lungs, produces diaphoresis or diuresis according as the patient is kept warm or cool, and acts upon the stomach as a tonic and carminative It is said also to be emmenagogue. Applied to the skin, it is irritant and rubefacient, and moreover exercises, in some degree, its peculiar influence upon the system, in consequence of absorption. Moderately employed, it is beneficial in enfeebled digestion and flatulence; and by many it is habitually used as a condiment. It has been given with advantage in chronic catarrh, and other pectoral affections in which the symptoms of inflammation have been subdued, and a relaxed state of the vessel remains. We have used it habitually, and with great benefit, in such affections in children, as well as in the nervous and spasmodic coughs to which the very young are peculiarly liable. Some have recommended it in old atonic dropsies and calculous disorders; and it has been employed in the treatment of intermittents. It is thought also to be an excellent anthelmintic, especially in cases of ascarides, in which it is given both by the mouth and the rectum. The juice is said sometimes to check nervous vomiting in the dose of a few drops. If taken too largely, or in excited states of the system, garlic is apt to occasion gastric irritation, flatulence, hemorrhoids, headache, and fever. As a medicine, it is at present more used externally than inwardly. Bruised, and applied to the feet, it acts very beneficially, as a revulsive, in disorders of the head; and is especially useful in the febrile complaints of children, by quieting restlessness and producing sleep. Its juice mixed with oil, or the garlic itself bruised and steeped in spirit, is frequently used as a liniment in infantile convulsions, and other spasmodic or nervous affections in children. The same application has been made in cutaneous eruptions. A clove of garlic, or a few drops of the juice, introduced into the ear, are said to prove efficacious in atonic deafness; and the bulb, bruised, and ap-

plied in the shape of a poultice above the pubes, has sometimes restored action to the bladder, in retention of urine from debility of that organ. In the same shape, it has been used to resolve indolent tumours.

Garlic may be taken in the form of a pill; or the clove may be swallowed either whole, or cut into pieces of a convenient size. Its juice is also frequently administered mixed with sugar. The infusion in milk was at one time highly recommended, and the syrup is officinal. The dose in substance is from half a drachm to a drachm, or even two drachms, of the fresh bulb. That of the juice is half a fluidrachm.

The inspissated juice of the leaves of Aloe Socotrina (*Lamarck*). *U. S.* The inspissated juice of the leaf of one or more undetermined species of Aloe. Produced chiefly in Socotra. *Br.*

Suc d'aloès, *Fr.;* Aloe, *Germ., Ital.;* Aloë, *Span.;* Musebber, *Arab.*

Most of the species belonging to the genus Aloe are said to yield a bitter juice, which has all the properties of the officinal aloes. It is impossible, from the various and sometimes conflicting accounts of writers, to determine exactly from which of the species the drug is in all instances actually derived. *Aloe spicata,* however, is generally acknowledged to be an abundant source of it; and *A. vulgaris* and *A. Socotrina* are usually ranked among the medicinal species. In Lindley's Flora Medica, *A. purpurascens, A. arborescens, A. Commelyni,* and *A. multiformis,* all natives of the Cape of Good Hope, are enumerated as yielding aloes; and others are, without doubt, occasionally resorted to. We shall confine ourselves to a description of the three following species, which probably yield most of the aloes of commerce.

ALOE. *Sex. Syst.* Hexandria Monogynia.—*Nat. Ord.* Liliaceæ.

Gen. Ch. Corolla erect, mouth spreading, bottom nectariferous. *Filaments* inserted into the receptacle. *Willd.*

Aloe spicata. Willd. *Sp. Plant.* ii. 185. This species of Aloe was first described by Thunberg. The stem is round, three or four feet high, about four inches in diameter, and leafy at the summit. The leaves are spreading, subverticillate, about two feet long, broad at the base, gradually narrowing to the point, channeled upon their upper surface, and with remote teeth upon their edges. The flowers are bell-shaped, and spread horizontally in very close spikes. Beneath each flower is a broad, ovate, acute bracte, white, with three green streaks, and nearly as long as the corolla. Of the six petals, the three inner are ovate, obtuse, white, with three green lines, and broader than the outer, which otherwise resemble them. The stamens are much longer than the corolla. The *spiked aloe* is a native of Southern Africa, growing near the Cape of Good Hope, and, like all the other species, preferring a sandy soil. In some districts of the colony it is found in great abundance, particularly at Zwellendam, near Mossel Bay, where it almost covers the surface of the country. Much of the Cape aloes is said to be derived from this species.

A. Socotrina. Lamarck, *Encycl.* i. 85; De Cand. *Plantes Grasses, fig.* 85; Curtis's *Bot. Mag. pl* 472; Carson's *Illust. of Med. Bot.* ii. 48, *pl.* 92.—*A. vera.* Miller, *Dict., ed* 8, *no.* 55. The stem of this species is erect, eighteen inches or more in height, woody, and leafless below, where it is very rough from the remains of former leaves. At top it is embraced by green, sword-shaped,

ascending leaves, somewhat concave on their upper surface, convex beneath, curved inward at the point, with numerous small white serratures at their edges. The flowers, which are in a cylindrical, simple raceme, are scarlet near the base, pale in the centre, and greenish at the summit, and have unequal stamens, of which three are longer than the corolla. The plant received its name from the Island of Socotra, of which it is said to be a native; and is supposed to be the source of the Socotrine aloes.

A. vulgaris. Lamarck, *Encycl.* i. 86; De Cand. *Plantes Grasses, fig* 27; Carson's *Illust. of Med. Bot.* ii. 46, *pl.* 90. This species has a very short woody stem, and lanceolate embracing leaves, which are first spreading, then ascending, of a glaucous-green colour, somewhat mottled with darker spots, flat on the upper surface, convex beneath, and armed with hard reddish spines, distant from each other, and perpendicular to the margin. The flower-stem is axillary, of a glaucous-reddish colour, and branched, with a cylindrical-ovate spike of yellow flowers, which are at first erect, then spreading, and finally pendulous, and do not exceed the stamens in length. A. vulgaris is a native of south-eastern Europe and the north of Africa, and is cultivated in Italy, Sicily, Malta, and especially in the West Indies, where it contributes largely to furnish the Barbadoes aloes.

The proper aloetic juice was formerly thought to exist in longitudinal vessels beneath the epidermis of the leaves, and readily flows out when these are cut transversely; but, according to M. Edmond Robiquet, who has made elaborate researches in relation to this drug, these vessels are air-ducts, and the juice flows in the inter-cellular passages between them. The liquid obtained by expression from the parenchyma is mucilaginous, and possessed of little medicinal virtue. The quality of the drug depends much upon the mode of preparing it. The finest kind is that obtained by exudation, and subsequent inspissation in the sun. Most of the better sorts, however, are prepared by artificially heating the juice which has spontaneously exuded from the cut leaves. The chief disadvantage of this process is the conversion of a portion of the soluble active principle into an insoluble and comparatively inert substance, through the influence of an elevated temperature. The plan of bruising and expressing the leaves, and boiling down the resulting liquor, yields a much inferior product; as a large portion of it must be derived from the mucilaginous juice of the parenchyma. The worst plan of all is to boil the leaves themselves in water, and evaporate the decoction. The quality of the drug is also affected by the careless or fraudulent mixture of foreign matters with the juice, and the unskilful management of the inspissation.

Commercial History and Varieties. Four chief varieties of aloes are known in commerce; the Cape aloes, the Socotrine, the hepatic, and the Barbadoes, of which the first two are most used in this country.

1. Cape Aloes is imported from the Cape of Good Hope, either directly, or through the medium of English commerce. It is collected by the Hottentots and Dutch boors indiscriminately from *A. spicata* and other species, which grow wild in great abundance. Dr. L. Pappe, of Cape Town, states that the best aloes is derived from *Aloe ferox* (*Lam.*) growing at Zwellendam, and a weaker product from *A. Africana* and *A. plicatilis* of Miller. (*Flor. Capens.* 28.) The process is very simple. According to Hallbeck, a Moravian missionary who resided at the Cape, a hole is made in the ground, in which a sheep skin is spread with the smooth side upward. The leaves are then cut off near the stem, and arranged around the hole, so that the juice which runs out may be received into the skin. The juice flows most freely in hot weather. (*United Breth. Mission. Intelligencer, N. Y.*, vi. 436.) When a sufficient quantity of the liquor has been collected, it is inspissated by artificial heat in iron cauldrons, care being taken, by constant stirring, to prevent its burning. When sufficiently concentrated, it is poured into boxes or skins, where it concretes upon cooling. The finest kind is collected at the Missionary Institution at Bethelsdorp, and hence called *Bethelsdorp aloes.* Its superiority is owing exclusively to the greater care ob-

served in conducting the evaporation, and in avoiding the intermixture of earth, stones, and other impurities.

Cape aloes has sometimes been confounded with the Socotrine, from which, however, it differs very considerably in appearance. By the German writers it is called *shining aloes*. When freshly broken, it has a very dark-olive or greenish colour approaching to black, presents a smooth bright almost glassy surface, and, if held up to the light, appears translucent at its edges. The small fragments also are semi-transparent, and have a tinge of yellow or red, mixed with the deep olive of the opaque mass. The same tinge is sometimes observable in the larger pieces The powder is of a fine greenish-yellow colour, and, being generally more or less sprinkled over the surface of the pieces as they are kept in the shops, gives them a somewhat yellowish appearance. Its odour is strong and disagreeable, but not nauseous, and in no degree aromatic. In mass, the drug has little or no smell. Cape aloes, when quite hard is very brittle, and readily powdered; but, in very hot weather, it is apt to become somewhat soft and tenacious, and the interior of the pieces is occasionally more or less so even in winter. It is usually imported in casks or boxes. Dr. Pereira says that a variety is sometimes imported into England from the Cape, of a reddish-brown colour like hepatic aloes.

2. Socotrine Aloes. The genuine Socotrine aloes is produced in the Island of Socotra, which lies in the Straits of Babelmandel, about forty leagues to the east of Cape Guardafui; but we are told by Ainslie that the greater part of what is sold under that name is prepared in the kingdom of Melinda, upon the eastern coast of Africa; and Wellsted states that the aloes of the neighbouring parts of Arabia is the same as that of Socotra. The commerce in this variety of aloes is carried on chiefly by the maritime Arabs, who convey it either to India, or up the Red Sea by the same channel through which it reached Europe before the discovery of the southern passage into the Indian Ocean. Mr. Vaughan states that nearly the whole product of the island is carried to Maculla, on the southern coast of Arabia, and thence transhipped to Bombay. (*Pharm. Journ. and Trans.*, xii. 268.) The species of Aloe which yields it is not certainly known, but is probably A. Socotrina. According to Wellsted, the plant grows on the sides and summits of mountains, from five hundred to three thousand feet above the level of the plains. It is found in all parts of the island, but most abundantly on the western portion, where the surface is thickly covered with it for miles. It appears to thrive best in parched and barren places. Much less of the drug is collected than formerly, and in the year 1833 only two tons were exported. The whole produce was formerly monopolized by the Arabian Sultan of Kisseen; but at present the business of collecting the drug is entirely free to the inhabitants. The leaves are plucked at any period of the year, and are placed in skins into which the juice is allowed to exude. In what way the inspissation is effected we are not informed by Wellsted; but, according to Hermann, it is by exposure to the heat of the sun. The aloes is exported in skins. Its quality differs much according to the care taken in its preparation. (*Wellsted's Voyage, &c.*) A portion ascends the Red Sea, and through Egypt reaches the Mediterranean ports, whence it is sent to London. Another portion is carried to Bombay, and thence transmitted to various parts of the world. That which reaches this country either comes by special order from London, or is brought by our India traders. We have known of two arrivals directly into the United States, said to be from Socotra, and have in our possession parcels of aloes brought by both. They are identical in character, and correspond with the following description.

Socotrine aloes is in pieces of a yellowish or reddish-brown colour, wholly different from that of the former variety. Sometimes the colour is very light, especially in the fresh and not fully hardened parcels; sometimes it is a deep brownish-red like that of garnets. It is rendered much darker by exposure to the air; and the interior of the masses is consequently much lighter-coloured than the exterior. Its surface is somewhat glossy, and its fracture smooth and

conchoidal, with sharp and semi-transparent edges. The colour of its powder is a bright golden yellow. It has a peculiar, not unpleasant odour, and a taste, which, though bitter and disagreeable, is accompanied with an aromatic flavour. Though hard and pulverulent in cold weather, it is somewhat tenacious in summer, and softens by the heat of the hand. "It dissolves entirely in proof spirit, and during solution exhibits under the microscope numerous minute crystals." *Br.*

Under the name of Socotrine aloes, are occasionally to be met with in the market small parcels beautifully semi-transparent, shining, and of a yellowish, reddish, or brownish-red colour. These, however, are very rare, and do not deserve to be considered as a distinct variety. They are probably portions of the juice carefully inspissated in the sun, and may accompany the packages brought from any of the commercial sources of aloes.

When in mass, as imported from the East, Socotrine aloes is soft and plastic, and of a very light yellowish-brown colour in the interior. It becomes hard and brittle when broken into pieces; and the London dealers hasten the result by exposing it to a very gentle heat, so as to evaporate the moisture.

Pereira tells us that impure and dirty pieces of the drug are melted and strained, and that the skins from which the best portions have been removed are washed with water, which is then evaporated.

Occasionally the juice has been imported into London in casks, not thoroughly inspissated. In this state it is of the consistence of molasses, of an orange or yellowish colour, and of a strong fragrant odour. It separates, upon standing, into a transparent liquid, and an opaque, lighter-coloured, granular portion which subsides. Pereira found the latter portion to consist of innumerable minute prismatic crystals, and believed it to be identical with or closely analogous to the aloin of the Messrs. Smith. When the juice is heated, the deposit dissolves, and the whole being evaporated yields a solid, transparent product, having the properties of fine Socotrine aloes. (*Pharm. Journ.*, xi. 439.)

Much of the aloes sold as Socotrine has never seen the Island of Socotra, nor even the Indian seas. It has been customary to affix this title, as a mark of superior value, to those parcels of the drug, from whatever source they may have been derived, which have been prepared with unusual care, and are supposed to be of the best quality. Thus, both in Spain and the West Indies, the juice which is obtained without expression, and inspissated in the sun without artificial heat, has been called Socotrine aloes; and is probably little inferior to the genuine drug.

Socotrine aloes has been very long known under this name, and in former times held the same superiority, in the estimation of the profession, which it still to a certain degree retains.

3. Hepatic Aloes. Much confusion and uncertainty have prevailed in relation to this kind of aloes. The name was originally applied to a product from the East Indies, of a reddish-brown or liver-colour, which gave origin to the designation. From a supposed resemblance between this and the aloes from the West Indies, the name was very commonly applied also to the latter variety, and was even extended to portions of the drug collected in Spain and other parts of the South of Europe. But the West India aloes is decidedly different from any now brought from the East, and deserves the rank of a distinct variety, with the name of Barbadoes aloes. In this country, we seldom meet with aloes bearing the name of the hepatic, although much that is sold as Socotrine probably deserves it. In the drug commerce of London, it is still recognised as a distinct variety. It is imported into England chiefly from Bombay; but, according to Ainslie, is not produced in Hindostan, being taken thither from Yemen in Arabia. It is probably obtained from the same plants which yield the Socotrine, but prepared with less care, or by a different process.* In relation

* Dr. Pereira inferred, we think somewhat prematurely, from his observations on the juice of aloes before referred to, that the Socotrine is prepared by evaporation by artifi-

to the Socotrine and hepatic aloes, we should probably not be far wrong in considering the former as embracing the finest, and the latter the inferior parcels of the same variety; and it is in fact stated that they sometimes come together, a large mass of the hepatic being crossed by a vein of the Socotrine.

Hepatic aloes is reddish-brown, but darker and less glossy than the Socotrine. Its odour is somewhat like that of the Socotrine, but less agreeable; its taste nauseous, and intensely bitter. The fracture is not so smooth, nor the edges so sharp and transparent as in either of the first-mentioned varieties. It softens in the hand, and becomes adhesive. The powder is of a dull-yellow colour.

4. Barbadoes Aloes. This is the name by which the aloes produced in the West Indies is generally designated. The aloes plants are largely cultivated in the poorer soils of Jamaica and Barbadoes, especially of the latter island. The species from which most of the drug is procured is *A. vulgaris;* but *A. Socotrina*, *A. purpurascens*, and *A. arborescens* are also said to be cultivated. The process employed appears to be somewhat different in different places, or at least as described by different authors. A fine kind was formerly prepared by the spontaneous inspissation of the juice, placed in bladders or shallow vessels, and exposed to the sun. The common Barbadoes aloes, however, is now made, either by boiling the juice to a proper consistence, or by first forming a decoction of the leaves, chopped and suspended in water in nets or baskets, and then evaporating the decoction. In either case, when the liquor has attained such a consistence that it will harden on cooling, it is poured into calabashes and allowed to concrete. A gentleman from Barbadoes, who had seen the aloes prepared, recently informed Mr. Squire that the leaves are cut transversely, and so placed that the juice flows from the incised surfaces into a trough, which inclines to the boiler. (*Med. T. and Gaz.*, Jan. 1868, p. 75.) It is imported into England in gourds weighing from 60 to 70 pounds, or even more. In consequence of the great demand for it in veterinary practice, it commands a high price in Great Britain.

The colour of Barbadoes aloes is not uniform. Sometimes it is dark-brown or almost black, sometimes of a reddish-brown or liver colour, and again of some intermediate shade. It has usually a dull fracture, and is almost perfectly opaque, even at the edges, and in thin layers. It is also distinguishable by its odour, which is disagreeable and even nauseous. The powder is of a dull olive-yellow. According to Mr. Giles, it yields 80 per cent. of aqueous extract, and is even more active than the Socotrine. (*Pharm. Journ.*, Dec. 1860, p. 301.) "It dissolves almost entirely in proof spirit, and during solution exhibits under the microscope numerous crystals." *Br.* According to M. Marais, Barbadoes aloes, from whatever part of the W. Indies derived, and however differing in colour, when dissolved in distilled water in the proportion of one part to 100,000 parts, has, in a high degree, the property of giving rise to a fine rose-colour on the addition of chloride of gold or tincture of iodine; while all other varieties, whether coming from Africa or India, with the exception of the hepatic, produce with these reagents either a feeble colour, slow in occurring, or no change of colour whatever. (*Journ. de Pharm. et de Chim.*, 4e sér., v. 326.)

Besides these varieties of aloes, others are mentioned by authors. A very inferior kind, supposed to consist of the dregs of the juice which furnished the better sorts, almost black, quite opaque, hard, of a rough fracture and very fetid odour, and full of various impurities, was formerly sold under the name of *fetid*, *caballine*, or *horse aloes*. It was used exclusively for horses; but, in consequence of the cheapness of better kinds, has been banished from veterinary practice, and is not now found in the market. Aloes has been imported from Muscat, and a considerable quantity came over in a vessel sent by the Sultan to the United States. Some of a similar origin has been called *Mocha aloes* in Lon-

cial heat, to which it owes its transparency; while the hepatic is opaque, because dried in the sun. If this were the case, Barbadoes aloes, which is wholly opaque, more so even than the hepatic, should have been dried in the sun, instead of being inspissated by heat, as it really is. (*Note to the tenth edition.*)

don; but it is nothing more than an inferior sort of hepatic. Several inferior kinds, produced in different parts of Hindostan, have been described by Pereira under the name of *India aloes;* but they are not brought, unless accidentally, into the markets of Europe or this country.

General Properties. The odour of aloes is different in the different varieties. The taste is in all of them intensely bitter and very tenacious. The colour and other sensible properties have been sufficiently described. Several distinguished chemists have investigated the nature and composition of aloes. Braconnot found it to consist of a bitter principle, soluble in water, and in alcohol of 38° B., which he considered peculiar, and named *resino-amer* (*resinous bitter*); and of another substance, in smaller proportion, inodorous and nearly tasteless, very soluble in alcohol, and scarcely soluble in boiling water, which he designated by the name of *flea-coloured principle.* These results were essentially confirmed by Trommsdorff, Bouillon-Lagrange, and Vogel, who considered the former substance as extractive matter, and the latter as a kind of resin. Besides these principles, Trommsdorff discovered, in a variety of hepatic aloes, a proportion of insoluble matter which he considered as albumen; and Bouillon-Lagrange and Vogel found that the Socotrine also yielded, by distillation, a small quantity of volatile oil, which they could not obtain from the hepatic. The proportions of the ingredients were found to vary greatly in the different varieties of the drug; and the probability is, that scarcely any two specimens would afford precisely the same results. Braconnot found about 73 per cent. of the *bitter*, and 26 of the *flea-coloured principle.* Trommsdorf obtained from Socotrine aloes about 75 parts of extractive and 25 of resin; and from the hepatic, 81·25 of extractive, 6·25 of resin, and 12·50 of albumen, in 100 parts. The former variety, according to Bouillon-Lagrange and Vogel, contains 68 per cent. of extractive and 32 of resin; the latter 52 of extractive, 42 of resin, and 6 of the albuminous matter of Trommsdorff. We are not aware that any analysis has been published of the Cape aloes as a distinct variety.

Berzelius considers the resin of Trommsdorff and others to belong to that form of matter which he calls *apothême* (see *Extracts*), and which is nothing more than extractive, altered by the action of the air. It may be obtained separate by treating aloes with water, and digesting the undissolved portion with oxide of lead, which unites with the apothême forming an insoluble compound, and leaves a portion of the unaltered extractive, which had adhered to it, dissolved in the water. The oxide of lead may be separated by nitric acid very much diluted; and the apothême remains in the form of a brown powder, insoluble in cold water, very slightly soluble in boiling water, to which it imparts a yellowish-brown colour, soluble in alcohol, ether, and alkaline solutions, and burning like tinder without flame, and without being melted. The *bitter extractive*, which constitutes the remainder of the aloes, may be obtained by treating the watery infusion with oxide of lead, to separate a portion of the apothême which adheres to it, and evaporating the liquor. It is a yellowish, translucent, gum-like substance, fusible by a gentle heat, of a bitter taste, soluble in ordinary alcohol, but insoluble in anhydrous alcohol, and in ether.

A subsequent analysis of aloes by M. Edmond Robiquet yielded the following results. A portion of hyacinthine, transparent aloes, considered as genuine Socotrine, was found to consist, in 100 parts, of 85 of *aloetin*, 2 of ulmate of potassa, 2 of sulphate of lime, 0·25 of gallic acid, 8 of albumen, and traces of carbonate of potassa, carbonate of lime, and phosphate of lime. To get pure aloetin, M. Robiquet exhausted aloes in powder with cold water; concentrated the infusion; added an excess of acetate of lead, which precipitated the gallate, ulmate, and aibuminate of that metal; poured into the clear liquor solution of ammonia; separated the yellowish-orange coloured precipitate, consisting of oxide of lead combined with aloetin, washed it with boiling water, and then decomposed it by a current of sulphuretted hydrogen with the exclusion of atmospheric air. Sulphuret of lead was deposited, and a colourless liquid floated above it, which being decanted, and evaporated in vacuo, yielded aloetin in slightly yellowish

scales. Thus procured, aloetin is uncrystallizable, very soluble in water and alcohol, but slightly soluble in ether, and quite insoluble in the fixed and volatile oils. It is entirely dissipated at a red heat. If exposed to the air during desiccation, it becomes intensely red, in consequence of the absorption of a minute proportion of oxygen, which, however, scarcely affects its properties in other respects. It possesses in a high degree the bitter taste and purgative property of aloes, and might be used as a substitute; 8 parts of it representing 10 of Socotrine and 50 of Cape aloes. (*Journ. de Pharm.*, 3e sér., x. 173.)*

Aloin. The bitter substances noticed above, viz., the *resino-amer* of Braconnot, the *bitter extractive* of Berzelius and others, and the *aloetin* of Robiquet, probably contain the active principle of aloes, but combined with impurities which render it insusceptible of crystallization. Messrs. T. and H. Smith, of Edinburgh, have succeeded in obtaining it quite pure and in crystals, and name it *aloin.* This has been examined by Mr. Stenhouse, and found, when quite free from water, to have a definite composition, represented by the formula $C_{34}H_{18}O_{14}$. There can be no doubt that it is the active principle of aloes; as it has been found to operate invariably as a cathartic in the dose of one or two grains, and occasionally in that of half a grain.

It is obtained most readily from Barbadoes aloes. The process consists of mixing this, previously powdered, with sand, exhausting it with cold water, evaporating the infusion in *vacuo* to the consistence of syrup, and allowing the residue to rest in a cool place. In two or three days the concentrated liquid becomes filled with a brownish-yellow granular mass of minute crystals, which is impure aloin. This is separated, by pressure between folds of bibulous paper, from a greenish-brown matter that contaminates it, and then repeatedly crystallized from hot water, the temperature of which should not exceed 150°, as aloin is rapidly oxidized at the boiling point. By dissolving it in hot alcohol, and allowing the solution to cool, it is obtained in the shape of minute needle-shaped crystals, arranged in a star-like form. These are pale-yellow, at first sweetish to the taste, but soon intensely bitter; combustible without residue;

* *Aloetic acid.* Aloes treated with nitric acid yields three distinct acids; the aloetic, chrysammic, and picric, separable by the different solubilities of their potassa salts. If these salts be dissolved in boiling water, the chrysammate is first deposited, then, especially after a little evaporation, the picrate, while the aloetate remains. To separate the aloetic acid, the residuary solution is treated with acetate of baryta, and evaporated on a water-bath. The aloetate is deposited in warty crystals, which are washed with cold water, then dissolved by hot water, and decomposed by dilute nitric acid. Aloetic acid separates, in the state of a yellow, amorphous powder, which melts at 248° F., losing one eq. of water. It has a bitter and acrid taste, detonates when heated on a plate of platinum, is freely soluble in alcohol, slightly in cold water, but is dissolved by hot water, to which it imparts a purple colour, which is changed to yellow by acid and to red by alkalies. The aloetate of potassa and of soda are very soluble in water. Aloetic acid was called by Scheele and Braconnot, "*the artificial bitter of aloes.*" (Finckh, *Ann. Chem. Pharm.*, cxxiv. p. 236; *J. de Pharm.*, 4e sér., ii. 77.)—*Note to the thirteenth edition.*

For certain views of M. Edmond Robiquet, contradictory in some respects of the statement of the Messrs. Smith, but which, having been shown to be incorrect, it seems hardly necessary to retain, the reader is referred to former editions of this work.

Mr. T. B. Groves has obtained aloin largely from Socotrine aloes. In the process of the Messrs. Smith, cold water was used in the extraction of the principle. But aloin is feebly soluble in cold water, while readily so in the same liquid heated. Mr. Groves availed himself of this fact. He exhausted the aloes by means of boiling water, acidulated the decoction slightly with muriatic acid, separated the precipitated matter by filtration, evaporated the liquor to the consistence of syrup, and set it aside to crystallize. In a fortnight the liquid had become a mass of crystals, which were separated by draining and compression, and purified by repeated solution in boiling water, and crystallization. The pure aloin obtained amounted to 10 per cent. of the aloes used. (*Pharm. Journ.*, xvi. 129.)—*Note to the eleventh edition.*

A more recent view of the constitution of aloes, resulting from the experiments of M. Kosmann, an apothecary at Thann, in France, is that it belongs to the family of glucosides; consisting of two electronegative resins, having acid properties in different degrees, and a carbohydrogen, which is converted into glucose or grape sugar by the action either of acids, or strong alkalies. (*Journ. de Pharm.*, Sept. 1861, p. 177.)—*Note to the twelfth edition.*

slightly soluble in cold water or alcohol, but readily dissolved by these liquids when moderately heated; soluble also readily in alkaline solutions, which are rendered of an orange-yellow colour, and become rapidly darker, especially when heated, in consequence of the oxidation of the aloin, and its conversion into resin. By the action of strong nitric acid it is converted into chrysammic acid. It is neither acid nor alkaline; but, with strong solution of subacetate of lead, is precipitated in combination with the oxide of that metal. (See *Ed. Monthly Journ. of Med. Sci.*, xii. 127, Feb. 1851, and *Pharm. Journ. and Trans.*, xi. 458.) There can be no doubt that aloin exists also in Socotrine and Cape aloes; and the Messrs. Smith, though they at first failed in obtaining it from these varieties, have subsequently succeeded with the Socotrine.

Aloes yields its active matter to cold water, and when good is almost wholly dissolved by boiling water; but the inert portion, or apothème of Berzelius, is deposited as the solution cools. It is also soluble in alcohol, rectified or diluted. Long boiling impairs its purgative properties by oxidizing the aloin, and rendering it insoluble. The alkalies, their carbonates, and soap alter in some measure its chemical nature, and render it of easier solution. It is inflammable, swelling up and decrepitating when it burns, and giving out a thick smoke which has the odour of the drug.

Those substances only are incompatible with aloes which alter or precipitate the soluble matter; as the insoluble portion is without action upon the system. Among these is the infusion of galls, which we have found, probably through its tannic acid, to afford a copious precipitate with an aqueous solution of aloes. It is said that such a solution will keep a long time, even for several months, without exhibiting mouldiness or putrescency, though it becomes ropy.

Medical Properties and Uses. Aloes was known to the ancients. It is mentioned in the works of Dioscorides and Celsus, the former of whom speaks of two kinds. The varieties are similar in their mode of action. They are all cathartic, operating very slowly but certainly, and having a peculiar affinity for the large intestines. Their action, moreover, appears to be directed rather to the muscular coat than to the exhalant vessels; and the discharges which they produce are, therefore, seldom very thin or watery. In a full dose they quicken the circulation, and produce general warmth. When frequently repeated, they are apt to irritate the rectum, giving rise, in some instances, to hemorrhoids, and aggravating them when already existing. Aloes has also a decided tendency to the uterine system. Its emmenagogue effect, which is often very considerable, is generally attributed to a sympathetic extension of irritation from the rectum to the uterus; but we can see no reason why the medicine should not act specifically upon this organ; and its influence in promoting menstruation is by no means confined to cases in which its action upon the neighbouring intestine is most conspicuous. A peculiarity in the action of this cathartic is, that an increase of the quantity administered, beyond the medium dose, is not attended by a corresponding increase of effect. Its tendency to irritate the rectum may be obviated, in some measure, by combining with it soap or an alkaline carbonate; but it does not follow, as supposed by some, that this modification of its operation is the result of increased solubility; for aloes given in a liquid state produces the same effect as when taken in pill or powder, except that it acts somewhat more speedily. Besides, when externally applied to a blistered surface, it operates exactly in the same manner as when internally administered, thus proving that its peculiarities are not dependent upon the particular form in which it may be given, but on specific tendencies to particular parts. (Gerhard, *N. Am. Med. and Surg. Journ.*, x. 155.) With its other powers, aloes combines the property of slightly stimulating the stomach. It is, therefore, in minute doses, an excellent remedy in habitual costiveness attended with torpor of the digestive organs. It has been supposed to stimulate the hepatic secretion, and certainly acts sometimes very happily in jaundice, producing bilious stools even after calomel has failed. From its special direction to the rectum, it has been found peculiarly useful in the

treatment of ascarides. In amenorrhœa it is perhaps more frequently employed than any other remedy, entering into almost all the numerous empirical preparations habitually resorted to by females in that complaint, and enjoying a no less favourable reputation in regular practice. It is frequently combined with more irritating cathartics, in order to regulate their liability to excessive action. In amenorrhœa, it is said to be peculiarly efficacious, when given, in the form of enema, about the period when the menses should appear. Aloes is contraindicated by hemorrhoids, and is unsuitable, unless modified by combination, to the treatment of inflammatory diseases.

The medium dose is 10 grains; but as a laxative it will often operate in the quantity of 2 or 3 grains; and, when a decided impression is required, the dose may be augmented to 20 grains. In consequence of its excessively bitter and somewhat nauseous taste, it is most conveniently administered in pills.*

Althæa. *Sex. Syst.* Monadelphia Polyandria.—*Nat. Ord.* Malvaceæ.

Gen. Ch. Calyx double, the exterior six or nine-cleft. *Capsules* numerous, one-seeded. *Willd.*

Althæa officinalis. Willd. *Sp. Plant.* iii. 770; Woodv. *Med. Bot.* p. 552, t. 198. Marshmallow is an herbaceous perennial, with a perpendicular branching root, and erect woolly stems, from two to four feet or more in height, branched and leafy towards the summit. The leaves are alternate, petiolate, nearly cordate on the lower part of the stem, oblong-ovate and obscurely three-lobed above, somewhat angular, irregularly serrate, pointed, and covered on both sides with a soft down. The flowers are terminal and axillary, with short peduncles, each bearing one, two, or three flowers. The corolla has five spreading, obcordate petals, of a pale-purplish colour. The fruit consists of numerous capsules united in a compact circular form, each containing a single seed. The plant grows throughout Europe, inhabiting salt marshes, the banks of rivers, and other moist places. It is found also in this country on the borders of salt marshes. In some parts of the Continent of Europe, it is largely cultivated for medical use. The whole plant abounds in mucilage. The flowers, leaves, and root are mucilaginous, and were formerly officinal; but the last only is employed to any considerable extent in this country.

The roots should be collected in autumn from plants at least two years old. They are cylindrical, branched, as thick as the finger or thicker, from a foot to

* Dr. Paris enumerates the following empirical preparations, containing aloes as a leading ingredient:—Anderson's pills, consisting of aloes, jalap, and oil of aniseed; Hooper's pills, of aloes, myrrh, sulphate of iron, canella, and ivory-black; Dixon's antibilious pills, of aloes, scammony, rhubarb, and tartarized antimony; Speediman's pills, of aloes, myrrh, rhubarb, extract of chamomile, and essential oil of chamomile; Dinner pills, of aloes, mastich, red roses, and syrup of wormwood; Fothergill's pills, of aloes, scammony, colocynth, and oxide of antimony; Peter's pills, of aloes, jalap, scammony, gamboge, and calomel; and Radcliff's Elixir, of aloes, cinnamon, zedoary, rhubarb, cochineal, syrup of buckthorn, and spirit and water as the solvent; to which may be added Lee's Windham pills, consisting of gamboge, aloes, soap, and nitrate of potassa; and Lee's New London pills, of aloes, scammony, gamboge, calomel, jalap, soap, and syrup of buckthorn.

a foot and a half long, externally of a yellowish colour, which becomes grayish by drying, within white and fleshy They are usually prepared for the market by removing the epidermis. Our shops are supplied from Europe.

Properties. Marshmallow root comes to us in pieces three or four inches or more in length, usually not so thick as the finger, generally round, but sometimes split, white externally and downy from the mode in which the epidermis is removed, light and easily broken with a short somewhat fibrous fracture, of a peculiar faint smell, and a mild, mucilaginous, sweetish taste. Those pieces are to be preferred which are plump and but slightly fibrous. The root contains a large proportion of mucilage, besides starch and saccharine matter, which it yields readily to boiling water. The mucilage, without the starch, is extracted by cold water, which thus becomes ropy. A principle was discovered in the root by M. Bacon, which he supposed to be peculiar to the marshmallow, but which has been ascertained to be identical with the *asparagin* of Robiquet MM. Boutron-Charlard and Pelouze found it to belong to that class of organic principles, which are convertible by strong acids, and other agencies, into ammonia and peculiar acids, and which are designated by the termination *amide*. Thus asparagin, which in this view should be called *asparamide*, is converted into ammonia and *asparmic*, or, as it was formerly named, *aspartic acid;* and one eq. of the resulting asparmate of ammonia corresponds with one eq. of asparamide and one of water. (*Journ. de Pharm.*, xix. 208.) Asparagin, being now considered as a derivative from malate of ammonia, has received the name of *malamide*, and asparmic acid is called, by a corresponding change, *malamidic acid.* (*Gregory's Chemistry.*) It is found in various other plants besides the marshmallow, as in the shoots of asparagus, in vetches grown in the dark, in all the varieties of the potato, and in the roots of the comfrey and liquorice plant. According to Professor Piria, asparagin has acid properties. It has no therapeutical value. Marshmallow is said to become somewhat acid by decoction. Those pieces should be rejected which are woody, discoloured, mouldy, of a sour or musty smell, or a sourish taste.

The roots of other *Malvaceæ* are sometimes substituted for that of marshmallow, without disadvantage, as they possess similar properties. Such are those of *Althæa rosea* or *hollyhock*, and *Malva Alcea.* The dark purple flowers of a variety of A. rosea are proposed by Prof Atkins, of the Univ. of Md., as a test for acids and alkalies. A strong infusion of these flowers imparts to slips of white filtering paper immersed in it a permanent purplish-blue colour, which is reddened by acids, and rendered bluish-green by alkalies.

Medical Properties and Uses. The virtues of marshmallow are exclusively those of a demulcent. The decoction of the root is much used in Europe in irritation and inflammation of the mucous membranes. The roots themselves, boiled and bruised, are sometimes employed as a poultice. The leaves and flowers are applied to similar uses. In France, the powdered root is much used in the preparation of pills and electuaries. Some prefer it to powdered liquorice root in the preparation of the mercurial pill.

ALUMEN. *U. S., Br.*

Alum.

Sulphate of alumina and potassa. *U. S.* A sulphate of ammonia and alumina crystallized from solution in water, $NH_4O,SO_3,Al_2O_3,3SO_3+24HO$. *Br.*

Alun, *Fr., Dan., Swed.;* Alaun, *Germ.;* Allume, *Ital.;* Alumbre, *Span.*

The U. S. officinal alum is a double salt, consisting of tersulphate of alumina, united with sulphate of potassa; the British salt differs in the substitution of sulphate of ammonia for that of potassa.

Alum is manufactured occasionally from earths which contain it ready formed, but most generally from minerals which, from the fact of their containing most

or all of its constituents, are called *alum ores*. The principal alum ores are the *alum stone*, which is a native mixture of sulphate of alumina and sulphate of potassa, found in large quantities at Tolfa and Piombino in Italy; and certain natural mixtures of bisulphuret of iron with alumina, silica, and bituminous matter, called *aluminous schist* or *alum-slate*.

At the Solfaterra, and other places in Southern Italy, alum was formerly extracted from earths containing it ready formed. The ground being of volcanic origin, and having a temperature of about 104°, an efflorescence of pure alum formed upon its surface. This was collected and lixiviated, and the solution crystallized by slow evaporation in leaden vessels sunk in the ground.

The alum stone is manufactured into alum by calcination, and subsequent exposure to the air for three months; the mineral being frequently sprinkled with water, in order that it may be brought to the state of a soft mass. This is lixiviated, and the solution obtained crystallized by evaporation. The alum stone may be considered as consisting of alum, united with a certain quantity of hydrate of alumina. The latter, by the calcination, loses its water, and becomes incapable of remaining united with the alum of the mineral, which is consequently set free. Alum of the greatest purity is obtained from this ore.

Alum-slate, when compact, is first exposed to the air for a month. It is then stratified with wood, which is set on fire. The combustion which ensues is slow and protracted. The sulphur is in part converted into sulphuric acid, which unites with the alumina; and the sulphate of alumina thus formed generates a portion of alum with the potassa derived from the ashes of the wood. The iron, in the mean time, is almost wholly converted into sesquioxide, and thus becomes insoluble. The matter is lixiviated, and the solution crystallized into alum by evaporation. The mother-waters, containing sulphate of alumina, are then drawn off, and made to yield a further portion of alum by the addition of sulphate of potassa or chloride of potassium; the latter being obtained usually from the soap boilers.

When the alum-slate is easily disintegrated, it is not subjected to combustion, but merely placed in heaps, and occasionally sprinkled with water. The bisulphuret of iron gradually absorbs oxygen, and passes into sulphate of the protoxide, which effloresces on the surface of the heap. Part of the sulphuric acid formed unites with the alumina; so that, after the chemical changes are completed, the heap contains both the sulphate of iron and the sulphate of alumina. At the end of about a year, the matter is lixiviated, and the solution of the two sulphates produced is concentrated to the proper degree in leaden boilers. The sulphate of iron crystallizes, while the sulphate of alumina, being a deliquescent salt, remains in the mother-waters. These are drawn off, and treated with sulphate of potassa in powder, heat being at the same time applied. The whole is then allowed to cool, that the alum may crystallize. The crystals are then separated from the solution, and purified by a second solution and crystallization. They are next treated with water, just sufficient to dissolve them at the boiling temperature; and the saturated solution is run into casks or tubs, so constructed as to be easily taken to pieces, and set up again. In the course of ten or fifteen days, the alum concretes into a crystalline mass, from which the mother-liquor is let off. The vessel is then taken to pieces, and the salt, having been broken up, is packed in barrels for sale. This process for forming the alum in large masses is called *rocking*.

Alum is now largely manufactured by the direct combination of its constituents. With this view, clays are selected as free from iron and carbonate of lime as possible, and calcined to sesquioxidize the iron, and render them more easily pulverizable; after which they are dissolved, by the assistance of heat, in weak sulphuric acid. Advantage has been found from mixing the clay, previously to calcination, with powdered charcoal, coke, or other carbonaceous matter, in the proportion of about one to six of the clay, and then applying heat by a reverberatory furnace till all the carbon is consumed. It is asserted that the alumina is thus rendered more soluble in the acid. (*Pharm. Journ. and*

Trans., Dec. 1857, p. 328.) The sulphate of alumina, thus generated, is next crystallized into alum by the addition of sulphate of potassa in the usual manner. Alum is made in this way from the ashes of the Boghead cannel-coal, which occurs near Edinburgh. These ashes, which form the residue of the combustion of the coke derived from the coal used for making gas, contain a considerable quantity of alumina in a state readily soluble in acids.

ALUMINÆ ET AMMONIÆ SULPHAS, *U. S.*; ALUMEN, *Br. Sulphate of Alumina and Ammonia. Ammonia-alum.* Besides the potassa-alum, which was formerly the only officinal variety of this salt, there are several others, in which the potassa is replaced by some other base, as, for example, ammonia or soda. Of these, *ammonia-alum*, or the sulphate of alumina and ammonia, was introduced into the U. S. Pharmacopœia at its late revision, under the name at the head of this paragraph, and in the present Br. Pharmacopœia has been adopted to the exclusion of the potassa alum. It is made by adding sulphate of ammonia to the solution of sulphate of alumina. This kind of alum has come into very general use, owing to the rise in value of potassa, and to the comparative cheapness of ammonia, obtained in the process for ferrocyanide of potassium, or derived from the liquor of gas-works. Ammonia-alum is extensively manufactured by Powers & Weightman of this city. Scotch alum, made near Paisley, generally contains both potassa and ammonia. Ammonia-alum resembles potassa-alum so exactly that it cannot be distinguished by simple inspection; and in composition it is perfectly analogous to the potassa-salt. It may, however, be distinguished by subjecting it to a strong calcining heat, after which alumina will be the sole residue; or by rubbing it with potassa or lime and a little water, when the smell of ammonia will be perceived.

Properties. Alum is a white, slightly efflorescent salt, crystallizing in regular octohedrons, and possessing an acid, sweetish, astringent taste.* It dissolves in between fourteen and fifteen times its weight of cold, and three-fourths of its weight of boiling water. Its solution is precipitated by ammonia and potassa and their carbonates, which throw down a gelatinous subsulphate of alumina, of variable composition, dependent upon the proportion of the precipitant employed. Alum is insoluble in alcohol and brandy. Its sp. gr. is 1·71. It reddens litmus, but changes the blue tinctures of the petals of plants to green. When heated a little above 212°, it undergoes the aqueous fusion; and, if the heat be continued, it loses its water, swells up, becomes a white, opaque, porous mass, and is converted into the officinal *dried alum.* (See *Alumen Exsiccatum.*) Exposed to a red heat, it gives off oxygen, together with sulphurous and anhydrous sulphuric acids; and the residue consists of alumina and sulphate of potassa. When calcined with finely divided charcoal, it forms a spontaneously inflammable substance, called *Homberg's pyrophorus*, which consists of a mixture of sulphuret of potassium, alumina, and charcoal.

The characters of the ammonia-alum, as stated in the British Pharmacopœia, are that its solution gives with caustic potassa or soda a white precipitate, soluble in an excess of the reagent, with the evolution of ammonia, especially when heated; and an immediate precipitate with chloride of barium; and does not acquire a blue colour from the addition of yellow or red prussiate of potassa, proving the absence of iron.

Several varieties of alum are known in commerce. *Roche alum*, so called from its having come originally from Rocca, in Syria, is a sort which occurs in fragments about the size of an almond, and of a pale-rose colour, which is given to it, according to Pereira, by bole or rose-pink. *Roman alum*, which is the purest variety found in commerce, also occurs in small fragments, covered with a reddish-brown powder, resembling ochre, which is put on by the manufacturers. It has been supposed that the powder contains iron; but this is probably a mistake. Roman alum crystallizes in cubes, from the fact that the crys-

* It may be made to crystallize in cubes by carefully evaporating a solution, to which ammonia has been added in as large quantities as possible without making the solution turbid. (M. de Hauer, *Journ. de Pharm. et de Chim.*, 4e sér., iii. 309.)—*Note to the thirteenth edition.*

tals are deposited from a solution always containing an excess of alumina, which decomposes any iron salt that may be present. This crystalline form of alum is, therefore, an index of its freedom from iron.

All the alums of commerce contain more or less sulphate of iron, varying from five to seven parts in the thousand. The iron is readily detected by adding to a solution of the suspected alum a few drops of the ferrocyanide of potassium, which will cause a greenish-blue tint, if iron be present. It may be detected also by precipitating the alumina as a subsulphate with a solution of potassa, and afterwards adding the alkali in excess. This will redissolve the precipitate, with the exception of any iron, which will be left in the state of sesquioxide. The proportion of iron usually present, though small, is an injurious impurity when the salt is used in dyeing. It may, however, be purified, either by dissolving it in the smallest quantity of boiling water, and stirring the solution as it cools, or by repeated solutions and crystallizations.

Incompatibles. Alum is incompatible with the alkalies and their carbonates, lime and lime-water, magnesia and its carbonate, tartrate of potassa, and acetate of lead.

Composition. Alum was regarded as a sulphate of alumina, until it was proved by Descroizilles, Vauquelin, and Chaptal to contain also sulphate of potassa, sulphate of ammonia, or both these salts. When its second base is potassa, it consists of one equivalent of tersulphate of alumina 171·4, one of sulphate of potassa 87·2, and twenty-four of water 216=474·6. In the ammonia-alum, the equivalent of sulphate of potassa is replaced by one of the sulphate of oxide of ammonium, that is, sulphate of ammonia and water. *Alumina* is classed as an earth, and may be obtained by subjecting ammonia-alum to a strong calcining heat. It consists of two eqs. of a metal called *aluminium* 27·4, and three of oxygen 24=51·4. It is, therefore, a sesquioxide. The existence of this metal was rendered probable by Sir H. Davy in 1808; but it was not fairly obtained until 1828, when Wöhler procured it in an impure state, in globules of the size of a pin's head, by the action of potassium on chloride of aluminium. In 1854 Deville succeeded in obtaining the pure metal in ingots by decomposing the same chloride with sodium. Aluminium is silver-white, sonorous, unalterable in the air, and lighter than glass, having the sp. gr. 2·56 only. Its fusing point is somewhat lower than that of silver. It is not attacked by sulphuric or nitric acid, nor tarnished by sulphuretted hydrogen. Its proper solvent is muriatic acid. After silver, gold, and platinum, it is the least alterable of the metals. According to Mr. A. Monier, of Camden, N. J., who first obtained the metal in this country, it is not in the least oxidized by fusion with nitre, a property which affords a ready means of purifying it from other metals. (*Am. Journ. of Pharm.*, March, 1857.) By reason of its valuable properties, it will be applied to many purposes in the arts, if obtainable in sufficient quantities, and at a moderate cost.

Medical Properties, &c. Alum, in ordinary doses, is astringent and antispasmodic; in large doses, purgative and emetic. It is employed as an astringent in passive hemorrhages, colliquative sweats, diabetes, and chronic dysentery and diarrhœa; also in gleet and leucorrhœa, in which diseases it is sometimes combined with cubebs. In connection with ice, it has been found effectual by Dr. de Ricci in a very bad case of hæmatemesis. (*Dub. Quart. Journ. of Med. Sci.*, Aug. 1860.) It has been recommended in dilatation of the heart, and in aortic aneurism, and as an antispasmodic in hooping-cough. As a purgative, it has been employed in colica pictonum. This practice was introduced by Grashuis, a Dutch physician, in 1752, was imitated by Dr. Percival with great success, and has been revived in recent times with the happiest results. It allays nausea and vomiting, relieves flatulence, mitigates the pain, and opens the bowels with more certainty than any other medicine. Sometimes it is advantageously conjoined with opium and camphor. It is also efficacious in nervous colic. Sir James Murray found it a useful remedy in the peculiar affection of the stomach, characterized by the frequent vomiting of a large quantity of glairy

fluid. He gave it in doses of ten or twelve grains three or four times a day, mixed with an equal quantity of cream of tartar to prevent constipation, and a little ginger to obviate flatulence. By Dr. C. D. Meigs alum has been strongly recommended, after an experience of more than twenty years, as an excellent emetic in pseudomembranous croup. In these cases, it has the merit of acting with promptness and certainty, and without producing that extreme prostration which often follows the use of antimonials. His son, Dr. J. F. Meigs, has also borne testimony to its value in this disease. In a case in which an ounce of opium had been swallowed, Dr. C. D. Meigs found alum an efficient emetic. After 30 grains of sulphate of zinc had been given without effect, half an ounce of alum was administered, followed by copious vomiting. Soon afterward, a second half ounce was given, with the same effect; and the result was that the patient recovered.

In various anginose affections, alum is found highly useful, applied topically either in powder or solution. When the affection is attended with membranous exudation, its efficacy has been particularly insisted on by Bretonneau, applied in solution prepared with vinegar and honey for adults, and in powder, by *insufflation*, in the cases of children. When used in the latter way, a drachm of finely powdered alum may be placed in one end of a tube, and then blown by means of the breath into the throat of the child. Velpeau, in 1835, extended the observations of Bretonneau, and has used alum successfully, not only in simple inflammatory sorethroat, but in those forms of angina dependent on small-pox, scarlatina, &c. In these cases, the powdered alum may be applied several times a day to the fauces, by means of the index finger. In relaxation of the uvula, and in the beginning of sorethroat, a solution of alum is one of our best gargles. It forms also a useful astringent wash in mercurial sore-mouth. In the form of lozenge, made with sugar and tragacanth, and allowed slowly to dissolve in the mouth, it is peculiarly applicable to chronic throat affections. In gleet and leucorrhœa the solution is an approved remedy, either alone or conjoined with sulphate of zinc. It is frequently applied as a styptic, in epistaxis, by means of a plug soaked in a saturated solution, and pressed up the nostril, and in menorrhagia, by the aid of a sponge soaked in a similar solution, and introduced into the vagina. It may be applied also by injection, both in these hemorrhages and in that from the rectum. In the latter stages of conjunctivitis it is often useful, and in the purulent ophthalmia of infants is our most efficacious remedy. In these cases, it is usually applied in the form of *cataplasm*, made by coagulating the whites of two eggs with a drachm of alum.

The ordinary dose of alum is from ten to twenty grains, repeated every two or three hours, mixed with syrup or molasses Sir James Murray objects to its administration in solution, and greatly prefers the form of an impalpable powder, mixed with molasses, as furnishing the means of presenting the remedy slowly to the surfaces intended to be acted upon. In hooping-cough the dose is from two to ten grains, according to the age of the child, repeated three times a day; in colica pictonum, from half a drachm to two drachms every three or four hours. In croup the dose, as an emetic, is a teaspoonful of the powder, mixed with honey, syrup, or molasses, and repeated every ten or fifteen minutes, until free vomiting is induced. An elegant mode of giving alum in solution is in the form of *alum-whey*, made by boiling two drachms of alum with a pint of milk, and then straining to separate the curd. The dose is a wineglassful, containing about fifteen grains of alum. As a collyrium, the solution is made of various strengths; as four, six, or eight grains to the fluidounce of water. A solution, containing from half an ounce to an ounce in a pint of water, and sweetened with honey, is a convenient gargle. Solutions for gleet, leucorrhœa, ulcers, &c., must vary in strength according to the state of the parts to which they are applied.

Alum is sometimes used to adulterate bread, with the view to increase its whiteness, and to conceal the defects of the flour.

AMMONIA.

Ammonia.

All the ammoniacal compounds owe their distinctive properties to the presence of a peculiar gaseous substance, composed of nitrogen and hydrogen, called *ammonia*. This is most easily obtained by the action of lime on muriate of ammonia or sal ammoniac; when the lime unites with the muriatic acid, so as to form chloride of calcium and water, and expels the ammonia. It is transparent and colourless, like common air, but possesses an acrid taste, and exceedingly pungent smell. It has a powerful alkaline reaction, and, from this property and its gaseous nature, was called the *volatile alkali* by the earlier chemists. Its sp. gr. is 0·59. It is irrespirable, the glottis closing spasmodically when the attempt is made to breathe it. It consists of one eq. of nitrogen 14, and three of hydrogen 3=17; or, in volumes, of one volume of nitrogen and three volumes of hydrogen, condensed into two. Its symbol is NH_3.

The salts of ammonia may be divided into hydracid salts and oxacid salts. Thus, when muriatic acid unites with ammonia, we have the hydracid salt called muriate of ammonia, with the symbol NH_3,HCl. But Berzelius supposed that, in the act of uniting, the hydrogen of the muriatic acid is transferred to the elements of the ammonia, and that the compound thus formed, uniting with the chlorine, gives rise to a salt, represented by NH_4Cl. To this hypothetical compound (NH_4) Berzelius gave the name of *ammonium*, and consequently to muriate of ammonia the appellation of *chloride of ammonium*.

Applying the same view to the oxacid salts of ammonia, Berzelius conceived that they are compounds of *oxide of ammonium* (NH_4O) with their several acids. It is found that the true oxacid salts of ammonia always contain one eq. of water, which cannot be separated from them without destroying their identity; and it is supposed that the elements of this eq. of water, united with the elements of one eq. of ammonia, form oxide of ammonium. To apply Berzelius's view to sulphate of ammonia, this salt is usually considered a monohydrated sulphate of ammonia (NH_3,SO_3+HO); but he made it the sulphate of oxide of ammonium without water (NH_4O,SO_3).

The atmosphere contains a minute proportion of ammonia, probably in the state of carbonate.

Ozonized oxygen oxidizes the elements of ammonia, producing water and nitric acid, which latter, by uniting with undecomposed ammonia, generates nitrate of ammonia. Ordinary oxygen, under the influence of platinum-black, or finely divided copper, likewise oxidizes the elements of ammonia, the nitrogen to the extent only of forming nitrous acid, with the result of producing nitrite of ammonia. (Schönbein, *Chem. Gaz.*, March 16, 1857.)

Medical Properties. The compounds of ammonia are stimulant, antispasmodic, antacid, and alexipharmic. According to Dr. Ogier Ward, they possess the property of dissolving the protein principles of the blood; and, while their primary action is stimulant, their remote operation is sedative, resolvent, and attenuant, implying the power of carrying the products of inflammation out of the system. (*Am. Journ. of the Med. Sci.*, April, 1857, from the *Lancet.*)

The following table contains a list of the principal officinal preparations of ammonia, with their synonymes.

I. In Aqueous Solution.

Aqua Ammoniæ Fortior, *U. S.;* Liquor Ammoniæ Fortior, *Br.*—*Stronger Water of Ammonia. Stronger Solution of Ammonia.*

Linimentum Camphoræ Compositum, *Br.*—*Compound Liniment of Camphor.*

Aqua Ammoniæ, *U. S.;* Liquor Ammoniæ, *Br.*—*Water of Ammonia. Solution of Ammonia.*

Hydrargyrum Ammoniatum, *U. S., Br.*—*Ammoniated Mercury. White Precipitate.*

Linimentum Ammoniæ, *U. S.*, *Br.* — *Liniment of Ammonia. Volatile Liniment.*

Linimentum Hydrargyri, *Br.* — *Liniment of Mercury.*

II. In Spirituous Solution.

Spiritus Ammoniæ, *U. S.* — *Spirit of Ammonia.*

Spiritus Ammoniæ Aromaticus, *U. S.*, *Br.* — *Aromatic Spirit of Ammonia.*

Tinctura Guaiaci Ammoniata, *U. S.*, *Br.* — *Ammoniated Tincture of Guaiac.*

Tinctura Valerianæ Ammoniata, *U. S.*, *Br.* — *Ammoniated Tincture of Valerian.*

Spiritus Ammoniæ Fœtidus, *Br.* — *Fetid Spirit of Ammonia.*

Tinctura Opii Ammoniata, *Br.* — *Ammoniated Tincture of Opium.*

III. In Saline Combination.

Aluminæ et Ammoniæ Sulphas, *U. S* ; Alumen, *Br.* — *Sulphate of Alumina and Ammonia. Ammonia-Alum.*

Ammoniæ Benzoas, *Br.* — *Benzoate of Ammonia.*

Ammoniæ Carbonas, *U. S.*, *Br.* — *Carbonate of Ammonia. Mild Volatile Alkali.*

Cuprum Ammoniatum, *U. S.* — *Ammoniated Copper.*

Liquor Ammoniæ Acetatis, *U. S.*, *Br.* — *Solution of Acetate of Ammonia. Spirit of Mindererus.*

Ammoniæ Murias, *U. S.*; Ammoniæ Hydrochloras, *Br.* 1864; Ammonii Chloridum, *Br.* — *Muriate of Ammonia. Hydrochlorate of Ammonia. Chloride of Ammonium. Sal Ammoniac.*

Ammoniæ Phosphas, *Br.* — *Phosphate of Ammonia.*

Ammoniæ Sulphas, *U. S.* — *Sulphate of Ammonia.*

Ammoniæ Valerianas, *U. S.* — *Valerianate of Ammonia.*

Ammonii Bromidum, *Br.* — *Bromide of Ammonium. Hydrobromate of Ammonia.*

Ferri et Ammoniæ Citras, *U. S.*, *Br.* — *Citrate of Iron and Ammonia.*

Ferri et Ammoniæ Sulphas, *U. S.* — *Sulphate of Iron and Ammonia.*

Ferri et Ammoniæ Tartras, *U. S.* — *Tartrate of Iron and Ammonia.*

Hydrargyrum Ammoniatum, *U. S.*, *Br.* — *Ammoniated Mercury.*

Liquor Ammoniæ Citratis, *Br.* — *Solution of Citrate of Ammonia.*

Liquor Bismuthi et Ammoniæ Citratis, *Br.* — *Solution of Bismuth and Ammonia.* B.

AQUA AMMONIÆ FORTIOR. *U. S.*

Stronger Water of Ammonia.

An aqueous solution of ammonia of the specific gravity 0·900, and containing 26 per cent. of the gas. *U.S.*

Off. Syn. LIQUOR AMMONIÆ FORTIOR. *Strong Solution of Ammonia.* Ammoniacal gas, NH_3, dissolved in water, and constituting 32·5 per cent. of the solution. *Br.*

This preparation is too strong for internal exhibition, but forms a convenient ammoniacal solution for reduction, with distilled water, to the strength of ordinary officinal water of ammonia (Aqua Ammoniæ), or for preparing strong rubefacient and vesicating lotions and liniments.

The U. S. Pharmacopœia includes this solution in the list of the Materia Medica; but in the British, the following formula is given for its preparation.

"Take of Chloride of Ammonium, in coarse powder, *three pounds* [avoirdupois]; Slaked Lime *four pounds* [avoird.]; Distilled Water *thirty-two fluidounces.* Mix the Lime with the chloride of ammonium, and introduce the mixture into an iron bottle, placed in a metal pot surrounded by sand. Connect the iron tube, which screws air-tight into the bottle, in the usual manner,

by corks, glass tubes, and caoutchouc collars, with a Woulf's bottle capable of holding a pint [Imperial measure]; connect this with a second Woulf's bottle of the same size, the second bottle with a matrass of the capacity of three pints [Imp. meas.], in which twenty-two [fluid]ounces of the Distilled Water are placed, and the matrass, by means of a tube bent twice at right angles, with an ordinary bottle containing the remaining ten [fluid]ounces of Distilled Water. Bottles 1 and 2 are empty, and the latter and the matrass which contains the twenty-two ounces of distilled water are furnished each with a siphon safety tube, charged with a very short column of mercury. The heat of a fire, which should be very gradually raised, is now to be applied to the metal pot, and continued until bubbles of condensible gas cease to escape from the extremity of the glass tube which dips into the water of the matrass. The process being terminated, the matrass will contain about forty-three fluidounces of Strong Solution of Ammonia.

"Bottles 1 and 2 will now include, the first about sixteen, the second about ten fluidounces of a coloured ammoniacal liquid. Place this in a flask closed by a cork, which should be perforated by a siphon safety tube containing a little mercury, and also by a second tube bent twice at right angles, and made to pass to the bottom of the terminal bottle used in the preceding process. Apply heat to the flask until the coloured liquid it contains is reduced to three-fourths of its original bulk. The product now contained in the terminal bottle will be nearly of the strength of Solution of Ammonia, and may be made exactly so by the addition of the proper quantity of Distilled Water, or of Strong Solution of Ammonia." *Br.*

In this process the ammonia is disengaged in the usual manner from muriate of ammonia by the action of lime, as explained under the head of *Aqua Ammoniæ*. But it is perceived, by the details of the process, that the purpose is to obtain both the *stronger* and *ordinary* solution of ammonia at one operation. This is done by connecting the iron bottle containing the materials with a series of four receivers, the first two being empty Woulfe's bottles, the third a matrass containing twenty-two fluidounces of distilled water, and the fourth an ordinary bottle containing the remainder of the distilled water. In the first two bottles, impurities are condensed with a considerable portion of ammonia; in the matrass, the officinal Strong Solution of Ammonia (*Br.*) has been formed by the absorption of the gas; and, in the fourth, is a weaker ammoniacal liquid formed by the absorption of a portion of the gas which has passed through the matrass unabsorbed. This last liquid is raised to the strength of the officinal Solution of Ammonia (*Br.*) by forcing into it a portion of ammoniacal gas from the impure contents of the first two bottles. We presume that the receivers are to be kept cool by means of cold water or ice, though no such direction is given in the process. If the solution in the fourth bottle be not of the required officinal strength (sp. gr. 0·959), it may be made so by the addition of stronger solution from the matrass if too weak, or of distilled water, if too strong.

Water of ammonia is seldom made by the formula of the Pharmacopœia, but is prepared on a large scale, from one of the products of the coal gas manufacture, by the following more economical process. *Gas liquor* is distilled, and the distillate, which is principally hydrosulphuret of ammonia, is converted into sulphate of ammonia by sulphuric acid. The rough sulphate is then gently distilled with milk of lime, the still being connected with a series of glass carboys, arranged like Woulfe's bottles, and three-fourths filled with distilled water. In this way solution of ammonia may be obtained of maximum strength. (See a paper by Mr. W. Lawson, in the *Am. Journ. of Pharm.* for July, 1855, p. 362, from the *Pharm. Journ. and Trans.* for April, 1855.)

Properties of Aqueous Ammonia of Maximum Strength. This is a colourless liquid, of an acrid taste, and very pungent smell. It is strongly alkaline, and immediately changes turmeric, when held over its fumes, to reddish-brown. Cooled to 40° below zero, it concretes into a gelatinous mass, and at 130° boils, owing to the rapid disengagement of the gas. Its sp. gr. is 0·875 at 50°.

Properties of the Officinal Stronger Water of Ammonia. This has similar properties to those above mentioned. Its sp. gr is 0·00, *U.S.*, 0·891, *Br.* When of the former density, it contains 26 per cent. of the gas, when of the latter 32 5 per cent. "By weight, 52·3 grains require for neutralization 1000 grain-measures of *the volumetric solution of oxalic acid.* One fluidrachm contains 15·83 grains of Ammonia, NH_3." *Br.* The stronger water of ammonia of the shops usually ranges in density from 0·900 to 0 920. Even when of proper officinal strength at first, it generally becomes weaker by the escape of ammonia. To prevent its deteriorating, it should be kept in closely stopped bottles in a cool place. If precipitated by lime-water, it contains carbonic acid. After having been saturated with nitric acid, a precipitate by carbonate of ammonia indicates earthy impurity, by nitrate of silver, a chloride, and by chloride of barium, a sulphate. "When diluted with four times its volume of distilled water, it does not give precipitates with solution of lime, oxalate of ammonia, sulphide of ammonium, or ammonio-sulphate of copper" (*Br.*); indicating the absence of carbonates, lime, metals, and sulphurets.

Aqua Ammoniæ Fortior is a convenient preparation for making *Aqua Ammoniæ* (sp. gr. 0·960, *U.S.*, 0·959, *Br.*) by dilution with distilled water. To effect this reduction, the U. S. stronger solution requires to be diluted with about one and a half measures of distilled water; the British, with two measures.

When purchasing the Stronger Solution of ammonia, the apothecary should not trust to its being of the officinal strength; but should ascertain the point by taking its density, either by the specific gravity bottle or the hydrometer. Another method of ascertaining its density is by the *ammonia-meter* of Mr. J. J. Griffin, of London, described and figured in the *Pharm. Journ. and Trans.* (x. 413). In reducing it to make Liquor Ammoniæ, the same precaution should be taken; and, if the mixture should not have the sp. gr. 0·960, it should be brought to that density by the addition either of the stronger solution or of distilled water, as the case may require.

Medical Properties and Uses. This solution is too strong for medical use in its unmixed state. Sufficiently diluted with spirit of camphor and rosemary, it has been much employed as a prompt and powerful rubefacient, vesicatory, or escharotic, in various neuralgic, gouty, rheumatic, spasmodic, and inflammatory affections, in which strong and speedy counter-irritation is indicated. When mere rubefaction is desired, a mixture may be used composed of five fluidounces of the ammoniacal liquid and eight of the diluent liquids; and this will answer even for blistering or cauterizing, unless a very prompt effect is necessary. In the latter case, a lotion may be resorted to consisting of five measures of the ammoniacal to three of the diluent liquid. These mixtures are applied by means of linen folded several times, or a thick piece of flannel saturated with the liniment. A convenient mode is to fill the wooden cover of a large pill or ointment box, an inch or two in diameter, with patent lint, saturate this with the liquid, and press it upon the part. The ammonia is thus prevented from escaping, and a definite boundary given to the inflammation. The application will generally produce rubefaction in from one to six or eight minutes, vesication in from three to ten minutes, and a caustic effect in a somewhat longer period.

When a solution of ammonia of 25° (sp. gr. 0·905) is mixed with fatty mattter, the mixture forms the *vesicating ammoniacal ointment* of Dr. Gondret. The amended formula of this ointment is as follows. Take of lard 32 parts, oil of sweet almonds 2 parts. Melt them together by the *gentle* heat of a candle or lamp, and pour the melted mixture into a bottle with a wide mouth. Then add 17 parts of solution of ammonia of 25°, and mix, with continued agitation, until the whole is cold. The ointment must be preserved in a bottle with a ground stopper, and kept in a cool place. When well prepared, it vesicates in ten minutes

A case of poisoning by stronger solution of ammonia, successfully treated by Dr. H. W. Reed, in which the stomach-pump, dilute acetic acid, olive oil, milk, hot fomentations, and strong purgative enemata were used, is related in the London *Med. Times and Gaz.* (xi. 59). The subsequent irritation and inflam-

mation were combated chiefly by morphia, and by leeches to the stomach and throat. The immediate effects, after swallowing the ammonia, were those of the strong corrosive poisons. There may be danger of excessive irritation and inflammation of the nostrils, mouth, and air-passages, from the inadvertent inhalation of the gas escaping from a bottle of the stronger water of ammonia, when freshly opened. The best antidote, under these circumstances, would be the inhalation of the vapours of vinegar or acetic acid.

AMMONIÆ CARBONAS. *U. S., Br.*

Carbonate of Ammonia.

Syn. AMMONIÆ SESQUICARBONAS, *Lond., Dub.* $2NH_4O,3CO_2$. *Br.*

This was transferred, in the last revision of the U. S. Pharmacopœia, from the Preparations to the Materia Medica, certainly the proper place for it, as it is prepared only by the manufacturing chemist.

There have been many methods of obtaining carbonate of ammonia, in all of which the ammonia originated in organic decomposition. It was probably originally prepared from putrid urine. A patent was taken out in England for manufacturing it from guano, and another for making it by the direct combination of its constituents; the carbonic acid and ammoniacal gases being introduced simultaneously into leaden chambers. (*Chem. News*, Dec. 29, 1865.) But at present the salt is manufactured by subliming a mixture of either the muriate or sulphate with chalk. Muriate of ammonia and chalk (carbonate of lime) are heated together in iron pots or retorts, and sublimed into large earthen or leaden receivers. By the reciprocal action of the salts employed, the carbonic acid of the chalk unites with the ammonia of the muriate, generating carbonate of ammonia, and the muriatic acid with the lime, forming water and chloride of calcium. The carbonate and water sublime together as hydrated carbonate of ammonia, and the residue is chloride of calcium. The relative quantities of chalk and muriate of ammonia, for mutual decomposition, are 50 of the former, and 53·5 of the latter, or one eq. of each. But a great excess of chalk is usually taken, in order to ensure the perfect decomposition of the muriate of ammonia, any redundancy of which would sublime with the carbonate and render it impure.

Sulphate of ammonia may be substituted for the muriate with much economy, as was shown by Payen. This double decomposition between sulphate of ammonia and carbonate of lime takes place in the dry way only, that is, by sublimation. In the wet way, the double decomposition is reversed; carbonate of ammonia and sulphate of lime reacting so as to form sulphate of ammonia and carbonate of lime. Large quantities of this carbonate are manufactured indirectly from *coal-gas liquor* and *bone-spirit;* the ammoniacal products in these liquors being converted successively into sulphate, muriate, and carbonate of ammonia. (See *Ammoniæ Murias.*) The salt as first obtained has a slight odour of tar, and leaves a blackish carbonaceous matter when dissolved in acids. Hence it requires to be purified, which is effected in iron pots, surmounted with leaden heads.

Properties. Carbonate (*sesquicarbonate*) of ammonia, recently prepared, is in white, moderately hard, translucent masses, of a fibrous and crystalline appearance, a pungent ammoniacal smell, and a sharp penetrating taste. It possesses an alkaline reaction, and, when held under a piece of turmeric paper, changes it to brown, owing to the escape of monocarbonate of ammonia. When long or insecurely kept, it gradually passes into the state of bicarbonate, becoming opaque and friable, and falling into powder. It is soluble without residue

in about four times its weight of cold water, but is decomposed by boiling water into two eqs. of monocarbonate which dissolve, and one eq of carbonic acid which escapes with effervescence. According to Dr. Barker (*Observations on the Dublin Pharmacopœia*), it dissolves abundantly in diluted alcohol, as also in heated alcohol of the sp. gr 0·836, with effervescence of carbonic acid. The Br Pharmacopœia states that it is more soluble in spirit than water When heated on a piece of glass, it should evaporate without residue, and, if turmeric paper held over it undergoes no change, it has passed into bicarbonate. As now prepared from coal-gas liquor, it sometimes contains traces of tarry matter, which gives a dark colour to its solution in acids. When it is saturated with nitric acid, neither chloride of barium nor nitrate of silver causes a precipitate. The non-action of these tests shows the absence of sulphate and muriate of ammonia. It is decomposed by acids, the fixed alkalies and their carbonates, lime-water and magnesia, solution of chloride of calcium, alum, acid salts, such as bitartrate and bisulphate of potassa, solutions of iron (except the tartrate of iron and potassa and analogous preparations), corrosive sublimate, the acetate and subacetate of lead, and the sulphates of iron and zinc. "Fifty-nine grains dissolved in one [fluid]ounce of distilled water, will be neutralized by 1000 grain-measures of *the volumetric solution of acetic acid.* Twenty grains neutralize 23·5 grains of citric acid and 25·5 grains of tartaric acid." *Br.*

Composition. The salt consists of three eqs of carbonic acid 66, two of ammonia 34, and two of water 18=118; or, which comes to the same thing, of one eq. of bicarbonate 61, and one of monocarbonate 39, combined with the same quantity of water. The medicinal carbonate of ammonia is, therefore, when perfect, a *sesquicarbonate*, as it is defined in the British Pharmacopœia. On the ammonium theory, the two eqs. of water disappear, and the salt becomes a sesquicarbonate of oxide of ammonium. Dalton and Scanlan have rendered it probable that it really consists of the two salts above mentioned; for, when treated with a small quantity of cold water, monocarbonate is dissolved and bicarbonate left. When converted into bicarbonate by exposure to the air, each eq. of the medicinal salt loses one eq. of monocarbonate, a change which leaves the acid and base in the proper proportion to form the bisalt. The mutual decomposition of the salts, employed in its preparation, would generate, if no loss occurred, the monocarbonate, and not the sesquicarbonate. The way in which the latter salt is formed may be thus explained. By the mutual decomposition of three eqs. of muriate of ammonia and three of chalk, three eqs. of monocarbonate of ammonia, three of water, and three of chloride of calcium are generated. During the operation, however, one eq. of ammonia, and one of water, forming together oxide of ammonium, are lost; so that there remain to be sublimed, three eqs. of carbonic acid, two of ammonia, and two of water; or, in other words, the constituents in the proper proportion for forming the hydrated sesquicarbonate of ammonia, or sesquicarbonate of oxide of ammonium. When the salt is re-sublimed in the process of purification, two eqs. are said to lose one eq. of carbonic acid, and to become one eq. of the 5-4 carbonate. Accordingly, the medicinal carbonate, after having been submitted to a second sublimation is not a perfect sesquicarbonate.

Medical Properties and Uses. Carbonate of ammonia is stimulant, diaphoretic, antispasmodic, powerfully antacid, and in large doses emetic. Under certain circumstances it may prove expectorant; as when, in the last stages of phthisis, it facilitates the excretion of the sputa by increasing the muscular power. As a stimulant, it is exhibited principally in typhus fever, and very frequently in connection with wine-whey. Its principal advantage, in this disease, is its power to increase the action of the heart and arteries without unduly exciting the brain. It is employed, with a view to the same effect, and as an antacid, in certain stages of atonic gout, and in the gastric derangement supervening on habits of irregularity and debauchery. As a diaphoretic, it is resorted to in gout and chronic rheumatism, particularly the latter, in conjunction with guaiac. Dr. Pereira has employed it in many cases of epilepsy with benefit. In diabetes

it has been recommended by Dr. Barlow in England, and Bouchardat in France. In cases of scrofula attended with languid circulation and dry skin, it is said to produce excellent effects. It is very seldom used as an emetic; but is supposed to act with advantage, in this way, in some cases of paralysis. In psoriasis and lepra vulgaris, Cazenave has used it with remarkable success. Two cases of glanders, successfully treated chiefly with five-grain doses of carbonate of ammonia, repeated every hour or two hours, are reported by Dr. Mackenzie, of London. (*Ranking's Abstract*, no. 18, p. 230.) As an external application, it is rubefacient, and may be employed in several ways. Reduced to fine powder, and mixed with some mild ointment, it is useful in local rheumatism. One part of it, incorporated with three parts of extract of belladonna, forms a plaster very efficacious in relieving local and spasmodic pains. Coarsely bruised, and scented with oil of lavender, it constitutes the common smelling salts, so much used as a nasal stimulant in syncope and hysteria.* The ordinary dose is five grains, every two, three, or four hours, given in the form of pill or mixture. The dose as an emetic is thirty grains, repeated if necessary, and assisted by free dilution. It should never be given in powder, on account of its volatile nature. Pills of it may be made with a vegetable extract, as of gentian, and should be dispensed in a wide-mouthed vial, and not in a box. Carbonate of ammonia is sometimes directed to be made into pills with sulphate of quinia. According to Mr. J. M. Maisch, these salts are incompatible; and, unless the physician wishes to give sulphate of ammonia and free quinia, they should not be ordered together. If so ordered, Mr. Maisch suggests that they should be rubbed up with a little strong alcohol, in order that the whole of the carbonic acid may be evolved, before they are made into pills. If this be not done, each pill will swell and burst from the gradual extrication of the acid. (*Am. Journ. of Pharm.*, xxviii. 309.)

Carbonate of ammonia is sometimes employed to make effervescing draughts, 20 grains of the salt requiring for this purpose 6 fluidrachms of lemon-juice, 24 grains of citric acid, or 25½ grains of tartaric acid.

AMMONIÆ MURIAS. *U. S.*

Muriate of Ammonia.

Off. Syn. AMMONII CHLORIDUM. *Chloride of Ammonium.* NH_4Cl. *Br.* AMMONIÆ HYDROCHLORAS, *Hydrochlorate of Ammonia. Br.* 1864.

Sal ammoniac, Hydrochlorate of ammonia; Hydrochlorate d'ammoniaque, Sel ammoniac, *Fr.;* Salmiak, *Germ.;* Sale ammoniaco, *Ital.;* Sal ammoniaco, *Span.*

This salt is placed in the Materia Medica list of the U. S. Pharmacopœia. It originally came from Egypt, where it was obtained by sublimation from the soot resulting from the burning of camels' dung, which is used in that country for fuel. It has also long been known in China, where it is obtained from the water of certain volcanic springs, and exists in commerce in various states of purity. (Hanbury, *Pharm. J. and Trans.*, April, 1865, p. 514.)

Preparation. At present muriate of ammonia is derived from two principal sources; the ammoniacal liquor, called *gas liquor*, found in the condensing vessels of coal gas-works, and the brown, fetid ammoniacal liquor, known under the name of *bone-spirit*, which is a secondary product, obtained from the destructive distillation of bones, in the manufacture of bone-black. These two liquors are the chief sources of ammoniacal compounds; for they are both used to procure muriate of ammonia, and this salt is employed, directly or in-

* In Mounsey's recipe for the English preparation, called *Preston salts*, the essence to be added to the carbonate is made as follows. Take of oil of cloves ʒss; oil of lavender ʒj; oil of bergamot ʒiiss; stronger solution of ammonia (sp. gr. 0·880) fʒx. Mix. The bottles are to be filled with carbonate of ammonia, half with the salt coarsely bruised, and the remainder with it in fine powder; and then as much of the above essences as the salt will absorb is to be added. (*Pharm. Journ. and Trans.*, xiii. 628.)

directly, for obtaining all the other salts of ammonia. Other sources are stale urine, coal soot, guano, peat, and bituminous schist.

Gas liquor contains carbonate, hydrocyanate, hydrosulphate, and sulphate of ammonia, but principally the carbonate It is saturated with sulphuric acid, and the solution obtained, after due evaporation, furnishes brown crystals of sulphate of ammonia. These are then sublimed with chloride of sodium in iron pots, lined with clay, and furnished with a leaden dome or head. By the mutual action of the sulphate, water, and chloride, there are formed muriate of ammonia which sublimes, and sulphate of soda which remains behind. Thus NH_3,HO,SO_3 and NaCl become NH_3HCl and NaO,SO_3. Sometimes, instead of the ammonia of the gas liquor being first converted into the sulphate, it is made at once into muriate by the addition of muriatic acid or chloride of calcium. When chloride of calcium is employed, the chief reaction takes place between carbonate of ammonia and the chloride, whereby muriate of ammonia is formed in solution, and carbonate of lime precipitated. The solution is duly evaporated, whereby brown crystals of the muriate are obtained. These, after having been dried, are purified by sublimation in an iron subliming pot, coated with a composition of clay, sand, and charcoal, and covered with a dome of lead. These pots are sometimes sufficiently large to hold 500 pounds. "A gentle fire is kept up under the subliming pot for seven or eight days, when, the dome having cooled down, and the sal ammoniac somewhat contracted, so as to loosen from the sides, the dome is thrown off from the iron pot, and about two or three hundred weight of white, semi-transparent sal ammoniac are knocked off in cakes." (Pereira, *Mat. Med.*, 3d ed., p 446)

In the destructive distillation of bones for making bone-black, the distilled products are the bone-spirit already mentioned, being chiefly an aqueous solution of carbonate of ammonia, and an empyreumatic oil called *animal oil.* These products all result from a new arrangement of the ultimate constituents of the animal matter. Thus, hydrogen and oxygen form the water; carbon and oxygen, the carbonic acid; nitrogen and hydrogen, the ammonia; and carbon, hydrogen, and oxygen, the animal oil.

Muriate of ammonia may be obtained from bone-spirit in the manner just described for procuring it from gas liquor. Sometimes, however, the sulphate of ammonia is not made by direct combination, but by digesting the bone-spirit with ground plaster of Paris (sulphate of lime). By double decomposition, sulphate of ammonia and carbonate of lime are formed The sulphate of ammonia is then converted into the muriate by sublimation with common salt, in the manner just explained. The muriate "may be formed by neutralizing hydrochloric acid with ammonia, and evaporating to dryness." *Br.*

Other processes have been proposed or practised for obtaining muriate of ammonia. For an account of the manufacture of ammoniacal salts, and for a list of the patents issued in Great Britain, since 1827, for their preparation, the reader is referred to the *Pharm. Journ. and Trans.* (xii. 29. 63. and 113).

Commercial History. All the muriate of ammonia consumed in the United States is obtained from abroad. Its commercial varieties are known under the names of the *crude* and *refined.* The crude is imported from Calcutta in chests containing from 350 to 400 pounds; and is consumed almost exclusively by coppersmiths and other artisans in brass and copper, being employed for the purpose of keeping the metallic surfaces bright, preparatory to brazing. The refined comes to us exclusively from England, packed in casks containing from 5 to 10 cwt.

Properties. Muriate of ammonia is a white, translucent, tough, fibrous salt, occurring in large cakes, about two inches thick, convex on one side and concave on the other. It has a pungent, saline taste, but no smell. Its sp. gr. is 1·45. It dissolves in three parts of cold, and one of boiling water, and cold is produced during its solution. It is less soluble in rectified spirit than in water, and sparingly so in absolute alcohol. This salt is very difficult to powder in the ordinary way. Its pulverization, however, may be readily effected by making a boiling saturated solution of the salt, and stirring it as it cools. The salt is thus made to granulate, and in this state, after having been drained from the remaining

solution and dried, may be easily powdered. At a red heat it sublimes without decomposition, and without residue. Exposed to a damp atmosphere it becomes slightly moist. It has the property of increasing the solubility of corrosive sublimate in water. It is decomposed by the strong mineral acids, and by the alkalies and alkaline earths; the former disengaging muriatic acid, the latter, ammonia, both sensible to the smell. Muriate of ammonia is usually employed for obtaining gaseous ammonia, which is conveniently disengaged by lime. It is incompatible with acetate of lead and nitrate of silver, producing a precipitate with the former of chloride of lead, with the latter of chloride of silver.

Muriate of ammonia is little subject to adulteration. If not entirely volatilized by heat and soluble in water, it contains impurity. Still, as ordinarily prepared, it contains iron in the state of protochloride. This metal may be detected by boiling a small portion of a saturated solution of the salt with a drop or two of nitric acid, and then adding ferrocyanide of potassium, when the characteristic blue colour occasioned by iron will be produced. If the salt is entirely volatilized by heat, and yet produces a precipitate with chloride of barium, the presence of sulphate of ammonia is indicated.

Composition. Muriate of ammonia is composed of one eq. of muriatic acid 36·5, and one of ammonia 17 = 53·5. Viewed as *chloride of ammonium*, it consists of one eq. of chlorine and one of ammonium (NH_4Cl).

Medical Properties. Muriate of ammonia acts primarily as a stimulant, purging in large doses, but rather constipating in small ones. Its secondary action is that of a resolvent, conjoined with a tonic power, derived probably from the presence of chlorine. By reason of these properties, it forms, according to Dr. O. Ward, an excellent substitute for mercury, in cases where that medicine, on account of its debilitating effect, is inadmissible. It has been recommended in chronic rheumatism; in pleuritis, chronic bronchitis, peritonitis, dysentery, and other inflammations of the serous and mucous membranes, after the first violence of the disease has abated; in chronic inflammation and enlargement of the thoracic and abdominal viscera; in scrofulous and syphilitic enlargements of the lymphatic glands; and in amenorrhœa, when dependent on deficient action of the uterus. Several cases of pectoral disease simulating incipient phthisis are reported, in Otto's Bibliothek for 1834, to have been cured by this salt. According to Dr. Watson, it is a very efficacious remedy in hemicrania. In the opinion of Dr. Ebden, of the Bengal medical service, it is a powerful remedy for neuralgic affections generally; such as tic douloureux, nervous headache, toothache, sciatica, and neuralgic dysmenorrhœa. He gives it in the amount of from twenty-five to thirty-five grains in a fluidounce of camphor mixture, or of mint-water, every twenty minutes, for three doses. Usually, after the second dose, the immediate pain is relieved. (*Ranking's Abstract*, no. xx. 55.) In 1851, Dr. Aran reported his success with this remedy in intermittent fever to the Academy of Medicine, of Paris, having cured eleven out of thirteen cases. M. Marrotte has used it advantageously, as a substitute for sulphate of quinia, in the treatment of affections assuming a remittent or intermittent character. (*Arch. Gén.*, 5e sér., ix. 734.) M. Fischer, of Dresden, in 1821, recommended it in chronic enlargement of the prostate; and, since then, several German practitioners have confirmed his statement. Dr. A. Lindsay, of Glasgow, has investigated the physiological and therapeutical effects of muriate of ammonia. Taken in health he found it to improve the appetite, and to give a certain buoyancy to the spirits. In his hands it proved particularly efficacious in chronic rheumatism, and chronic bronchitis. In the latter disease, when the sputa were tough and tenacious, it speedily improved their quality. (*Med. Exam.* for Jan. 1856, from the *Glasgow Med. Journ.*) Similar testimony is borne to its value in chronic bronchitis by M. Delvaux, of Brussels, who found it to diminish dyspnœa, mitigate cough, and facilitate and lessen expectoration. (*Ann. de Thérap.*, 1855, p. 99.)

The dose of muriate of ammonia is from five to thirty grains, repeated every two or three hours, and given in sweetened water or mucilage. When given in

enlarged prostate, the dose recommended is fifteen grains every two hours, gradually increased until nearly half an ounce is taken daily. When the dose is greater than the system can safely bear, it produces disordered digestion, a miliary eruption, profuse sweats, and scorbutic symptoms.

Externally, muriate of ammonia is used in solution, as a stimulant, and resolvent, in contusions, indolent tumours, &c. An ounce of the salt, dissolved in nine fluidounces of water and one of alcohol, forms a solution of convenient strength. When the solution is to be used as a wash for ulcers, or an injection in leucorrhœa, it should not contain more than from one to four drachms of the salt to a pint of water. Such a solution, with addition of wine of opium, had been advantageously employed by M. Guinau de Mussy in milky engorgement and scrofulous swellings of the breast, being applied upon cataplasms.

The vapour of muriate of ammonia has been administered by inhalation, employed several times a day, in chronic catarrh, with marked advantage, by Dr. Gieseler, of Germany. Dr. Herman Beigel, of London, strongly recommends its inhalation in the nascent state, resulting from a mixture of the two gases composing it. Three bottles are used, one containing water of ammonia, the second an equivalent quantity of liquid muriatic acid, and the third half filled with water, connected with the first two by tubes, and supplied itself with a tube for inhalation. By inhalation the patient draws the two gases from their respective bottles into the third, where they combine to form the muriate of ammonia, which is freed from any excess of either gas by the water. The greater or less force of the inspiration will determine the depth to which the medicine will penetrate; and this will depend on the part of the respiratory passages specially affected. (*Lancet*, Oct. 1867, p. 512.) Another mode of inhaling muriate of ammonia, is in the form of *spray*, by means of the atomizer; from 10 to 20 grains being dissolved for the purpose in a fluidounce of water.

AMMONIÆ SULPHAS. *U. S.*

Sulphate of Ammonia.

This salt has been introduced into the Materia Medica list of the U. S. Pharmacopœia, as a substance employed in the preparation of other medicines. It is usually obtained as one of the steps in the preparation of muriate of ammonia. (See *Ammoniæ Murias.*) The impure salt resulting from the sublimation of gas liquor or fetid bone-spirit, saturated with sulphuric acid, is submitted repeatedly to solution and crystallization until obtained pure. It is in colourless rhombic prisms, unalterable in the air at common temperatures, but effloresecing in heated air with the loss of half its water, soluble in twice its weight of cold and its own weight of boiling water, fusible by heat, and wholly volatilizable, but, according to Berzelius, with partial decomposition. It contains 24·3 per cent. of water. It is known to be a sulphate by giving a white precipitate with chloride of barium, and scarcely any with a dilute solution of nitrate of silver, and to contain ammonia by emitting the smell of that gas when rubbed with hydrate of lime or of potassa. It is not used as a medicine, but enters into the composition of two officinals; ammonia-alum and the sulphate of iron and ammonia.

Off. Prep. Ferri et Ammoniæ Sulphas, *U. S.* B.

AMMONII BROMIDUM. *Br.*

Bromide of Ammonium.

This is a new officinal of the British Pharmacopœia, not yet introduced into ours. By those who consider the ammoniacal salts as compounds of acids with ammonia, it is called *hydrobromate of ammonia* (NH_3HBr); but by the British

authorities, the claims of ammonium as a compound radical being now admitted, the salt is recognised as a bromide of ammonium (NH_4Br).

Preparation. Bromide of ammonium may be prepared by dissolving bromine in water of ammonia. The liquid becomes heated, nitrogen escapes with effervescence, and the solution assumes a yellow colour in consequence of a slight excess of bromine after saturation. By evaporation the bromide is obtained in the form of four-sided prisms, which sometimes cross one another at right angles (*Berzelius.*) A better mode, according to Prof. Procter, of obtaining the salt is by acting on bromide of iron with carbonate of ammonia, as in the U. S. officinal process for bromide of potassium; and a still better, by adding to bromine and water sufficient solution of hydrosulphate of ammonia (sulphuret of ammonium) to discharge the colour, filtering to separate the sulphur, and then evaporating to dryness.

Properties. Bromide of ammonium is in colourless crystals, which on exposure to the air gradually become yellowish, in consequence of a partial decomposition, by which hydrobromic acid appears to be liberated, as they now change litmus red. The salt has a saline, pungent taste. Exposed to heat, it sublimes unchanged. It is soluble in 1·5 parts of water, and in 13 parts of alcohol. (*Squire.*) The British Pharmacopœia requires that it should not give rise to a blue colour with mucilage of starch and chlorine, thus proving the absence of an iodide. It is incompatible with acids, acid salts, and spirit of nitrous ether. (*Squire.*)

Medical Uses. This bromide probably produces on the system effects analogous to those of bromide of potassium, and has been thought by some practitioners preferable in certain cases. Attention was called by Dr. Gibb to its value as a therapeutic agent. He has found it peculiarly applicable to functional nervous diseases, more especially those of the ganglionic system, and considers it also as having some influence over affections of the mucous membranes and the skin. In epilepsy he has experienced decided advantage from it; and in the milder forms of ovaritis it sometimes acts almost as if by magic. He has also found it remarkably beneficial in strumous ophthalmia in the young, and believes that it tends to promote the absorption of fatty matter. He gave it in doses varying from two to ten grains three times a day. (*Lancet*, Jan. 3, 1863, p. 12.)

Others have borne testimony to its efficiency in epilepsy; and it has been recommended in sleeplessness when dependent on nervous disorder. Good might be expected from it in various forms of hysteria. The dose is from two to twenty grains. A solution containing five grains in a fluidounce of water may be used as a gargle in relaxation of the larynx. W.

AMMONIACUM. *U. S., Br.*

Ammoniac.

The concrete juice of Dorema Ammoniacum. *U. S.* A gum-resinous exudation from Dorema Ammoniacum. *Br.*

Gomme ammoniaque, *Fr.;* Ammoniak, *Germ.;* Gomma ammoniaco, *Ital.;* Gomma amoniaco, *Span.;* Ushek, *Arab.;* Semugh belsheren, *Persian.*

Much uncertainty long existed as to the ammoniac plant. It was generally believed to be a *Ferula* till Willdenow raised, from some seeds mixed with the gum-resin found in the shops, a plant which he ascertained to be a *Heracleum*, and named *H. gummiferum*, under the impression that it must be the source of the medicine. On this authority, the plant was adopted by the British Colleges, and recognised in former editions of our national Pharmacopœia. Willdenow expressly acknowledged that he could not procure from it any gum-resin, but ascribed the result to the influence of climate. The *Heracleum*, however, did not correspond exactly with the representations given of the ammoniac plant by travellers; and Sprengel ascertained that it was a native of the Pyrenees, and never produced gum. Mr. Jackson, in his account of Morocco, imperfectly described a plant of that country, supposed to be a *Ferula*, from

which gum-ammoniac is procured by the natives. This plant was ascertained by Dr. Falconer to be *Ferula Tingitana* (Royle's *Mat. Med.*), and its product is thought to be the ammoniacum of the ancients, which was obtained from Africa; but this is not the drug now used under that name, which comes exclusively from Persia. M. Fontanier, who resided many years in Persia, saw the ammoniac plant growing in the province of Fars, and sent a drawing of it with specimens to Paris. From these it was inferred to be a species of Ferula; and Merat and De Lens proposed for it the name, originally given to it by Lemery, of *F. ammonifera*. It was subsequently, however, ascertained, from specimens obtained in Persia by Colonel Wright, and examined by Dr. David Don, that it belonged to a genus allied to Ferula, but essentially different, which was named, by Dr. Don, *Dorema*. It is described in the 16th vol. of the Linn. Transactions, under the name of *Dorema Ammoniacum*. This is now acknowledged by the officinal authorities. The same plant was described and figured by Jaubert and Spach in their "*Illustrations of Oriental Plants*" (Paris, 1842, t. 40, p. 78), by the name of *Diserneston gummiferum*, under the erroneous impression that it belonged to a previously undescribed genus.

The ammoniac plant is umbelliferous, and belongs to the class and order Pentandria Digynia of Linnæus. It grows spontaneously in Farsistan, Irauk, Chorassan, and other Persian provinces. Dr. Grant found it abundantly in Syghan near Bameean, on the northwest slope of the Hindoo Coosh mountains. It attains the height of six or seven feet, and in the spring and early part of summer abounds in a milky juice, which flows out upon the slightest puncture. From the accounts of travellers, it appears that, in the month of May, the plant is pierced in innumerable places by an insect of the beetle kind. The juice, exuding through the punctures, concretes upon the stem, and when quite dry is collected by the natives. M. Fontanier states that the juice exudes spontaneously, and that the harvest is about the middle of June. According to Dr. Grant, the drug is collected in Syghan, like assafetida, from the root of the plant. The gum-resin is sent to Bushire, whence it is transmitted to India, chiefly to Bombay. A small portion is said to be taken to the ports of the Levant, and thence distributed. The name of the drug is thought to have been derived from the temple of Jupiter Ammon in the Libyan desert, where the ammoniac of the ancients is said to have been collected; but Dr. Don considers it a corruption of *Armeniacum*, originating in the circumstance that the gum-resin was formerly imported into Europe through Armenia.

Properties. Ammoniac comes either in the state of tears, or in aggregate masses, and in both forms is frequently mixed with impurities. That of the tears, however, is preferable, as the purest may be conveniently picked out and kept for use. These are of an irregular shape, usually more or less globular, from two to eight lines in diameter, opaque, yellowish on the outside, whitish within, compact, homogeneous, brittle when cold, and breaking with a conchoidal, shining fracture. The masses are of a darker colour and less uniform structure, appearing, when broken, as if composed of numerous white or whitish tears, embedded in a dirty-gray or brownish substance, and frequently mingled with foreign matters, such as seeds, fragments of vegetables, and sand or other earth. We have seen masses composed of agglutinated tears alone.

The smell of ammoniac is peculiar, and stronger in the mass than in the tears. The taste is slightly sweetish, bitter, and somewhat acrid. The sp. gr. is 1·207. When heated, the gum-resin softens and becomes adhesive, but does not melt. It burns with a white flame, swelling up, and emitting a smoke of a strong, resinous, slightly alliaceous odour. It is partly soluble in water, alcohol, ether, vinegar, and alkaline solutions. Triturated with water, it forms an opaque milky emulsion, which becomes clear upon standing. The alcoholic solution is transparent, but is rendered milky by the addition of water. Bucholz obtained from 100 parts of ammoniac, 22·4 parts of gum, 72·0 of resin, 1·6 of bassorin, and 4·0 of water including volatile oil and loss. Braconnot obtained 18·4 per cent. of gum, 70·0 of resin, 4·4 of a gluten-like substance (bassorin), and 6·0 of

water, with 1·2 per cent. of loss. Hagen succeeded in procuring the volatile oil in a separate state by repeated distillation with water. It has a penetrating disagreeable odour, and a taste at first mild, but afterwards bitter and nauseous. The resin of ammoniac is dissolved by alcohol, and by the fixed and volatile oils; but it is divided by ether into two resins, of which one is soluble, the other insoluble in that menstruum.

Medical Properties and Uses. This gum-resin is stimulant and expectorant, in large doses cathartic, and, like many other stimulants, may be so given as occasionally to prove diaphoretic, diuretic, or emmenagogue. It has been employed in medicine from the highest antiquity, being mentioned in the writings of Hippocrates. The complaints in which it is most frequently used are chronic catarrh, asthma, and other pectoral affections attended with deficient expectoration without acute inflammation, or with a too copious secretion from the bronchial mucous membrane, dependent upon debility of the vessels. It is thought to have been useful in some cases of amenorrhœa, and in chlorotic and hysterical conditions of the system arising out of that complaint. It has also been prescribed in obstructions or chronic engorgements of the abdominal viscera, under the vague notion of its deobstruent power. Any good which it may do in these affections, is more probably ascribable to its revulsive action upon the alimentary mucous membrane. Authors speak of its utility in long and obstinate colics dependent on mucous matter lodged in the intestines; but it would be difficult to ascertain in what cases such mucous matter existed, and, even admitting its presence, to decide whether it was a cause or a result of the diseased action. Ammoniac is usually administered in combination with other expectorants, with tonics, or emmenagogues. It is much less used than formerly. Externally applied, in the shape of a plaster, it is thought to be useful as a discutient or resolvent in white swellings of the joints, and other indolent tumours. (See *Emplastrum Ammoniaci.*) It is given in substance, in the shape of pill or emulsion. The latter form is preferable. (See *Mistura Ammoniaci.*) The dose is from ten to thirty grains.

AMYGDALUS. *Sex. Syst.* Icosandria Monogynia.—*Nat. Ord.* Amygdaleæ.

Gen. Ch. Calyx five-cleft, inferior. *Petals* five. *Drupe* with a nut perforated with pores. *Willd.*

Amygdalus communis. Willd. *Sp. Plant.* ii. 982; Woodv. *Med. Bot.* p. 507, t. 183. The almond-tree rises usually from fifteen to twenty feet in height, and divides into numerous spreading branches. The leaves stand upon short footstalks, are about three inches long, and three-quarters of an inch broad, elliptical, pointed at both ends, veined, minutely serrated, with the lower serratures and petioles glandular, and are of a bright-green colour. The flowers are large,

of a pale-red colour varying to white, with very short peduncles, and petals longer than the calyx, and usually stand in pairs upon the branches. The fruit is of the peach kind, with the outer covering thin, tough, dry, and marked with a longitudinal furrow, where it opens when fully ripe. Within this covering is a rough shell, containing the kernel or almond.

There are several varieties of this species of Amygdalus, differing chiefly in the size and shape of the fruit, the thickness of the shell, and the taste of the kernel. The two most important are *Amygdalus* (*communis*) *dulcis* and *Amygdalus* (*communis*) *amara*, the former bearing sweet, the latter bitter almonds. Another variety is the *fragilis* of De Candolle, which yields the *soft-shelled almonds*.

The almond-tree is a native of Persia, Syria, and Barbary, and is very extensively cultivated in various parts of the south of Europe. It has been introduced into the United States; but in the northern and middle sections the fruit does not usually come to perfection. We are supplied with sweet almonds chiefly from Spain and the south of France. They are distinguished into the soft shelled and hard-shelled, the former of which come from Marseilles and Bordeaux, the latter from Malaga. From the latter port they are sometimes brought to us without the shell. In British commerce, the two chief varieties are the *Jordan* and *Valencia* almonds, the former imported from Malaga, the latter from Valencia.* The former are longer, narrower, more pointed, and more highly esteemed than the latter. The bitter almonds are obtained chiefly from Morocco, and are exported from Mogador.

Properties. The shape and appearance of almonds are too well known to require description. Each kernel consists of two white cotyledons, enclosed in a thin, yellowish-brown, bitter skin, which is easily separable after immersion in boiling water. Deprived of this covering, they are called *blanched almonds*. On exposure to the air, they are apt to become rancid; but, if thoroughly dried, and kept in well closed glass vessels, they may be preserved unaltered for many years. The two varieties require each a separate notice.

1. Amygdala Dulcis. *Sweet Almonds.* These are without smell when blanched, and have a sweet, very pleasant taste, which has rendered them a favourite article of diet in all countries where they are readily attainable. They are, however, generally considered of difficult digestion. By the analysis of M. Boullay, it appears that they contain, in 100 parts, 5 parts of pellicle, 54 of fixed oil, 24 of albumen, 6 of uncrystallizable sugar, 3 of gum, 4 of fibrous matter, 3·5 of water, and 0·5 of acetic acid comprising loss. The albumen is somewhat peculiar, and is called *emulsin*. It may be obtained separate by treating the emulsion of almonds with ether, allowing the mixture, after frequent agitation, to stand until a clear fluid separates at the bottom of the vessel, drawing this off by a syphon, adding alcohol to it so as to precipitate the emulsin, then washing the precipitate with fresh alcohol, and drying it under the receiver of an air-pump. In this state it is a white powder, inodorous and tasteless, soluble in water, and insoluble in ether and alcohol. Its solution has an acid reaction, and, if heated to 212°, becomes opaque and milky, and gradually deposits a snow-white precipitate, amounting to about 10 per cent. of the emulsin employed. (*Am. Journ. of Pharm.*, xxi. 354, from *Liebig's Annalen.*) Its distinguishing property is that of producing certain changes, presently to be noticed, in amygdalin, which property it loses when its solution is boiled, though not by exposure in the solid state to a heat of 212°. (*Ibid.*, 357.) It consists of nitrogen, carbon, hydrogen, and oxygen, with a minute proportion of sulphur, and is probably identical with the

* Upon a visit to Spain, in the winter of 1860–61, the author was informed, when at Valencia, that the thin, paper-shelled almonds, exported from that town, were produced, not in the immediate neighbourhood of Valencia, but chiefly in the Balearic Islands, and the Province of Alicante, whence they are sent to that port; and, in a journey through the interior from Valencia to Alicante, he noticed that the almond-tree, then in full bloom, was very abundant in the region back of the latter city, while there were comparatively few near the former. (*Note to the twelfth edition.*)

synaptase of Robiquet. The fixed oil is described under the head of *Oleum Amygdalæ*, to which the reader is referred. Almonds, when rubbed with water, form a milky emulsion, the insoluble matters being suspended by the agency of the albuminous, mucilaginous, and saccharine principles.

2. AMYGDALA AMARA. *Bitter Almonds.* These are smaller than the preceding variety. They have the bitter taste of the peach kernel, and, though when dry inodorous or nearly so, have, when triturated with water, the fragrance of the peach blossom. They contain the same ingredients as sweet almonds, and like them form a milky emulsion with water. It was formerly supposed that they also contained hydrocyanic acid and volatile oil, to which their peculiar taste and smell, and their peculiar operation upon the system were ascribed. It was, however, ascertained by MM. Robiquet and Boutron that these principles do not pre-exist in the almond, but result from the reaction of water; and Wöhler and Liebig proved, what was suspected by Robiquet, that they are formed out of a peculiar substance denominated *amygdalin*, which is the characteristic constituent of bitter almonds. This substance, which was discovered by Robiquet and Boutron, is white, crystallizable, inodorous, of a sweetish-bitter taste, unalterable in the air, freely soluble in water and hot alcohol, very slightly soluble in cold alcohol, and insoluble in ether. Its elementary constituents are nitrogen, carbon, hydrogen, and oxygen; and it is supposed to be an *amide*; as, when treated with an alkali, it yields ammonia, and a peculiar acid which has been named *amygdalic acid*. Liebig and Wöhler recommend the following process for procuring it, in which the object of the fermentation is to destroy the sugar with which it is associated. Bitter almonds, previously deprived of their fixed oil by pressure, are to be boiled in successive portions of alcohol till exhausted. From the liquors thus obtained all the alcohol is to be drawn off by distillation; care being taken, near the end of the process, not to expose the syrupy residue to too great a heat. This residue is then to be diluted with water, mixed with good yeast, and placed in a warm situation. After the fermentation which ensues has ceased, the liquor is to be filtered, evaporated to the consistence of syrup, and mixed with alcohol. The amygdalin is thus precipitated in connection with a portion of gum, from which it may be separated by solution in boiling alcohol, which will deposit it upon cooling. If pure, it will form a perfectly transparent solution with water. Any oil which it may contain may be separated by washing it with ether. One pound of almonds yields at least 120 grains of amygdalin. (*Annalen der Pharm.*, xxii. and xxiii. 329)*

Amygdalin, mixed with emulsion of *sweet* almonds, gives rise, among other products, to the volatile oil of bitter almonds and hydrocyanic acid—the emulsin of the sweet almonds acting the part of a ferment, by causing a reaction between the amygdalin and water; and the same result is obtained when pure *emulsin* is added to a solution of amygdalin. It appears then that the volatile oil and hydrocyanic acid, developed in bitter almonds when moistened, result from the mutual reaction of amygdalin, water, and emulsin. Certain substances have the effect of preventing this reaction, as, for example, alcohol and acetic acid. It is asserted that emulsin procured from other seeds, as those of the poppy, hemp, and mustard, is capable of producing the same reaction between water and amygdalin, though in a less degree. (*Annal. der Pharm.*, xxviii. 290.) Amygdalin appears not to be poisonous when taken pure into the stomach; as there is nothing in the system capable of acting the part of emulsin. Nevertheless, large quantities given to a dog have produced narcotic effects.

Bitter almonds yield their fixed oil by pressure; and the volatile oil, impreg-

* Amygdalin appears to be extensively diffused in plants, having been noticed not only in the different genera of the Amygdaleæ, as *Amygdalus*, *Cerasus*, and *Prunus*, but also by Wicke in various Pomaceæ, as *Pyrus Malus*, *Sorbus Aucuparia*, *Sorbus hybrida*, *Sorbus torminalis*, *Amelanchier vulgaris*, *Cotoneaster vulgaris*, and *Crataegus Oxycantha*. (*Ann. der Chem. und Pharm.*, lxxix. 79.) It may be advantageously procured from peach kernels, which have been found to yield 80 grains for each avoirdupois pound, or more than 1 per cent. (*Am. Journ. of Pharm.*, xxvii. 227.)

nated with hydrocyanic acid, may be obtained from the residue by distillation with water. (See *Oleum Amygdalæ Amaræ.*)

Confectioners employ bitter almonds for communicating flavour to the syrup of orgeat. (See *Syrupus Amygdalæ.*) The kernel of the peach possesses similar properties, and is frequently used as a substitute. It has been ascertained that bitter almond paste, and other substances which yield the same volatile oil, such as bruised cherry-laurel leaves, peach leaves, &c., have the property of destroying the odour of musk, camphor, most of the volatile oils, creasote, cod-liver oil, the balsams, &c.; and M. Mahier, a French pharmaceutist, has employed them successfully to free mortars and bottles from the odour of assafetida, and other substances of disagreeable smell. All that is necessary is first to remove any oily substance by means of an alkali, and then to apply the paste or bruised leaves. (*Am. Journ. of Pharm.*, xviii. 209.)

Medical Properties and Uses. Sweet almonds have no other influence on the system than that of a nutrient and demulcent. The emulsion formed by triturating them with water is a pleasant vehicle for the administration of other medicines, and is itself useful in catarrhal affections. From their nutritive properties, and the absence of starch in their composition, they have been recommended by Dr. Pavy as an ingredient in the diet of diabetic patients. (*Guy's Hosp. Rep.*, 1862, p. 213.) Bitter almonds are more active, and might be employed with advantage in cases to which hydrocyanic acid is applicable. An emulsion made with them has proved useful in pectoral affections with cough, and is said to have cured intermittents. It probably operates by diminishing the excitability of the nervous centres. Dr. A. T. Thomson found it useful as a lotion in acne rosea and impetigo. Bitter almonds are said by Hufeland to have been successfully employed for the expulsion of the tape-worm. In some persons they produce urticaria, in the smallest quantities. Largely taken, they have sometimes proved deleterious. Landerer mentions the case of a lady, who was alarmingly affected by a bath, made from the residue of bitter almonds after expression of the fixed oil. (See *Am. Journ. of Pharm.*, xxviii. 321.)

Wöhler and Liebig propose, as a substitute for cherry-laurel water, which owes its effects to the hydrocyanic acid it contains, but is objectionable from its unequal strength, an extemporaneous mixture, consisting of seventeen grains of amygdalin, and one fluidounce of an emulsion made with two drachms of *sweet* almonds, and a sufficient quantity of water. This mixture contains, according to the above named chemists, one grain of anhydrous hydrocyanic acid, and is equivalent to two fluidounces of fresh cherry-laurel water. If found to answer in practice, it will have the advantage of certainty in relation to the dose; as amygdalin may be kept any length of time unaltered. If the calculation of Wöhler and Liebig is correct as to the quantity of acid it contains, not more than a fluidrachm should be given as a commencing dose.

AMYLUM. *U. S., Br.*

Starch.

The fecula of the seed of Triticum vulgare. *U. S.* The starch procured from the seeds of common wheat, Triticum vulgare. *Br.*

Amidon, *Fr.;* Stärkmehl, *Germ.;* Amido, *Ital.;* Almidon, *Span.*

Starch is a proximate vegetable principle contained in most plants, and especially abundant in the various grains, such as wheat, rye, barley, oats, rice, maize, &c.; in other seeds, as peas, beans, chestnuts, acorns, &c; and in numerous tuberous roots, as those of the potato (*Solanum tuberosum*), the sweet potato (*Convolvulus Batatus*), the arrow-root, the cassava plant, and different species of Curcuma. The process for obtaining it consists essentially in reducing

the substances in which it exists to a state of minute division, agitating or washing them with cold water, straining or pouring off the liquid, and allowing it to stand till the fine fecula which it holds in suspension has subsided. This, when dried, is starch, more or less pure, according to the care taken in conducting the process. The starch of commerce is procured chiefly from wheat, sometimes also from potatoes. Our space will not allow us to enter into details in relation to the particular steps of the operation to which those substances are subjected; and the omission is of less consequence, as starch is never prepared by the apothecary.

Starch is white, pulverulent, opaque, and, as found in the shops, is usually in columnar masses, having a somewhat crystalline aspect, and producing a peculiar sound when pressed between the fingers. Its specific gravity is 1·505 at 67° F. (*Payen.*) When exposed to a moist air, it absorbs a considerable quantity of water, which may be driven off by a gentle heat. It is insoluble in alcohol, ether, and cold water; but unites with boiling water, which, on cooling, forms with it a soft semi-transparent paste, or a gelatinous opaline solution, according to the proportion of starch employed. The paste placed on folds of blotting paper, renewed as they become wet, abandons its water, contracts, and assumes the appearance of horn. If the proportion of starch be very small, the solution, after slowly depositing a very minute quantity of insoluble matter, continues permanent, and upon being evaporated yields a semi-transparent mass, which is partially soluble in cold water. The starch has, therefore, been modified by the combined agency of water and heat; nor can it be restored to its original condition. Exposed, in the dry state, to a temperature somewhat above 212°, it undergoes, according to Caventou, a similar modification; and a degree of heat sufficient to roast it slightly converts it into a substance soluble in cold water, called *British gum*, and applicable to the same purposes as gum in the arts.* The same change in regard to solubility is, to a certain extent, produced by mechanical means, as by trituration in a mortar; and that the effect is not the result of heat evolved by friction is evinced by the fact, that it takes place when the starch is triturated with water.

Iodine forms with starch, whether in its original state or in solution, a blue compound; and the tincture of iodine is the most delicate test of its presence in any mixture. The colour varies somewhat according to the proportions employed. When the two substances are about equal, the compound is of a beautiful indigo-blue; if the iodine is in excess, it is blackish-blue; if the starch, violet-blue. A singular property of the iodide of starch is that its solution becomes colourless if heated to about 200°, and afterwards recovers its blue colour upon cooling. By boiling, the colour is permanently lost. Alkalies unite with starch, forming soluble compounds, which are decomposed by acids, the starch being precipitated. It is thrown down from its solution by lime-water and baryta-water, forming insoluble compounds with these earths. The solution of subacetate of lead precipitates it in combination with the oxide of the metal. Starch may be made to unite with tannin by boiling their solutions together; and a compound results, which, though retained by the water while hot, is deposited when it cools. By long boiling with diluted sulphuric, muriatic, or oxalic acid, it is converted into *dextrin*† and glucose or grape sugar. A simi-

* The chief constituent of this substance is dextrin; but there is also produced another substance to which it owes its brown colour, and for which M. Gélis proposes the name *pyrodextrin*. This is solid, black, insipid, inodorous, insoluble in alcohol or ether, but readily dissolved by water, with which it forms a viscid solution. It is always produced when substances containing much starch are exposed to a high heat. (*Journ. de Pharm.*, 3e sér., xxxiii. 405.)—*Note to the twelfth edition.*

† *Dextrin* is a substance resembling gum in appearance and properties, but differing from it in not affording mucic acid by the action of nitric acid. It is largely dissolved by water, hot or cold, and forms a mucilaginous solution, from which it is precipitated by alcohol. This fluid has no action on dextrin. Large quantities of dextrin are now manufactured in England, and employed for various purposes in the arts, under the name of *artificial gum*. It is found in the market in the form of mucilage, in that of a white bril-

lar conversion into dextrin and glucose is effected by means of a principle called *diastase*, discovered by MM Payen and Persoz in the seeds of barley, oats, and wheat, after germination. (See *Hordeum.*) Strong muriatic and nitric acids dissolve it; and the latter, by the aid of heat, converts it into oxalic and malic acids. By the action of strong nitric, sulphuric, or crystallizable acetic acid, used with certain precautions, the starch is rendered soluble, and may be obtained in this state by separating the acid by means of alcohol. (*Chem. Gaz.*, Dec 1, 1854, p. 450.) By the continued action of concentrated sulphuric acid it is decomposed. When it is dissolved in strong nitric acid, and precipitated by water, a white powder is thrown down, called *xyloidin*, in which one equivalent of the hydrogen of the starch is replaced by one eq. of hyponitric acid (NO_4); the formula of xyloidin being, according to Bechamp and Laurent, $C_{12}H_9NO_{14}$. Mixed with hot water, and exposed to a temperature of 70° or 80°, it undergoes chemical changes, which result in the formation of several distinct principles, among which are sugar, a gummy substance (perhaps *dextrin*), and a modification of starch which De Saussure called *amidine*. With yeast starch undergoes the vinous fermentation, being, however, first converted into sugar. Mixed with cheese and chalk it is said to yield alcohol without the previous saccharine conversion. (Berthelot, *Journ. de Pharm.*, 3e ser., xxxii. 260.)

Nature of Starch. The views now generally entertained in relation to starch, by which the above-mentioned phenomena may be most conveniently explained, are those originally presented by Raspail, and subsequently confirmed and extended by Guibourt, Guérin, and others. According to these views, starch consists of organized granules, which, examined by the microscope, appear to be of various form and size. Different opinions have been held as to the precise structure of the granules. The one first adopted is that they consist of a thin exterior coating, and of an interior substance; the former wholly insoluble, the latter soluble in water. The former constitutes, according to M. Payen, only 4 or 5 thousandths of the weight of starch. In relation to the interior portion, there is not an exact coincidence of opinion. M. Guérin supposed that it consisted of two distinct substances, one soluble in cold water, the other soluble at first in boiling water, but becoming insoluble by evaporation. Thus, when one part of starch is boiled for fifteen minutes in one hundred parts of water, and the liquid is allowed to stand, a small portion, consisting of the broken teguments, is gradually deposited. If the solution be now filtered and evaporated, another portion is deposited which cannot afterwards be dissolved. When wholly deprived of this portion, and evaporated to dryness, the solution yields the part soluble in cold water. According to MM. Payen and Persoz, the interior portion of the globules consists only of a single substance, which is converted into the two just mentioned by the agency of water; and Thenard is inclined to the same opinion. An appropriate name for the interior soluble portion of starch is *amidin*, which has been adopted by some chemists. Starch, in its perfect state, is not affected by cold water, because the exterior insoluble teguments prevent the access of the liquid to the interior portion; but, when the pellicle is broken by the agency of heat, or by mechanical means, the fluid is admitted, and the starch partially dissolved.

Another view of the structure of the starch granule, founded on microscopic observation, has been advanced by Schleiden. According to this view, it consists of concentric layers, all of which have the same chemical composition;

liant powder, and in small masses or fragments resembling natural gum. According to M. Emile Thomas, it may be distinguished from gum arabic by the taste and smell of potato oil which it always possesses. It is made by the action either of acids or of diastase on starch. For particulars as to the manufacture, the reader is referred to a paper by M. Thomas, republished in the *American Journal of Pharmacy* (vol. xix. p. 284).

Dextrin, according to Payen, is converted into glucose, through the action of diastase; but the glucose impedes the action unless removed; as, however, during the alcoholic fermentation, the glucose is consumed, no obstacle prevents the influence of diastase. Hence dextrin by conversion into sugar may contribute to the alcoholic product. (*Journ. de Pharm.*, 4e sér., i. 363.)—*Note to the thirteenth edition.*

but the outer layers, having been first formed, have more cohesion than the inner, and are consequently more difficult of solubility. The rings observed upon the surface of the granules, in some varieties, are merely the edges of these layers; and the point or hylum about which the rings are concentrically placed, is a minute hole, through which probably the substance of the interior layers was introduced. (*Pharm. Central Blatt*, 1844, p. 401.)

Mr. J. J. Field thinks he has demonstrated that the granule consists, as at first supposed, of an interior matter surrounded by a distinct membranous envelope. Having saturated some canna starch with glycerin, and then added a little water, an endosmose of the thinner outer liquid took place into the granules, distending them so as to rupture their investing membrane, which was distinctly visible, under the microscope, in longitudinal wrinkles. The concentric rings he thinks nothing more than folds of the membrane, produced probably by the contraction of the granules. (*Pharm. Journ.*, xiv. 253.) The idea has been advanced that the starch granule is a true vegetable cell with a nucleus, which surrounds itself by a cell-wall, which then secretes the contents of the cell in successive layers. This view combines that of Schleiden with that of Raspail. (Grundy, *Ibid.*, p. 447.) In accordance with it, the hylum may be considered as the effete nucleus in the cell-wall. The cell-wall has been supposed to have a different composition from the interior; as, when separated, as above stated, by the action of boiling water, which leaves it alone undissolved, it is not coloured blue by iodine. (*Ibid.*, p. 448.) If the granule be really a cell, it probably contains nitrogenous matter; and this may exist in the envelope. This idea is supported by the fact that, when treated with boiling solution of potassa, starch gives out a little nitrogen in the state of ammonia. (*Journ. de Pharm.*, Juin, 1855, p. 409.)

The tegumentary portion of starch, for which the name of *amylin* has been proposed, is, when entirely freed from the interior soluble matter, wholly insoluble in water even by prolonged boiling, insoluble in alcohol, and said to suffer no change by the action of diastase. The acids, however, act upon it as they do upon starch. It is thought to approach nearer in properties to lignin than to any other principle.

Varieties. Starch, as obtained from different substances, is somewhat different in its characters. *Wheat starch*, when examined with a microscope, is found to consist of granules of various sizes, the smaller being spheroidal, the larger rounded and flattened, with the hylum in the centre of the flattened surface, and surrounded by concentric rings, which often extend to the edge. The granules are mixed with loose integuments, resulting from the process of grinding. This variety of starch has a certain degree of hardness and adhesiveness, owing, according to Guibourt, to the escape of a portion of the interior substance of the broken granules, which attracts some moisture from the air, and, thus becoming glutinous, acts as a bond between those which remain unbroken. Another opinion attributes this peculiar consistence to the retention of a portion of the gluten of the wheat flour, which causes the granules to cohere. Under the name of *corn starch*, a variety of fecula obtained from the meal of maize or Indian corn, is much used for nutritive purposes in the U. States. It is an excellent preparation. The granules of maize starch are very small, with a diameter not exceeding, according to Payen, one-sixth of that of the potato, and little more than one-half that of the wheat granules. (*Gmelin*, xv. 79.) *Potato starch* is employed in various forms, being prepared so as to imitate more costly amylaceous substances, such as arrow-root and sago. In its ordinary state, it is more pulverulent than wheat starch, has a somewhat glistening appearance, and may be distinguished, with the aid of the microscope, by the size of its granules, which are larger than those of any other known fecula, except canna or *tous les mois*. They are exceedingly diversified in size and shape, though their regular form is thought to be ovate. They are characterized by concentric rings or rugæ, which are most readily distinguishable in the fresh starch, and are said by Raspail to disappear upon desiccation. These surround a minute circular hole or hylum upon the

surface of the granule. In some instances there are two of these holes, one at each end, or both at the same end. The characters of other kinds of fecula will be given under the heads of the several officinal substances of which they constitute the whole or a part. Starch consists of carbon, hydrogen, and oxygen; its formula, from whatever source it may be derived, being, according to the latest opinions, $C_{12}H_{10}O_{10}$, or, doubling the numbers, $C_{24}H_{20}O_{20}$.

According to Chevallier, starch is sometimes adulterated with carbonate and sulphate of lime; and the fraud is also practised of saturating it with moisture, of which it will absorb 12 per cent. without any obvious change.

Medical Properties, &c. Starch is nutritive and demulcent, but in its ordinary form is seldom administered internally. Powdered and dusted upon the skin, it is sometimes used to absorb irritating secretions, and prevent excoriation. Dissolved in hot water and allowed to cool, it is often employed in enemata, either as a vehicle of other substances, or as a demulcent application in irritated states of the rectum. It may be used as an antidote to iodine taken in poisonous quantities.*

ANETHI FRUCTUS. *Br.*

Dill Fruit.

The fruit of Anethum graveolens. *Br.*

OLEUM ANETHI. *Br.*

Oil of Dill.

The oil distilled in Britain from dill fruit.

Aneth à odeur forte, *Fr.;* Dill, *Germ.;* Aneto, *Ital.;* Eneldo, *Span.*

Anethum. *Sex. Syst.* Pentandria Digynia. —*Nat. Ord.* Umbelliferæ or Apiaceæ.

Gen. Ch. Fruit nearly ovate, compressed, striated. *Petals* involuted, entire. *Willd.*

Anethum graveolens. Willd. *Sp. Plant* i. 1469; Woodv. *Med. Bot.* p. 125, t. 48. Dill is an annual plant, three or four feet high, with a long spindle-shaped root; an erect, striated, jointed branching stem; and bipinnate or tripinnate, glaucous leaves, which stand on sheathing footstalks, and have linear and pointed leaflets. The flowers are yellow, and in large, flat, terminal umbels, destitute of involucre. The plant is a native of Spain, Portugal, and the south of France; and is found growing wild in various parts of Africa and Asia. It is cultivated in all the countries of Europe, and has been introduced into our gardens. The seeds, as the fruit is commonly called, are the only part used. They are usually rather more than a line in length, and less than a line in breadth, of an oval shape, thin, concave on one side, convex and striated on the other, of a brown colour, and surrounded by a yellowish membranous expansion. Their smell is strong and aromatic, but less agreeable than that of fennel seed; their taste, moderately warm and pungent. These properties depend on a volatile oil, which may be obtained separate by distillation. The bruised seeds impart their virtues to alcohol and to boiling water.

**Glycerate of Starch.* A preparation which may be thus denominated (*Glycerolé d'Amidon* Fr.) has been recommended as a substitute for unctuous preparations, whether as a demulcent application, or as an excipient of other substances, such as sulphate of copper, corrosive sublimate, red oxide of mercury, &c., intended for external use; its advantage being that it is not likely to become irritant to the surface through chemical change. It may be prepared by heating together 15 parts of glycerin and one of starch, with constant stirring until the mixture becomes clear. (*Journ. de Pharm.*, Mai, 1862, p. 363.) We propose the word *glycerate* for the title of solutions in which glycerin is the menstruum, as preferable to *glycerole*, perverted from the French *glycerolé*, and inappropriate, as words with this termination are used to designate a class of organic proximate principles, as *benzole*, &c. (*Note to the twelfth edition.*)

Oil of dill is of a pale-yellow colour, with the odour of the fruit, and a hot, sweetish, acrid taste. Its sp. gr. is said to be 0·881. The fruit yields about 3·5 per cent. of it. The oil is sometimes used for preparing dill water.

Medical Properties. Dill seeds have the properties common to the aromatics, but are very seldom used in this country. They may be given in powder or infusion. The dose of the fruit is from fifteen grains to a drachm, of the oil three or four drops.

Off. Prep. of Dill. Aqua Anethi, *Br.* W.

ANGELICA. *U. S. Secondary.*

Angelica.

The root of Angelica Archangelica. *U. S.*

Angelique, *Fr.;* Engelwurzel, *Germ.;* Arcangelica, *Ital.;* Angelica, *Span.*

Angelica. *Sex. Syst.* Pentandria Digynia. — *Nat. Ord.* Umbelliferæ or Apiaceæ.

Gen. Ch. Fruit elliptic, compressed, somewhat solid and corticate, ridges 3, dorsal acute, intervals grooved, margin alated. *Gen. involucre* none. (*Sprengel.*) *Umbel* large, many-rayed, spreading; *umbellet* dense, subhemispheric; *involucell* about eight-leaved. *Calyx* five-toothed. *Petals* inflected. (*Nuttall.*)

In former editions of the U. S. Pharmacopœia it was our indigenous species, *Angelica atropurpurea*, which was recognised under the name of *angelica*, in the secondary list. In the present edition this species has been rejected, and the root of the European A. Archangelica substituted. It nevertheless deserves a brief notice here. *Angelica atropurpurea*, sometimes called *masterwort*, has a perennial purplish root, and a smooth herbaceous stem, the dark colour of which has given rise to its specific name. The leaves are ternate, and supported by very large inflated petioles. The partitions of the leaf are nearly quinate, with ovate, acute, deeply serrate, somewhat lobed leaflets, of which the three terminal are confluent. The flowers are greenish-white. The purple angelica extends throughout the United States from Canada to Carolina, growing in meadows and marshy woods, and flowering in June and July. It is smaller than *A. Archangelica*, with a less succulent stem. The whole plant was officinal. It has a strong odour, and a warm aromatic taste. The juice of the recent root is acrid, and is said to be poisonous; but the acrimony is dissipated by drying. The medical virtues of the plant are similar to those of the garden angelica of Europe, for which it has been proposed as a substitute. It is, however, little employed. An infusion is occasionally used in flatulent colic; and we are told that the stems are sometimes candied by the country people.

Angelica Archangelica. Willd. *Sp. Plant.* i. 1428; Woodv. *Med. Bot.* p. 86, t. 35. — *Archangelica officinalis.* Hoch, De Cand., &c. *Garden Angelica* has a long, thick, fleshy, biennial root, furnished with many fibres, and sending up annually a hollow, jointed, round, channeled, smooth, purplish stem, which rises five feet or more in height, and divides into numerous branches. The leaves, which stand upon round fistulous footstalks, are very large, doubly pinnate, with ovate-lanceolate, pointed, acutely serrate leaflets, the terminal being three-lobed. The flowers are small, greenish-white, and disposed in very large, many-rayed, terminal umbels, composed of numerous dense, hemispherical umbellets.

This plant is a native of the north of Europe, and is found in the high mountainous regions in the southern section of that continent, as in Switzerland and among the Pyrenees. It is cultivated in various parts of Europe, and may be occasionally met with in the gardens of this country. It flowers during the summer. The whole plant has a fragrant odour and aromatic properties; but the root and fruit only are officinal.

1. The *root* should be dug up in the autumn of the first year, as it is then least liable to become mouldy and worm-eaten. It is spindle-shaped, an inch or more thick at top, and beset with long descending radicles. The fresh root has

a yellowish-gray epidermis, a fleshy yellow parenchyma, and when wounded yields a honey-coloured juice, having all the aromatic properties of the plant. The dried root is grayish-brown and much wrinkled externally, whitish and spongy within, and breaks with a starchy fracture, exhibiting shining resinous points. It is very apt to be attacked by worms, and is said to keep best, in the state of powder, in full and well-closed vessels. The smell is strong and fragrant, and the taste at first sweetish, afterwards warm, aromatic, bitterish, and somewhat musky. These properties are extracted by alcohol, and less perfectly by water. The constituents of the root, according to the younger Buchner, are volatile oil, a volatile acid which he calls *angelicic acid*, a wax-like substance, a crystallizable sub-resin, a brittle amorphous resin, a bitter principle, tannic acid, malic acid, sugar, starch, albumen, pectic acid, fibrin, and various salts Five hundred parts yield nearly four parts of volatile oil.

2. The *seeds*, as the fruit is commonly called, are two or three lines long, oval, obtuse or somewhat notched at the ends, flat, with a longitudinal furrow on one side, convex with three angular ridges on the other. They are ash-coloured, and have the smell and taste of the root. They are said to keep well.

Medical Properties. Garden angelica is an elegant aromatic tonic, but is little employed in the United States. The Laplanders, in whose country it flourishes, esteem it highly as a condiment and medicine. In Europe, the stems are frequently made into a preserve, and used in desserts in order to excite the stomach. The dose of the root or seeds is from thirty grains to a drachm. W.

ANGUSTURA. *U. S.*

Angustura.

The bark of Galipea officinalis (*Hancock*). *U. S.*

Off. Syn. CUSPARIÆ CORTEX. The bark of Galipea Cusparia. *Br.*

Angusture, *Fr.;* Angusturarinde, *Germ.;* Corteccia dell' Angustura, *Ital.;* Corteza de Angostura, *Span.*

The subject of Angustura bark, in its botanical relations, has been involved in some confusion. The drug was at first supposed to be derived from a species of Magnolia, and was referred by some to *Magnolia glauca* of this country. Humboldt and Bonpland were the first to throw light upon its true source. When at Angustura, a South American city on the Orinoco, they received specimens of the foliage of the plant from which the bark was obtained; and afterwards believed that they had found the same plant in a tree growing in the vicinity of Cumana. This latter they had the opportunity of personally inspecting, and were therefore enabled to describe accurately. Unable to attach it to any known genus, they erected it into a new one, with the title of *Cusparia*, a name of Indian origin, to which they added the specific appellation of *febrifuga*. On their authority, *Cusparia febrifuga* was generally believed to be the true source of the medicine, and was recognised as such by the London College. A specimen having in the mean time been sent by them to Willdenow, the name of *Bonplandia* was imposed on the new genus by that celebrated botanist; and it was subsequently adopted by Humboldt and Bonpland themselves, in their great work on equinoctial plants. Hence the title of *Bonplandia trifoliata*, by which the tree is described in many works on Materia Medica. De Candolle, however, having found in the description all the characters of the genus *Galipea* of Aublet, rejected both these titles, and substituted that of *Galipea Cusparia*, which was adopted by the London College, and has been retained in the British Pharmacopœia. But, after all these commutations, it appears from the researches of Dr. Hancock, who resided for several months in the country of the Angustura bark tree, that the plant described by Humboldt and Bonpland is not that which yields the medicine, but probably another species of the same genus. Among other striking differences between them is that of their size; the tree described by Humboldt and Bonpland being not less than sixty or eighty feet in height, while that from which the bark is obtained is never more

than twenty feet. Hancock proposes for the latter the title of *Galipea officinalis*, which has been adopted in the U. S. Pharmacopœia.

GALIPEA. *Sex. Syst.* Diandria Monogynia. — *Nat. Ord.* Rutaceæ.

Gen. Ch. Corolla inferior, irregular, four or five cleft, hypocrateriform. *Stamens* four; two sterile. *Loudon's Encyc.*

Galipea officinalis. Hancock, *Trans. Lond. Medico-bot. Soc.* This is a small tree, irregularly branched, rising to the medium height of twelve or fifteen feet, with an erect stem from three to five inches in diameter, and covered with a smooth gray bark. The leaves are alternate, petiolate, and composed of three leaflets, which are oblong, pointed at each extremity, from six to ten inches in length, from two to four in breadth, and supported upon the common petiole by short leafstalks. They are very smooth and glossy, of a vivid green colour, marked occasionally with small whitish round spots, and, when fresh, of a strong odour resembling that of tobacco. The flowers are numerous, white, arranged in axillary and terminal peduncled racemes, and of a peculiar unpleasant odour. The fruit consists of five bivalve capsules, of which two or three are commonly abortive. The seeds, two of which are contained in each capsule, one often abortive, are round, black, and of the size of a pea. The tree grows abundantly on the mountains of Carony, between the 7th and 8th degrees of N. latitude; and is well known in the missions, near the Orinoco, upwards of two hundred miles from the ocean. It flourishes at the height of from six hundred to one thousand feet above the level of the sea. Its elegant white blossoms, which appear in vast profusion in August and September, add greatly to the beauty of the scenery.

The bark is generally brought from the West Indies, packed in casks; but, according to Mr. Brande, the original package, as it comes from Angustura, consists of the leaves of a species of palm, surrounded by a network of sticks.

Properties. The pieces are of various lengths, for the most part slightly curved, rarely quilled, sometimes nearly flat, from half a line to a line or more in thickness, pared away towards the edges, covered externally with a light yellowish-gray or whitish wrinkled epidermis, easily scraped by the nail, and internally of a yellowish-fawn colour. They are very fragile, breaking with a short, resinous fracture, and yield, on being pulverized, a pale-yellow powder; but, when macerated for a short time in water, they become soft and tenacious, and may be cut into strips with scissors. The cut surface usually exhibits under the microscope numerous white points or minute lines. *Br.* The smell of Angustura bark is peculiar and disagreeable when fresh, but becomes fainter with age; the taste is bitter and slightly aromatic, leaving a sense of pungency at the end of the tongue. According to Fischer, it contains volatile oil, bitter extractive, a hard and bitter resin, a soft resin, a substance analogous to caoutchouc, gum, lignin, and various salts. The volatile oil, which may be obtained by distillation with water, is of a pale-yellowish colour, lighter than water, of an acrid taste, and with the odour of the bark. Its formula is given as $C_{13}H_{12}O$ by Dr. C. Herzog, who states that its boiling point is 511° F., probably one of the highest of the volatile oils. (*Chem. Gaz.*, May 15, 1858.) *Cusparin* is the name given by Saladin to a principle, deposited in tetrahedral crystals, when an infusion of the bark is treated with absolute alcohol, at common temperatures, and allowed to evaporate spontaneously. It is neutral, fusible at a gentle heat, by which it loses 23·09 per cent. of its weight, soluble in 200 parts of cold and 100 parts of boiling water, soluble in the concentrated acids and in the alkalies, and precipitated by the infusion of galls. (*Journ. de Pharm.*, xxii. 662.) Herzog was unable to isolate this principle. The virtues of the bark reside in the volatile oil and bitter constituent, and are extracted by water and alcohol.

Dr. A. T. Thomson states that precipitates are produced with the infusion by the solutions of sulphate of iron, tartrate of antimony and potassa, sulphate of copper, acetate and subacetate of lead, bichloride of mercury, nitrate of silver, and pure potassa; by nitric and sulphuric acids; and by the infusions of galls and yellow cinchona; but how far these substances are medicinally incompatible with the bark, it would be difficult to determine.

False Angustura. Under this title, European writers describe a bark which was introduced on the continent mixed with true Angustura bark, and, being possessed of poisonous properties, produced in some instances unpleasant effects, when dispensed by mistake for that medicine. It is distinguished by its greater thickness, hardness, weight, and compactness; by its resinous fracture; by the appearance of its epidermis, which is sometimes covered with a ferruginous efflorescence, sometimes is yellowish-gray, and marked with prominent white spots; by the brownish colour and smoothness of its internal surface, which is not, like that of the genuine bark, separable into laminæ; by the white slightly yellow powder which it yields; by its total want of odour, and its intense tenacious bitterness. When steeped in water, it does not become soft like the true Angustura. Analyzed by Pelletier and Caventou, it was found to contain a peculiar alkaline principle which they called *brucia*, and upon which its poisonous operation depends. (See *Nux Vomica.*) In consequence of the presence of this principle, a drop of nitric acid upon the internal surface of the bark produces a deep-red spot. The same acid, applied to the external surface, renders it emerald-green. In true Angustura bark, a dull-red colour is produced by the acid on both surfaces. The *false Angustura* was at first supposed to be derived from *Brucea antidysenterica;* and was afterwards referred to some unknown species of Strychnos, in consequence of containing *brucia*, which is a characteristic ingredient of that genus of plants. At present, it is ascribed to *Strychnos Nux Vomica*, the bark of which, according to Dr. O'Shaughnessy, exactly corresponds with the description of false Angustura, and like it contains brucia.

Medical Properties and Uses. Angustura bark had been long used by the natives of the countries where it grows, before it became known elsewhere. From the continent its employment extended to the West Indies, where it acquired considerable reputation. It was first taken to Europe about eighty years since. It is now ranked among the officinal remedies throughout Europe and America; but it has not sustained its early reputation, and in the United States is not much prescribed. Its operation is that of a stimulant tonic. In large doses it also evacuates the stomach and bowels, and is often employed for this purpose in South America. It was at one time considerably used as a febrifuge in the place of Peruvian bark; but has not been found generally successful in the intermittents of northern latitudes. It is said to be peculiarly efficacious in bilious diarrhœas and dysenteries; and has been recommended in dyspepsia and other diseases requiring a tonic treatment. The testimony, however, of practitioners in Europe and the United States is not strongly in its favour; and it is probably better adapted to tropical diseases than to those of temperate climates. Hancock employed it extensively in the malignant bilious intermittent fevers, dysenteries, and dropsies of Angustura and Demarara; and speaks in strong terms of its efficacy in these complaints. He used it in the form of fermented infusion, as recommended by the native practitioners.

It may be given in powder, infusion, tincture, or extract. The dose in substance is from ten to thirty grains. In larger quantities it is apt to produce nausea. From five to fifteen grains is the dose of the extract, which, however, according to Dr. Hancock, is inferior to the powder or infusion. To obviate nausea, it is frequently combined with aromatics.

Off. Prep. Infusum Angusturæ, *U. S.;* Infusum Cuspariæ, *Br.* W.

ANISUM. *U. S.*

Anise.

The fruit of Pimpinella Anisum. *U. S.*

Graines d'anis, *Fr.;* Anissame, *Germ.;* Semi d'aniso, *Ital.;* Simiente de anis, *Span.*, Anison, *Arab.*

Pimpinella. *Sex. Syst.* Pentandria Digynia. — *Nat. Ord.* Umbelliferæ or Apiaceæ.

Gen. Ch. Fruit ovate-oblong. *Petals* inferior. *Stigma* nearly globular. Willd

Pimpinella Anisum. Willd. *Sp. Plant.* i. 1473; Woodv. *Med. Bot.* p. 135, t. 52. This is an annual plant, about a foot in height, with an erect, smooth, and branching stem. The leaves are petiolate, the lower roundish-cordate, lobed, incised-serrate, the middle pinnate-lobed with cuneate or lanceolate lobes, the upper trifid, undivided, linear. The flowers are white, and in terminal compound umbels, destitute of involucres.

The anise plant is a native of Egypt and the Levant, but has been introduced into the south of Europe, and is cultivated in various parts of that continent. It is also cultivated occasionally in the gardens of this country. The fruit is abundantly produced in Malta and Spain, and especially so in Romagna, in Italy, whence it is largely exported through Leghorn. The Spanish is smaller than the German or French, and is usually preferred.

Anise seeds (botanically fruit) are about a line in length, oval, striated, somewhat downy, attached to their footstalks, and of a light greenish-brown colour, with a shade of yellow. Their odour is fragrant, and increased by friction; their taste, warm, sweet, and aromatic. These properties, which depend upon a peculiar volatile oil, are imparted sparingly to boiling water, freely to alcohol. The volatile oil exists in the envelope of the seeds, and is obtained separate by distillation. (See *Oleum Anisi.*) Their internal substance contains a bland fixed oil. By expression, a greenish oil is obtained, which is a mixture of the two. The seeds are sometimes adulterated with small fragments of argillaceous earth, which resembles them in colour; and their aromatic qualities are occasionally impaired by a slight fermentation, which they are apt to undergo in the mass, when collected before maturity.

A case of poisoning is on record from the accidental admixture of the fruits of Conium maculatum, which bear some resemblance to those of anise, but may be distinguished by their crenate or notched ridges. They are, moreover, broader in proportion to their length, and are generally separated into half-fruits, while those of anise are whole.

Star aniseed, the *badiane* of the French writers, though analogous in sensible properties to the common aniseed, is derived from a different plant, being the fruit of *Illicium anisatum*, an evergreen tree growing in China, Japan, and Tartary. The fruit consists of from five to ten brownish ligneous capsules, four or five lines long, united together in the form of a star, each containing a brown shining seed. It is much used in France to flavour liquors; and the volatile oil, upon which its aromatic properties depend, and of which it is said to yield about 2·3 per cent., is imported into this country from the East Indies, and sold as common oil of anise, to which, however, it is thought by some to be much superior.

Dr. Ruschenberger, U. S. N., has shown that oil of anise has a remarkable power of deodorizing sulphuret of potassium; a drop of the oil having entirely deprived of offensive odour a drachm of lard with which five grains of the sulphuret had been incorporated. (*Am. Journ. of Med. Sci.*, N. S., xlviii. 419.)

Medical Properties and Uses. Anise is a grateful aromatic carminative; and is supposed to have the property of increasing the secretion of milk. It has been in use from the earliest times. In Europe it is much employed in flatulent colic, and as a corrigent of griping or unpleasant medicines; but in this country fennel-seed is preferred. Anise may be given bruised, or in powder, in the dose of twenty or thirty grains or more. The infusion is less efficient. The volatile oil may be substituted for the seeds in substance. Much use is made of this aromatic for imparting flavour to liquors.

ANTHEMIS. *U. S.*

Chamomile.

The flowers of Anthemis nobilis. *U. S.*

Off. Syn. ANTHEMIDIS FLORES. *Chamomile Flowers.* The dried single and double flower heads of the common chamomile, Anthemis nobilis; wild and cultivated. *Br.*

Camomille Romaine, *Fr.;* Romische Kamille, *Germ.;* Camomilla Romana, *Ital.;* Manzanilla Romana, *Span.*

ANTHEMIS. *Sex. Syst.* Syngenesia Superflua. — *Nat. Ord.* Compositæ Senecionideæ. *De Cand.* Asteraceæ. *Lindley.*

Gen. Ch. Receptacle chaffy. *Seed-down* none or a membranaceous margin. *Calyx* hemispherical, nearly equal. *Florets of the ray* more than five. *Willd.*

Several species of Anthemis have been employed in medicine. *A. nobilis*, which is the subject of the present article, is by far the most important. *A. Cotula*, or mayweed, is also recognised by the U. S. Pharmacopœia. (See *Cotula.*) *A. Pyrethrum*, which affords the pellitory root, is among the officinal plants. (See *Pyrethrum.*) *A. arvensis*, a native of this country and of Europe, bears flowers which have an acrid bitter taste, and possess medical properties analogous though much inferior to those of common chamomile. They may be distinguished by their want of smell.* *A. tinctoria* is occasionally employed as a tonic and vermifuge in Europe.

Anthemis nobilis. Willd. *Sp. Plant.* iii. 2180; Woodv. *Med. Bot.* p. 47, t. 19. This is an herbaceous plant with a perennial root. The stems are from six inches to a foot long, round, slender, downy, trailing, and divided into branches, which turn upwards at their extremities. The leaves are bipinnate, the leaflets small, thread-like, somewhat pubescent, acute, and generally divided into three segments. The flowers are solitary, with a yellow convex disk, and white rays. The calyx is common to all the florets, of a hemispherical form, and composed of several small imbricated hairy scales. The receptacle is convex, prominent, and furnished with rigid bristle-like *paleæ*. The florets of the ray are numerous, narrow, and terminated with three small teeth. The whole herb has a peculiar fragrant odour, and a bitter aromatic taste. The flowers only are officinal.

This plant is a native of Europe, and grows wild in all the temperate parts of that continent. It is also largely cultivated for medicinal purposes. In France, Germany, and Italy, it is generally known by the name of *Roman chamomile.* By cultivation the yellow disk florets are often converted into the white ray florets. Thus altered, the flowers are said to be *double*, while those which remain unchanged are called *single;* but, as the conversion may be more or less complete, it generally happens that with each of the varieties there are intermingled some flowers of the other kind, or in different stages of the change. The double flowers are generally preferred; though, as the sensible properties are found in the greatest degree in the disk, the single are the most powerful. It is rather, however, in aromatic flavour than in bitterness that the radial florets are surpassed by those of the disk. If not well and quickly dried, the flowers lose their beautiful white colour, and are less efficient. Those which are whitest should be preferred. The seeds yield by expression a fixed oil, which is said to be applied in Europe to various economical uses.†

* M. Pattone, an apothecary in the civil hospital of Alexandria, has announced the discovery in Anthemis arvensis of a new alkaloid, and a new organic acid, which he proposes to call, respectively, *anthemine* (*anthemia*) and *anthemic acid.* The former he procured by subjecting the flowers to distillation with water so as to separate all the volatile oil, expressing the residue, filtering the expressed liquor, evaporating this to the consistence of an extract, exhausting the extract by boiling alcohol of 85°, which dissolves the resinous matter and the peculiar acid, treating the residue with boiling distilled water, filtering the liquor and allowing it to cool, and then dropping in solution of ammonia until the liquid became decidedly alkaline. After a short time, beautiful, shining, prismatic crystals were deposited. To complete the process, the liquor was allowed to stand for 24 hours, after which the mother-water was decanted, and the crystals washed repeatedly with cold distilled water. Anthemia is inodorous and tasteless, very slightly soluble in cold water, somewhat more soluble in boiling water, *insoluble in alcohol and ether*, but freely dissolved by acetic acid. It is carbonized by a high heat. (*Journ. de Pharm.*, Mars, 1859, p. 198.)—*Note to the twelfth edition.*

† To those who may be disposed to cultivate the flowers for the shops, the following statements made by Mr. Jacob Bell, from observations at the flower gardens at Mitcham, in Surrey, England, may not be without interest. The plant is usually propagated by dividing the root, though the seeds are employed when it is desired to introduce new varieties. Each root will serve as the source of thirty or forty plants. They are set in

Though not a native of America, chamomile grows wild in some parts of this country, and is occasionally cultivated in our gardens for family use, the whole herb being employed. The medicine, as found in our shops, consists chiefly of the double flowers, and is imported from Germany and England. From the former country the flowers of *Matricaria Chamomilla* are also occasionally imported, under the name of chamomile. (See *Matricaria.*) In France, the flowers of two other plants are sold in the shops, indiscriminately with those of Anthemis nobilis; viz. those of *Pyrethrum Parthenium* (the *Chrysanthemum Parthenium* of Persoon) or feverfew, and those of *Anthemis parthenoides*, De Cand., or the *Matricaria parthenoides*, Desf. (*Journ. de Pharm.*, Mai, 1859, p. 347.) For the peculiar character by which these two flowers may be distinguished from the Chamomile, see *Pyrethrum Parthenium* in Part III.

Properties. Chamomile flowers, as usually found in the shops, are large, almost spherical, of a dull-white colour, a fragrant odour, and a warmish, bitter, aromatic taste. When fresh, their smell is much stronger, and was fancied by the ancients to resemble that of the apple. Hence the name *chamæmelum* (χαμαι on the ground, and μηλόν an apple); and it is somewhat singular that the Spanish name *manzanilla* (a little apple) has a similar signification. The flowers impart their odour and taste to water and alcohol, the former of which, at the boiling temperature, extracts nearly one-fourth of their weight. They contain a volatile oil, a bitter principle, resin, gum, a small quantity of tannin, and various salts. The first two are probably their active ingredients. (See *Oleum Anthemidis.*) A volatile acid, in minute proportion, has been obtained from them by Schendler, said to resemble, if it be not identical with valerianic acid.

Medical Properties and Uses. Chamomile is a mild tonic, in small doses acceptable and corroborant to the stomach, in larger quantities capable of acting as an emetic. In cold infusion it is often advantageously used in cases of enfeebled digestion, whether occurring as an original affection, or consequent upon some acute disease. It is especially applicable to that condition of general debility, with languid appetite, which often attends convalescence from idiopathic fevers. As a febrifuge it formerly enjoyed much reputation, and was employed in intermittents and remittents; but we have remedies so much more efficient, that it is now seldom used in this capacity. The tepid infusion is very often given to promote the operation of emetics, or to assist the stomach in relieving itself when oppressed by its contents. The flowers are sometimes applied externally in the form of fomentation, in cases of irritation or inflammation of the abdominal viscera, and as a gentle incitant in flabby, ill-conditioned ulcers. The dose of the powder as a tonic is from half a drachm to a drachm three or four times a day, or more frequently. The infusion is usually preferred. The decoction and extract cannot exert the full influence of the medicine; as the volatile oil is driven off at the boiling temperature.

ANTIMONIUM.

Antimony.

Stibium, *Lat.;* Antimoine, *Fr.;* Antimon, Spiessglanz, *Germ.;* Antimonio, *Span., Ital.*

Metallic antimony, sometimes called *regulus of antimony*, is not officinal in the British or United States Pharmacopœias; but, as it enters into the compo-

rows a yard apart, at intervals of about eighteen inches. The proper period for planting is March; and the flowers are in perfection in July, but continue to appear throughout the season. Extremely wet or extremely dry weather is injurious to the crop. It is more productive in a rather heavy loam, than either in light sandy soil, or in stiff clay. It requires little manure, but attention to weeding is necessary. Over-manuring increases the leaves at the expense of the flowers. When gathered, the flowers are dried upon canvass trays in a drying room, artificially warmed, where they remain about a day. The crop varies from three to ten hundred weight per acre. The single flowers are more productive than the double by weight; but, as they command a less price, the value of the crop is about the same. (*Pharm. Journ. and Trans.*, x. 118.)—*Note to the ninth edition.*

sition of a number of important pharmaceutical preparations, we have thought it proper to notice it under a distinct head.

Antimony exists in nature, 1. uncombined; 2. as an oxide; 3. as a tersulphuret; and 4. as a sulphuretted oxide. It is found principally in France and Germany; but has recently been discovered in the British province of New Brunswick.

Extraction. All the antimony of commerce is extracted from the native tersulphuret. The ore is first separated from its gangue by fusion It is then reduced to powder, and placed on the floor of a reverberatory furnace, where it is subjected to a gentle heat, being constantly stirred with an iron rake. This process of roasting is known to be completed, when the matter is brought to the state of a dull grayish-white powder, called *antimony ash.* By this treatment the antimony is partly teroxidized, and partly converted into antimonious acid; while nearly all the sulphur is dissipated in the form of sulphurous acid gas: a portion of tersulphuret, however, remains undecomposed. The matter is then mixed with charcoal impregnated with a concentrated solution of carbonate of soda, and the mixture heated in crucibles, placed in a melting furnace. The charcoal reduces the teroxide of antimony, while the alkali unites with the undecomposed tersulphuret, and forms with it melted scoriæ, which cover the reduced metal, and diminish its loss by volatilization.

The purest commercial antimony is not entirely free from foreign metals, chiefly iron, lead, and arsenic. M. Lefort purifies it for the purposes of pharmacy, by gradually adding twenty-five parts of the metal, in fine powder, to fifty parts of nitric acid, by the action of which the antimony is precipitated as antimonious acid, while the foreign metals remain in solution. The precipitate is then thoroughly washed with water, containing a hundredth part of nitric acid, drained completely, mixed with three or four parts of powdered sugar, and reduced to the metallic state by being heated to redness in a Hessian crucible. (*Journ. de Pharm.*, Août, 1855, p. 93.)

Antimony is imported into the United States principally from France, packed in casks. A portion is also shipped from Trieste, from Holland, and occasionally from Cadiz. The Spanish antimony is generally in the form of pigs; the French, in circular cakes of about ten inches in diameter, flat on one side and convex on the other; the English, in cones. The French is most esteemed.

Properties, &c. The time of the discovery of antimony is not known; but Basil Valentine was the first to describe the method of obtaining it, in his work entitled *Currus Triumphalis Antimonii*, published towards the end of the fifteenth century. It is a brittle, brilliant metal, ordinarily of a lamellated texture, of a silver-white colour when pure, but bluish-white as it occurs in commerce. When rubbed between the fingers, it imparts a sensible odour. Its equivalent number is 129, symbol Sb, sp. gr. 6·7, and fusing point 810°, or about a red heat. Recent experiments of Schneider, confirmed by Weber, make the eq. of antimony 120·2; but we shall adhere to 129, until the new number is fully confirmed. On cooling after fusion, antimony assumes an appearance on the surface bearing some resemblance to a fern leaf. When strongly heated, it burns with the emission of white vapours, consisting of teroxide, formerly called *argentine flowers of antimony.* A small portion, being fused, and then thrown upon a flat surface, divides into numerous globules, which burn rapidly as they move along. It forms three combinations with oxygen; one oxide—teroxide of antimony, and two acids—antimonious and antimonic acids. The teroxide contains three, antimonious acid four, and antimonic acid five eqs. of oxygen, combined with one of the metal. In addition to these, a *suboxide* is said to exist, which, according to Marchand, has a composition represented by the formula Sb_3O_4. The teroxide will be noticed under the head of *Antimonii Oxidum. Antimonic acid* is a lemon-coloured powder, which may be prepared by oxidizing the metal by digestion in nitric acid, and then driving off the excess of the acid by a heat not exceeding 600°. When exposed to a red heat, it parts with oxygen, and is converted into *antimonious acid.* This is a white

powder, and, though medicinally inert, frequently forms a large proportion of the preparation called antimonial powder. (See *Pulvis Antimonialis.*)

Antimony is officinal in the following states of combination.

I. SULPHURETTED.

Antimonii Sulphuretum, *U. S.;* Antimonium Nigrum, *Br.* — *Sulphuret of Antimony; Black Antimony.* (*Prepared Sulphuret of Antimony, Br.* 1864.)

IV. IN SALINE COMBINATION.

Antimonii et Potassæ Tartras, *U. S ;* Antimonium Tartaratum, *Br.*— *Tartrate of Antimony and Potassa. Tartarated Antimony. Tartar Emetic.*

Unguentum Antimonii, *U. S.;* Unguentum Antimonii Tartarati, *Br.* —*Ointment of Antimony. Ointment of Tartarated Antimony.*

Vinum Antimonii, *U. S.;* Vinum Antimoniale, *Br.* — *Wine of Antimony. Antimonial Wine.*

The antimonial preparations are active in proportion to their solubility in the gastric juice. According to Mialhe, those antimonials which contain the hydrated teroxide, or are easily converted into it, are most active. Hence metallic antimony in fine powder, and tartar emetic act with energy. The teroxide is much more active when prepared in the moist than in the dry way. According to Serullas, all the antimonial preparations, except tartar emetic and butter or terchloride of antimony, contain a minute proportion of arsenic. Tartar emetic is an exception, because it separates entirely, in the act of crystallizing, from any minute portion of arsenic in the materials from which it is prepared; the poisonous metal being left behind in the mother-water of the process. B.

ANTIMONII SULPHURETUM. *U. S.*

Sulphuret of Antimony.

Native tersulphuret of antimony, purified by fusion. *U. S.*

Off. Syn. ANTIMONIUM NIGRUM. *Black Antimony.* (*Prepared Sulphuret of Antimony.* Br. 1864.) Native sulphide of antimony, SbS_3, purified from siliceous matter by fusion, and afterwards reduced to fine powder. *Br.*

Artificial sulphuret of antimony; Antimoine sulfuré, *Fr.;* Schwefelantimon, Schwefelspiessglanz, *Germ.;* Solfuro d'antimonio, *Ital.;* Antimonio crudo, *Span.*

Preparation, &c. The sulphuret of antimony of the Pharmacopœias is obtained from the native sulphuret, called *antimony ore*, by different processes of purification; the following being an outline of that generally pursued. The ore is placed in melting pots in a circular reverberatory furnace, and these are made to connect, by means of curved earthen tubes, with the receiving pots, situated outside the furnace. This arrangement affords facilities for removing the residue of the operation, and allows of the collection of the melted sulphuret without interrupting the fire, and, consequently, without loss of time or fuel. In the U. S. Pharmacopœia it is directed to be melted in order to purify it from infusible substances; in the British to be reduced to fine powder, to fit it for pharmaceutic use. In order to bring it to this state, it should be submitted to the process of levigation. (See *Creta Præparata.*)

Properties, &c. Sulphuret of antimony is mostly prepared in France and Germany. It is called, in commerce, antimony, or *crude antimony*, and occurs

in fused conical masses, denominated loaves. These are dark gray externally, and exhibit internally, when broken, a brilliant steel-gray colour, and a striated crystalline texture. Their goodness depends upon their compactness and weight, and the largeness and distinctness of the fibres. The quality of the sulphuret cannot well be judged of, except in mass; hence it ought never to be bought in powder. It is entirely soluble in muriatic acid, by the aid of heat, with the evolution of sulphuretted hydrogen. The muriatic solution, when added to water, is decomposed with the production of a white powder (*oxychloride of antimony*). If the muriatic acid should have dissolved some lead or copper, the filtered solution, after the precipitation of the white powder, will give a dark-coloured precipitate with sulphuretted hydrogen; but if these metals should be absent, it will yield, with the same test, an orange-coloured precipitate, derived from a small quantity of antimony, not thrown down by the water. Arsenic, which is often present in considerable quantities, may be detected by the usual tests for that metal. (See *Acidum Arseniosum.*)

Composition. The officinal sulphuret of antimony is a tersulphuret, consisting of one eq. of antimony 129, and three of sulphur 48=177.

When prepared by pulverization and levigation, it is in the form of an insoluble powder, without taste or smell, usually of a dull blackish colour, but reddish brown, when perfectly pure. By exposure to the air, it absorbs, according to Buchner, a portion of oxygen, and becomes partially converted into teroxide.

Medical Properties and Uses. This preparation is very uncertain in its operation; being sometimes without effect, at other times, if it meet with acid in the stomach, acting with violence by vomiting and purging. The effects attributed to it are those of a diaphoretic and alterative; and the principal diseases in which it has been used are scrofula, glandular obstructions, cutaneous diseases, and chronic rheumatism. It is not employed by physicians in the United States; its use in this country being confined to veterinary practice. The dose is from ten to thirty grains, given in powder or bolus.

APOCYNUM ANDROSÆMIFOLIUM. *U. S. Secondary.*

Dog's-Bane.

The root of Apocynum androsæmifolium. *U. S.*

Apocynum. *Sex. Syst.* Pentandria Digynia.—*Nat. Ord.* Apocynaceæ.

Gen. Ch. Calyx very small, five-cleft, persistent. *Corolla* campanulate, half five-cleft, lobes revolute, furnished at the base with five dentoid glands alternating with the stamens. *Anthers* connivent, sagittate, cohering to the stigma by the middle. *Style* obsolete. *Stigma* thick and acute. *Follicles* long and linear. *Seed* comose. *Nuttall.*

Apocynum androsæmifolium. Willd. *Sp. Plant.* i. 1259; Bigelow, *Am. Med. Bot.* ii. 148. Dog's-bane is an indigenous, perennial, herbaceous plant, from three to six feet in height, and abounding in a milky juice, which exudes when the plant is wounded. The stem is erect, smooth, simple below, branched above, usually red on the side exposed to the sun, and covered with a tough fibrous bark. The leaves are opposite, petiolate, ovate, acute, entire, smooth on both sides, and two or three inches long. The flowers are white, tinged with red, and grow in loose, nodding, terminal or axillary cymes. The peduncles have very small acute bractes. The tube of the corolla is longer than the calyx, and its border spreading. The fruit consists of a pair of long, linear, acute follicles, containing numerous imbricated seeds, attached to a central receptacle, and each furnished with a long seed-down.

The plant flourishes in all parts of the United States from Canada to the Carolinas. It is found along fences and the skirts of woods, and flowers in June and July. The root is the part employed.

This is large, and, like other parts of the plant, contains a milky juice. Its taste is unpleasant and intensely bitter. Dr. Bigelow inferred from his experiments that it contained bitter extractive, a red colouring matter soluble in water and not in alcohol, caoutchouc, and volatile oil. He states that its activity is diminished and eventually destroyed by keeping.

Medical Properties. The powder of the recently dried root acts as an emetic in the dose of thirty grains, and is said to be sometimes employed by practitioners in the country for this purpose. By Dr. Zollickoffer it is considered a useful tonic, in doses of from ten to twenty grains. Dr. Lannon, of Ohio, has found it useful in dyspepsia, and states that in small doses it is laxative, and in large probably cathartic. He recommends the recently dried root in the form of infusion or decoction. (*Proceed. of the Am. Pharm. Assoc.*, A.D. 1858, p. 72.) It is among the remedies employed by the Indians in lues venerea. Dr. John F. Mettauer, of Virginia, has found it, in scrofula, the safest and most valuable aperient in our possession; having given it in the form of tincture in cases attended with debility, and in that of infusion, when the strength is not materially impaired. The tincture he prepares in the proportion of four ounces of the bruised root and a drachm and a half of coriander to half a pint of diluted alcohol, and gives in the dose of from one to three fluidrachms night and morning; the infusion, by macerating for an hour four ounces of the root in a pint of boiling water, to be given in the dose of from two to four fluidrachms, repeated as often. (*Boston Med. and Surg. Journ.*, Oct. 17, 1867, p. 231.) W.

APOCYNUM CANNABINUM. *U. S. Secondary.*

Indian Hemp.

The root of Apocynum cannabinum. *U. S.*

APOCYNUM. See APOCYNUM ANDROSÆMIFOLIUM.

Apocynum cannabinum. Willd. *Sp. Plant.* i. 1259; Knapp, *Am. Med. Rev.* iii. 197. In general appearance and character, this species bears a close resemblance to the preceding. The stems are herbaceous, erect, branching, of a brown colour, and two or three feet in height; the leaves are opposite, oblong-ovate, acute at both ends, and somewhat downy beneath; the cymes are paniculate, many-flowered, and pubescent; the corolla is small and greenish, with a tube not longer than the calyx, and an erect border; the internal parts of the flower are pinkish or purple. The plant grows in similar situations with *A. androsæmifolium*, flowers about the same period, and bears a similar fruit. It abounds in a milky juice, and has a tough fibrous bark, which, by maceration, affords a substitute for hemp. From this circumstance its common name was derived.

The root, which is the officinal part, is horizontal, five or six feet in length, about one-third of an inch thick, dividing near the end into branches which terminate abruptly, of a yellowish-brown colour when young, but dark-chestnut when old, of a strong odour, and a nauseous, somewhat acrid, permanently bitter taste. The internal or ligneous portion is yellowish-white, and less bitter than the exterior or cortical part. The fresh root, when wounded, emits a milky juice, which concretes into a substance resembling caoutchouc. In the dried state, it is brittle and readily pulverized, affording a powder like that of ipecacuanha. Dr. Knapp found it to contain a bitter principle, extractive, tannin, gallic acid, resin, wax, caoutchouc, fecula, lignin, and a peculiar active principle which he proposed to call *apocynin*. (*Am. Med. Review*, iii. 197.) Dr. Griscom, by a subsequent analysis, obtained similar results, with the addition of gum. The root yields its virtues to water and alcohol, but, according to Dr. Griscom, most readily to the former.

Medical Properties and Uses. Indian hemp is powerfully emetic and cathartic, sometimes diuretic, and, like other emetic substances, promotes diaphoresis and expectoration. It produces much nausea, diminishes the frequency of the pulse, and appears to induce drowsiness independently of the exhaustion con-

sequent upon vomiting. The disease in which it has been found most beneficial is dropsy. An aggravated case of ascites, under the care of the late Dr. Joseph Parrish, was completely cured by the decoction of the plant, which acted as a powerful hydragogue cathartic. Dr. Knapp also found it useful in a case of dropsy. Other instances of its efficacy in this complaint have been published by Dr. Griscom, of New York. (*Am. Journ. Med. Sciences*, xii. 55.) Dr. R. S. Cauthorn, of Richmond, Va., has employed the bark of the root successfully in several cases of intermittent fever, and considers it scarcely inferior in antiperiodic power to quinia. He gave from four to six grains, in the form of pill, every two or three hours, augmenting the dose to three times the quantity.* From fifteen to thirty grains of the powdered root will generally produce copious vomiting and purging. The decoction is a more convenient form for administration. It may be prepared by boiling half an ounce of the dried root in a pint and a half of water to a pint, of which from one to two fluidounces may be given two or three times a day, or more frequently if requisite. The watery extract, in doses of three or four grains three times a day, will generally act on the bowels. W.

AQUA. *U. S.*, *Br.*

Water.

Natural water in the purest attainable state. *U. S.* Natural water, the purest that can be obtained, cleared, if necessary, by filtration. *Br.*

Ὕδωρ, *Gr.;* Eau, *Fr.;* Wasser, *Germ.;* Acqua, *Ital.;* Agua, *Span.*

Water has always been included in the Materia Medica of the U. S. Pharmacopœia, on account of its great importance as a medical and pharmaceutical agent. It was not admitted into the officinal lists of the British Pharmacopœias until 1839, when it was first recognised by the Edinburgh College. It is more or less concerned in almost all the changes which take place in inorganic matter, and is essential to the growth and existence of living beings, whether animal or vegetable. In treating of a substance of such diversified agency, our limits will allow of a sketch only of its properties and modifications We shall speak of it under the several heads of *pure water*, *common water*, and *mineral waters*.

Pure Water. Water, in a pure state, is a transparent liquid, without colour, taste, or smell. Its sp. gr. is assumed to be unity, and forms the term of comparison for that of solids and liquids. A cubic inch of it, at the temp. of 60°, weighs very nearly 252 5 grains It is compressible to a small extent, as was proved first by Canton, and afterwards, in an incontestable manner, by Perkins. Reduced in temp. to 32°, it becomes a solid or ice, with the sp. gr. 0·9175 (Dufour, *Comptes Rendus*, Juin, 1860); and raised to 212°, an elastic fluid called steam. In the latter state its bulk is increased nearly 1700 fold, and its sp. gr. so far lessened as not to be much more than half that of atmospheric air. At the temp. of about 39° its density is at the maximum; and consequently, setting out from that point, it is increased in bulk by being either heated or cooled. It has the power of dissolving more or less of all gases, including common air, the constituents of which are always present in natural water. It uniformly exists in the atmosphere, in the form of invisible vapour, even in the driest weather.

Water consists of one eq. of hydrogen 1, and one of oxygen 8 = 9; or, in volumes, of one volume of hydrogen and half a volume of oxygen condensed into one volume of aqueous vapour or steam. On these data, it is easy to calculate the sp gr. of steam; for its density will be 0·0689 (sp. gr. of hydrogen) + 0·5512 (half the sp. gr. of oxygen) = 0·6201.

Common Water. By reason of its extensive solvent powers, water, in its natural state, must be more or less contaminated with foreign matter. Thus, it

* In a paper published in the *Va. Monthly Stethoscope and Med. Reporter* (i. 7), Dr. Cauthorn ascribes these effects to Asclepias Syriaca; but, in a subsequent communication to the *Va. Med. Journ.* (ix. 425), he informs us that the plant employed was really the Apocynum cannabinum, and that he had been led into the error by the common name of milk-weed attached to both plants. (*Note to the twelfth edition.*)

becomes variously impregnated, according to the nature of the strata through which it percolates. When the foreign substances present are in so small an amount as not materially to alter its taste and other sensible qualities, it constitutes the different varieties of *common water*.

There are almost innumerable shades of difference in common water, as obtained from different localities and sources; but all its varieties may be conveniently arranged under the two heads of soft and hard. A *soft water* is one which contains but inconsiderable impurities, and which, when used in washing, forms a lather with soap. By a *hard water* is understood a variety of water which contains calcareous or magnesian salts, or other impurities, through which it curdles soap, and is unfit for domestic purposes. Tincture of soap is a convenient test for ascertaining the quality of water. In distilled water it produces no effect; in soft water, only a slight opalescence; but in hard water, a milky appearance. The milkiness is due to the formation of an insoluble compound between the oily acids of the soap and the lime or magnesia of the foreign salt.

The most usual foreign substances in common water, besides oxygen and nitrogen, and matters held in a state of mechanical suspension, are carbonic acid, sulphate and carbonate of lime, and chloride of sodium (common salt). Carbonic acid is detected by lime-water, which produces a precipitate before the water is boiled, but not afterwards, as ebullition drives off this acid. The presence of sulphate of lime is shown by precipitates being produced by nitrate of baryta, and, after ebullition, by oxalate of ammonia. The former test shows the presence of sulphuric acid, and the latter, after boiling the water, indicates lime not held in solution by carbonic acid. Carbonate of lime, when held in solution by an excess of carbonic acid, may be detected by boiling the water, which causes it to precipitate; but, even after ebullition and filtration, the water will retain enough carbonate of lime to give a precipitate with acetate of lead; carbonate of lime being itself to a minute extent soluble in water. Nitrate of silver will produce a precipitate, if any soluble chloride be present; and, ordinarily, the one present may be assumed to be common salt. Arsenic in minute quantity has been found in water used as drink. At Whitbeck, in Cumberland, England, the inhabitants employ, both as drink and for culinary purposes, a water holding enough arsenic in solution to be quite sensible to tests, without any known injurious consequences. (*Chem. News*, Aug. 25, 1860, p. 128.)

Dr. Clark has proposed to purify hard water, when the hardness arises from bicarbonate of lime, by a process which he calls *liming*. This consists in adding to the water sufficient lime-water to convert the bicarbonate into the very sparingly soluble carbonate. This procedure renders the water soft, and gets rid of all the lime, except that in the minute portion of carbonate dissolved. The merit of this process consists chiefly, not in the removal of lime, but in preventing the formation of organic matters, principally confervæ, the decomposition of which renders the water offensive and unwholesome. Dr. Clark's process has been for some time in successful operation on the water obtained by boring, at the Plumstead water-works near Woolwich. (*Pharm. Journ. and Trans.*, June, 1856.) River water containing the usual amount of calcareous matter, if allowed to stagnate in open reservoirs, in the summer, will become contaminated with myriads of microscopic plants and animals. Now this change is prevented, according to Dr. Clark, by his peculiar treatment, which deprives the living organism of the nutriment, derived from loosely combined carbonic acid.

The oxygen and nitrogen present in natural waters are not usually in the same proportion as in atmospheric air; the oxygen in atmospheric air amounting to about 20 per cent. in volume, while the usual gaseous mixture, expelled from fresh water by boiling, contains about 32 per cent.

Common water is also divided into varieties according to its source. Thus we have rain, snow, spring, river, well, lake, and marsh water.

Rain and *snow waters* are the purest kinds of natural water. Rain water, to be obtained as pure as possible, must be collected in large vessels in the open fields, at a distance from houses, and some time after the rain has commenced

falling; otherwise it will be contaminated with the dust which floats in the atmosphere, and with other impurities derived from roofs. The rain water of large cities contains nitrogenized organic matter, as shown by the odour produced by burning the residue left after the water has been evaporated.

Rain water ordinarily contains atmospheric air, and, according to Liebig, a little nitric acid, the amount of which is increased when the rain descends during a storm. According to an analysis, made by M. Martin, of rain water which fell at Marseilles during a violent storm, 1000 parts by weight contained 0·004 of chlorine and 0·003 of ammonia. Not a trace of iodine or of nitric acid was discovered. Boussingault has ascertained that the rain which falls in towns contains considerably more ammonia than that which falls in the country. Thus, the rain of Paris was found by him to contain three or four parts of ammonia per million; while that collected in a mountainous region contained about four-fifths of one part only in a million. The average results of Mr. J. B. Lawes and Dr. J. H. Gilbert give one part of ammonia to the million of rain water. (*Chem. Gaz.*, Nov. 1, 1854.) Snow water has a peculiar taste, which was supposed to depend on the presence of air more oxygenous than that of the atmosphere; but in point of fact it contains no air, and this accounts for its vapid taste. Both rain and snow water are sufficiently pure for employment in most chemical operations.

Spring water (aqua fontana) depends entirely for its quality on the strata through which it flows; being purest when it passes through sand or gravel. It almost always contains a trace of common salt, and generally other impurities, which vary according to the locality of the spring.

River water (aqua fluvialis) is, generally speaking, less impregnated with saline matter than spring water, because made up in considerable part of rains; while its volume bears a larger proportion to the surface of its bed. It is, however, much more apt to have mechanically suspended in it insoluble matters, of a vegetable and earthy nature, which impair its transparency.

Well water, like that from springs, is liable to contain various impurities. As a general rule, the purity of the water of a well will be in proportion to its depth and the constancy with which it is used. Well water in large cities always contains a large amount of impurity, both organic and inorganic. Dr. R. D. Thomson found 147·6 grs., per Imperial gallon, of impurity in a well in London. From the organic matter he extracted much nitric acid and ammonia, evidently the product of animal excretions. (*Pharm. Journ. and Trans.*, July, 1856, p. 27.) The presence of nitrates in water prevents the formation of organic beings, which cannot be detected by the microscope, even after it has been long kept. *Artesian* or *overflowing wells*, from their great depth, generally afford a pure water.

Lake water cannot be characterized as having any invariable qualities. That of most of the lakes in the United States is pure and wholesome.

Marsh water is generally stagnant, and contains vegetable remains undergoing decomposition. It is an unwholesome water, and ought never to be used for medicinal purposes.

Common waters are apt to contain various organic matters in solution, not only substances of the nature of *ulmin* or *gein*, but many others, both solid and gaseous, which have not been well determined. Among them are living organized microscopic beings, both vegetable and animal, which often have an injurious influence on the health, and sometimes give rise to special diseases. As an example may be mentioned the extremely pernicious effects of swamp water on the health of the troops, encamped in its vicinity, during the late war; a severe and obstinate diarrhœa, which often resisted treatment for months, being among the most frequent. From the researches of Prof. Aug. Vogel, of Munich, it appears that when inorganic and organic matters exist at the same time in water, the proportion of the two jointly increases with the depth of the water, while that of the organic matters by themselves diminishes with the depth; so that the deeper the water the purer it will be in reference to these substances. (*Neues Repertorium für Pharm.*, xv. 488, A.D. 1866.) In

order to ascertain whether the amount of organic matter exceeds the minute quantity usually present in good water, Dupasquier has proposed chloride of gold as a test. From one to two fluidounces of the water to be tested is put into a small flask, and a few drops of solution of chloride of gold, free from excess of muriatic acid, are added, so as to give the water a slightly yellow tint. The liquid is then boiled. If the water contain the ordinary proportion of organic matter, the yellow tint will remain unchanged; but if its quantity be greater than this, the liquid will at first become brownish, and afterwards violet or bluish, in consequence of the reduction of the gold. Organic matter is also detected by its decolorizing effect on a solution of permanganate of potassa.* Water rendered impure and discoloured by organic impregnation, or the presence of animalcula, is freed from its impurities, partially at least, by the presence of a coil of bright iron wire, or admixture with sesquioxide of iron, and subsequent filtration. It is proposed by M. Scheerer that such waters should be treated with solution of sulphate of sesquioxide of iron, which precipitates the organic matter; but care must be taken to use only so much of the salt as is strictly necessary for the purpose. (*Journ. de Pharm. et de Chim.*, 4e sér., i. 394.) Another method has been patented by Mr. Alfred Bird, of Birmingham, consisting in the use of neutral sulphate of alumina, by which the carbonate of lime, the presence of which favours the growth of organized beings through the food afforded by its carbonic acid, is converted into sulphate of lime; while the organic matter subsides, combined with alumina. (*Chem. News*, Aug. 3, 1866.) The boiling of water contaminated with organic ferments, or other microscopic living bodies, before using it for drink or mixed with food, should always be carried into effect, when the use of such water is unavoidable. Filtration no doubt is to a certain degree effectual in ridding water of these poisonous agents, and will prove still more advantageous if in connection with charcoal, magnesia, &c. For an account of different filters for this purpose, consult the *London Lancet* (Jan. 12, March 23, April 13 and 27, 1867, pp. 58, 371, 473, and 526).

The term *Aqua*, in the U. S. and Br. Pharmacopœias, may be considered as designating any natural water of good quality. A good water may be known by its being limpid and inodorous. It answers well for cooking, and does not curdle soap. Upon the addition of nitrate of baryta, nitrate of silver, or oxalate of ammonia, its transparency is but slightly affected; and, upon being evaporated to dryness, it leaves but an inconsiderable residue.

Water should never be kept in leaden cisterns, on account of the risk of its dissolving a small portion of lead. This risk is greater in proportion to the softness and purity of the water; for it is found that the presence of a minute proportion of saline matter, as for example of sulphate of lime, protects the water from the slightest metallic impregnation. According to Mr. R. Phillips, jun., the chlorides are not protective; as they give rise to chloride of lead, which is slightly soluble. The protection has been ascribed to an insoluble film on the

* It may become desirable in certain cases to determine the quantity of these organic matters in solution; and various modes of accomplishing this object have been proposed, but as yet none perfectly satisfactory. One of the readiest of these methods is the use of permanganate of potassa referred to in the text. By adding gradually a solution of permanganate of potassa, of known strength, to the contaminated liquid until the solution ceases to be decolorized, the quantity of that salt consumed in the process may be determined, and thus the quantity of oxygen, and approximatively the amount of organic matter oxidized. Various other methods have been proposed; as 1. by incineration; 2. the process of Messrs. Wankyn, Chapman, and Smith, which determines the product of ammonia during distillation with caustic potassa, by which the quantity of nitrogenous matter is approximatively ascertained; especially important, as it is this kind of impurity that is most noxious; and 3. the more complicated processes of Dr. Frankland, which determine the quantity of nitrogen of immediate organic origin, as distinct from that which may result from any nitrates or nitrites that may be present, and with this also the quantity of carbon exclusive of that derived from the mineral carbonates. From the want of space, we must content ourselves with referring to articles on the subject in the *Pharm. Journ. and Trans.* (Dec. 1867, p. 293, and Jan. 1868, p. 335); and the *Chem. News* (Nov. 29, 1867, p. 280).—*Note to the thirteenth edition.*

surface of the lead, formed by the decomposition of the saline matter. Upon this principle is based a plan of protection by Dr. Schwartz, of Breslau, who proposes to fill leaden pipes through which water is conducted with a strong solution of an alkaline sulphide, which forms a perfectly insoluble coating of sulphide (sulphuret) of lead, said to be quite impermeable by the water afterwards introduced (*Chem. News*, Sept. 26, 1863, p. 157.) A coating of zinc has been employed for protecting the surface of iron pipes and reservoirs against the action of water, but has failed. Experiment has shown that the water becomes impregnated with the salts of both metals. (*Ibid.*, Ap. 5, 1862, p. 188.)*

The *Schuylkill water*, introduced into Philadelphia, possesses all the characteristics of a good water, except that it is occasionally turbid after heavy rains. It contains, on an average, in a wine gallon, according to an analysis by Prof. M. H. Boyè, of Philadelphia, 4·42 grains of solid matter, nearly one-half of which is carbonate of lime, with only a trace of organic matter. It is perfectly free from lead, even after standing in leaden pipes for thirty-six hours. (*Prof. E. N. Horsford.*) The solid matter in the same quantity of the *Delaware water* at Philadelphia, is 3 53 grains, a little over one-third of which is carbonate of lime. (*Henry Wurtz.*) The *Croton water* of New York is also a good water. It contains 10·93 grs. of solid matter to the gallon Brackish or hard water ought never to be employed in compounding prescriptions. For some pharmaceutical purposes, no natural water is sufficiently pure; and hence the necessity of resorting to distillation. (See *Aqua Destillata.*)

Matters mechanically suspended in a natural water may be removed by filtration through sand. On a large scale they may be separated by causing the water to percolate a bed of gravel and sand. Rest, causing subsidence, effects the same purpose, but in a less perfect manner, and requires time.

Mineral Waters. When natural spring waters are so far impregnated with foreign substances as to have a decided taste, and a peculiar operation on the economy, they are called *mineral waters*. These are conveniently arranged under the heads of *carbonated*, *sulphuretted*, *chalybeate*, and *saline*.

1. *Carbonated waters* are characterized by containing an excess of carbonic acid, which gives them a sparkling appearance, and the power of reddening litmus paper. These waters frequently contain the carbonates of lime, magnesia, and iron, which are held in solution by the excess of carbonic acid. The waters of Seltzer, Spa, and Pyrmont in Europe, and of the sweet springs in Virginia, belong to this class.

2. *Sulphuretted waters* are such as contain sulphuretted hydrogen, and are distinguished by the peculiar fetid smell of that gas, and by yielding a brown precipitate with the salts of lead or silver. Examples of this kind are the waters of Aix la Chapelle and Harrogate in Europe, and those of the white, red, and salt sulphur springs in Virginia.

3. *Chalybeate waters* are characterized by a strong inky taste, and by striking a black colour with the infusion of galls, and a blue one with ferrocyanide of potassium. The iron is generally in the state of carbonate of the protoxide, held in solution by excess of carbonic acid. By standing, the carbonic acid is given off; and the protoxide, by absorbing oxygen, is precipitated as a hydrated sesquioxide of an ochreous colour. The principal chalybeate waters are those of Tunbridge and Brighton in England, of Wiesbaden in Germany, and of Bed-

* Experiments by M. Roux, pharmaceutist of the marine at Rochefort, made by order of the naval authorities, have satisfactorily shown that reservoirs of iron coated with zinc are attacked with great facility by water contained in them, which becomes more or less impregnated with both metals in the state of oxides and salts, and especially with those of zinc, to such a degree as to render such vessels improper, as recipients of water for drinking. Of the different kinds of water tried, distilled water deprived as far as possible of atmospheric air produced least effect; next in degree of action was spring water; still more energetic was distilled water containing carbonic acid furnished by the earthy bicarbonates of the water submitted to distillation; and more powerful than all was river water containing a certain proportion of common salt (*Jour. de Pharm. et de Chim.*, 4e sér., i. 99, A.D. 1865.)—*Note to the thirteenth edition.*

ford, Pittsburg, and Brandywine in the United States. The sediments of many of the chalybeate springs of Germany have been ascertained by Walchner to contain both arsenic and copper in minute quantities. These results have been confirmed by Dr. H. Will, who finds in some of these springs a minute proportion of tin, lead, and antimony, in addition to the arsenic and copper. In three springs Will found the ratio of the sesquioxide of iron to the other metals to be, on an average, as 48 to 1. According to M. Lassaigne, the arsenical impregnation exerts no poisonous action on the inferior animals, a result which he ascribes to the antidotal power of the iron. The mineral water of Mont Dore, in France, was found by Thenard to contain arseniate of soda, in the proportion of about one-fifteen thousandth of a grain to two pints.

4. *Saline waters* are those, the predominant properties of which depend upon saline impregnation. The salts most usually present are sulphates and carbonates of soda, lime, and magnesia, and the chlorides of sodium, calcium, and magnesium. Potassa is occasionally present, and lithia has been detected by Berzelius in the spring of Carlsbad, and other salt springs of Germany. Cæsia and rubidia have also been detected in certain mineral waters. Promine is found in the saline at Theodorshalle, in Germany, as also in the salt wells of western Pennsylvania. The mineral springs at Saratoga contain a small proportion of iodine and bromine. The principal saline waters are those of Seidlitz in Bohemia, Cheltenham and Bath in England, and Harrodsburg and Saratoga in the United States. To these may be added the water of the ocean.

We subjoin a summary view of the composition of most of the mineral waters enumerated under the foregoing heads.

1. Carbonated. *Seltzer.* In a wine pint. Carbonic acid 17 cubic inches. *Solid contents;*—carbonate of soda 4 grs.; carbonate of magnesia 5; carbonate of lime 3; chloride of sodium 17. Total 29 grs. (*Bergmann.*)

Spa. In a wine pint. Carbonic acid 13 cubic inches. *Solid contents;*—carbonate of soda 1·5 grs; carbonate of magnesia 4·5; carbonate of lime 1·5; chloride of sodium 0·2; oxide of iron 0·6. Total 8·3 grs. (*Bergmann.*)

Pyrmont. In a wine pint. Carbonic acid 26 cubic inches. *Solid contents;*—carbonate of magnesia 10 grs.; carbonate of lime 4·5; sulphate of magnesia 5·5; sulphate of lime 8·5; chloride of sodium 1 5; oxide of iron 0·6. Total 30·6 grs. (*Bergmann.*)

Vichy. Grand-Grille spring. In 1000 parts by weight. Water 992·572; carbonic acid 0·983; carbonate of soda 4·971; carbonate of lime 0·349; carbonate of magnesia 0·084; carbonate of iron 0·012; chloride of sodium 0·570; sulphate of soda 0·472; silica 0·073. (*Longchamp.*)

Gettysburg Mineral Spring. This spring, situated near the town of Gettysburg, Pa., is distinguished by containing lithia among its constituents. Analyzed by Prof. Mayer, it was found to contain, in an Imperial gallon, the following solid contents; viz. of bicarbonate of soda and bicarbonate of lithia, jointly, 46·05 Troy grains; bicarbonate of potassa a trace; bicarbonate of magnesia 76·05 grs.; bicarbonate of lime 81·00; bicarbonate of iron a trace; sulphate of lime 53·20 grs.; silica 10·00 grs.; and traces of chlorides and phosphates. (Dr. J. Bell, *Med. and Surg. Reporter*, Sept. 28, 1867, p. 262.)

2. Sulphuretted. *Aix la Chapelle.* In a wine pint. Sulphuretted hydrogen 5 5 cubic inches. *Solid contents;*—carbonate of soda 12 grs.; carbonate of lime 4·75; chloride of sodium 5. Total 21·75 grs. (*Bergmann.*)

Harrogate old sulphur well. Sp. gr. 1·01113; temp. 48·2°. In an Imperial gallon. *Gaseous contents;*—carbonic acid 22·03 cubic inches; carburetted hydrogen 5·84; sulphuretted hydrogen 5·31; nitrogen 2·91. Total 36·09 cubic inches. *Solid contents;*—sulphate of lime 0·181 grs.; carbonate of lime 12·365; chloride of calcium 81·735; chloride of magnesium 55·693; chloride of potassium 64·701; chloride of sodium 866·180; sulphuret of sodium 15·479; silica 0·246; with traces of fluoride of calcium, bromide and iodide of sodium, ammonia, carbonate of iron, carbonate of manganese, and organic matter. Total 1096·580 grs. (*Hofmann. Pharm. Journ. and Trans.*, xiv. 123.)

In one of the springs of Harrogate, which he distinguishes as the *strong chalybeate*, Dr. Muspratt found 16·011 grains of *protochloride of iron* and 7·717 of chloride of barium in the Imp. gallon; whereas in another well within the distance of a yard, which he calls the *mild chalybeate*, there is not a trace of either. The protochloride of iron of the former spring renders it, according to Dr. Muspratt, without a parallel. (*Chem. News*, April 27, 1866, p. 203.)

White Sulphur. Gaseous contents in a wine gallon;—sulphuretted hydrogen 2·5 cubic inches; carbonic acid 2; oxygen 1·448; nitrogen 3·552. Total 9·5. *Solid contents* in a pint;—sulphate of magnesia 5·588 grs.; sulphate of lime 7·744; carbonate of lime 1·150; chloride of calcium 0·204; chloride of sodium 0·180; oxide of iron a trace; loss 0 410. Total 15·276 grs. (*W. B. Rogers*)

3. Chalybeate. *Tunbridge.* In a wine gallon. *Solid contents;*—chloride of sodium 2·46 grs.; chloride of calcium 0 39; chloride of magnesium 0·29; sulphate of lime 1·41; carbonate of lime 0·27; oxide of iron 2·22; manganese, vegetable fibre, silica, &c. 0 44; loss 0·13. Total 7·61 grs. (*Scudamore.*)

Brighton. In a wine pint. Carbonic acid 2·5 cubic inches. *Solid contents;*—sulphate of iron 1·80 grs.; sulphate of lime 4·09; chloride of sodium 1·53; chloride of magnesium 0·75; silica 0·14; loss 0·19. Total 8·5 grs. (*Marcet.*)

Cheltenham (*chalybeate*). In a wine pint. *Gaseous contents;*—carbonic acid 2·5 cubic inches. *Solid contents;*—carbonate of soda 0·5 grs.; sulphate of soda 22·7; sulphate of magnesia 6; sulphate of lime 2·5; chloride of sodium 41 3; oxide of iron 0·8. Total 73·8 grs. (*Brande and Parkes.*)

Bedford. In a wine pint. Carbonic acid not estimated. *Solid contents;*—carbonate of lime 2·120 grs.; sulphate of lime 11 274; sulphate of magnesia 3·974; sulphates of alumina and sesquioxide of iron 1·280; sulphate of soda 3·092; chloride of sodium 0·343; free sulphuric acid [?] 0·128; silica and organic matter a trace. Total 22·211 grs. (*J. Cheston Morris. Med. Exam.*, June, 1852.)

Sharon (*chalybeate*). *Gaseous contents* in a wine gallon;—sulphhydric acid gas [sulphuretted hydrogen] 0·7702 cubic inches. *Solid contents* in a gallon;—bicarbonate of magnesia 15·1148 grains; sulphate of lime 63·8024; sulphate of magnesia 8·1546; protosulphate of iron 1·4040; sulphate of soda 3·7401; sulphate of potassa a trace; organic matter 28·48. This analysis was of water which had been kept several months, and there was a precipitate of sulphide (sulphuret) of iron in the vessel, showing that the fresh water must have contained more of this metal than that obtained upon analysis. (*Maisch. Am. Journ. of Pharm.*, March, 1861, p. 105.)

Rockbridge alum spring. In a wine gallon. Carbonic acid 7·536 grs. *Solid contents;*—sulphate of potassa 1·765 grs.; sulphate of lime 3·263; sulphate of magnesia 1·763; protoxide of iron 4·863; alumina 17·905; crenate of ammonia 0·700; chloride of sodium 1·008; silica 2·840; free sulphuric acid 15·224. Total 49·331. (*Hayes.*) A free acid and free bases are here made to coexist.

Church Hill alum water, Richmond, Va. Sp. gr. 1 0069. In a wine gallon. *Solid contents;*—sulphate of potassa 2·444 grs.; sulphate of soda 1·943; chloride of sodium 4·627; sulphate of ammonia 0·643; sulphate of lime 88 836; sulphate of magnesia 86·064; tersulphate of alumina 72 928; sulphate of protoxide of iron 24·991; tersulphate of sesquioxide of iron 51·270; bisulphate of sesquioxide of iron 83·355; silica 10·429; phosphoric acid a trace. Total 427·530 grs (*J. C. Booth. Am. Journ. of Pharm.*, May, 1854.)

4. Saline. *Seidlitz.* In a wine pint. *Solid contents;*—carbonate of magnesia 2·5 grs.; carbonate of lime 0·8; sulphate of magnesia 180; sulphate of lime 5; chloride of magnesium 4·5. Total 192·8 grs. (*Bergmann.*)

Cheltenham (*pure saline*). In a wine pint. *Solid contents;*—sulphate of soda 15 grs.; sulphate of magnesia 11; sulphate of lime 4·5; chloride of sodium 50. Total 80·5 grs. (*Parkes and Brande.*)

Bath. King's well. Sp. gr. 1·0025; temp. 115°. In an Imperial gallon. *Solid contents;*—carbonate of lime 8·820 grs.; carbonate of magnesia 0·329; carbonate of iron 1·064; sulphate of lime 80·052; sulphate of potassa 4·641; sulphate of soda 19·229; chloride of sodium 12·642; chloride of magnesium

14·581; silica 2·982; with traces of iodine and oxide of manganese. Total 144·34 grs. (*Merck and Galloway. Chem. Gaz.*, 1846, p. 496.)

Balston Spa. Sans Souci spring. In a wine gallon. *Solid contents;*—chloride of sodium 143·733 grs.; bicarbonate of soda 12·66; bicarbonate of magnesia 39·1; carbonate of lime 43·407; carbonate of iron 5·95; iodide of sodium 1·3; silica 1. Total 247 15 grs. (*Steel.*)

Saratoga. Iodine spring. In a wine gallon. *Gaseous contents;*—carbonic acid 336 cubic inches; atmospheric air 4. Total 340 cubic inches. *Solid contents;*—chloride of sodium 187 grs.; carbonate of magnesia 75; carbonate of lime 26; carbonate of soda 2; carbonate of iron 1; iodine 3·5. Total 294·5 grs. (*Emmons.*)

Saratoga. Pavilion spring. In a wine gallon. *Gaseous contents;*—carbonic acid 359 05 cubic inches; atmospheric air 5·03. Total 364·08 cubic inches. *Solid contents;*—chloride of sodium 187·68 grs.; carbonate of soda 4·92; carbonate of lime 52·84; carbonate of magnesia 56·92; carbonate of iron 3 51; sulphate of soda 1·48; iodide of sodium 2·59; alumina 0·42; silica 1·16; posphate of lime 0·19; bromide of potassium a trace. Total 311·71 grs. (*Chilton.*)

Saratoga. Union spring. In a wine gallon. *Gaseous contents;*—carbonic acid 314·16 cubic inches; atmospheric air 4·62. Total 318·78 cubic inches. *Solid contents;*—chloride of sodium 243·620 grs.; carbonate of magnesia 84·265; carbonate of lime 41·600; carbonate of soda 12 800; carbonate of iron 5 452; iodide of sodium and iodine 3·600; silica and alumina 1·570; bromide of potassium a trace. Total 392·907 grs. (*J. R. Chilton.*) This spring is now called *Excelsior Rock spring*, having been re-tubed to the depth of 56 feet, of which 11 feet are in the solid rock. The following are given by Messrs. Booth and Garrett, of Philadelphia, as the solid contents in grains of a gallon of the water; of chloride of sodium 375·8996 grs., carbonate of lime 76·0160, carbonate of magnesia 30·4437, carbonate of soda 10·3520, silicate of potassa 6·9829, silicate of soda 3·7672, carbonate of iron 2·8086, sulphate of soda 1·5563, total 507·8263 grains.

Saratoga. Congress spring. Gaseous contents in 100 cubic inches;—carbonic acid 114 cubic inches. *Solid contents* in a pound Troy;—chloride of ammonium 0·0326 grs.; chloride of potassium 1·6256; chloride of sodium 19 6653; iodide of sodium 0·0046; bromide of sodium 0·1613; carbonate of soda 0 8261; carbonate of lime 5 8531; carbonate of magnesia 4·1155; carbonate of strontia 0 0672; carbonate of protoxide of iron 0 0173; carbonate of protoxide of manganese 0·0202; sulphate of potassa 0·1379; nitrate of magnesia 0·1004; alumina 0·0069; silica 0·1112. Total 32·7452 grs. (*Schweitzer.*)

Sea Water. English Channel. In a thousand grains. Water 964·744 grs., chloride of sodium 27·059; chloride of potassium 0·765; chloride of magnesium 3·667; bromide of magnesium 0 029; sulphate of magnesia 2·296; sulphate of lime 1·407; carbonate of lime 0·033. Total 1000 grs. (*Schweitzer.*) The proportion of chloride of sodium is from 36 to 37 parts in 1000 in the ocean, at a distance from land. Its amount is small in the interior of the Baltic. It is perceived that bromine is present in very minute amount; 100 pounds of sea water yielding only 3⅓ grs. of this element. According to Balard, iodine exists in the water of the Mediterranean; but it has not been detected in the water of the ocean, the bromine being supposed to mask its presence. Besides these ingredients, others are alleged to exist in minute proportion in sea water; as fluorine by Dr. G. Wilson; lead, copper, and silver, by MM. Malaguti, Durocher, and Sarzeau; and iron and manganese by M. Uziglio. Anterior to Wilson's researches, Mr. Middleton and Prof. Silliman, jun. had inferred the existence of fluorine in sea water, from its presence in marine animals. The lead and copper above mentioned, were found in certain fuci only; the silver, in the sea water itself. The presence of silver in sea water has been rendered probable by Mr. F. Field, by a comparative analysis of the same copper sheathing, when new, and after having been on a vessel for many years. The old sheathing was always found to contain more silver than the new (*Chem. Gaz.*, March 2, 1857); and the observations of Mr. Field have been subsequently confirmed by others. Schweitzer's analysis

gives a small proportion of carbonate of lime; but Bibra could not detect any. Dr. John Davy's examinations of sea water show that carbonate of lime does not exist at a great distance from land, except in very minute proportion; but becomes quite evident in water, taken at a distance of from fifty to a hundred miles from coasts. Boracic acid has been found by Mr. Veatch in the sea water on the coast of California. (See *Am. Journ. of Pharm.*, July, 1860, p. 330.)*

Sea water, filtered, and charged with five times its volume of carbonic acid, forms, according to Pasquier, a gentle purgative, which keeps very well, and is not disagreeable to take. The dose is from half a pint to a pint.

By freezing, sea water is almost entirely freed from saline matter, the ice being nearly pure water. It is obvious that the unfrozen water contains much more than its ordinary proportion of salts; and this is one of the methods of concentrating this and other saline solutions.

Medical Properties of Water. Water is a remedy of great importance. When taken into the stomach, it acts by its temperature, by its bulk, and by being absorbed. When of the temperature of about 60°, it gives no positive sensation either of heat or cold; between 60° and 45°, it creates a cool sensation; and below 45°, a decidedly cold one. Between 60° and 100°, it relaxes the fibres of the stomach, and is apt to produce nausea, particularly if the effect of bulk be added to that of temperature. By its bulk and solvent powers, it allays irritation by diluting the acrid contents of the stomach and bowels, and favouring their final expulsion; and by its absorption, it promotes the secretion of urine and cutaneous transpiration. Indeed, its influence is so great in the latter way, that it may be safely affirmed that sudorifics and diuretics will not produce their proper effect, unless assisted by copious dilution.

Water, externally applied as a bath, is also an important remedy. It may act by its own specific effect as a liquid, or as a means of modifying the heat of the body. It acts in the latter way differently, according to the temperature at which it may be applied. When this is above 97°, it constitutes the vapour or hot bath; when between 97° and 85°, the warm bath; between 85° and 65°, the tepid bath; and between 65° and 32°, the cold bath.

The general action of the *vapour bath* is to accelerate the circulation, and produce profuse sweating. It acts locally on the skin, by softening and relaxing its texture. In stiffness of the joints, and in various diseases of the skin, it has often proved beneficial.

The *hot bath*, like the vapour bath, is decidedly stimulant. By its use the pulse becomes full and frequent, the veins turgid, the face flushed, the skin red, and the respiration quickened. If the temperature be high, and the constitution peculiar, its use is not without danger; as it is apt to produce a feeling of suffocation, violent throbbing in the temples, and vertigo with tendency to apoplexy. When it acts favourably, it produces profuse perspiration.

* The following analysis of sea water, taken at 2 leagues from Fécamp, on the coast of France, merits special notice from the care with which it was made, and the large quantity operated on. The sp. gr. was 1·026, at 57° F.

(*Journ. de Pharm. et de Chim.*, 4e sér., i. 381, A.D. 1865.)—*Note to the thirteenth edition.*

The *warm bath*, though below the animal heat, nevertheless produces a sensation of warmth; as its temperature is above that of the surface. It diminishes the frequency of the pulse, renders the respiration slower, lessens the heat of the body, and relaxes the skin. It cannot, therefore, be deemed a stimulant. By relieving certain diseased actions and states, accompanied by morbid irritability, it often acts as a soothing remedy, producing a disposition to sleep. It is proper in febrile exanthematous diseases, in which the pulse is frequent, the skin hot and dry, and the general condition characterized by restlessness. It is contra-indicated in diseases of the head and chest.

The *tepid bath* is not calculated to have much modifying influence on the heat of the body. Its peculiar effects are to soften and cleanse the skin, and to promote insensible perspiration.

The *cold bath* acts differently according to its temperature and manner of application, and the condition of the system to which it is applied. When of low temperature and suddenly applied, it acts primarily as a stimulant, by the sudden and rapid manner in which the caloric is abstracted; next as a tonic, by condensing the living fibres; and finally as a sedative. It is often useful in diseases of relaxation and debility, when practised by affusion or plunging. But it is essential to its efficacy and safety, that the stock of vitality should be sufficient to create, immediately after its use, those feelings of warmth and invigoration, included under the term reaction. Currie used it with advantage, by affusion, in certain febrile diseases, especially typhus and scarlatina. To make it safe, the heat must be steadily above the natural standard, and the patient free from all sense of chilliness, and not in a state of profuse perspiration.

Cold water is frequently applied as a sedative in local inflammations, and as a means of restraining hemorrhage. Its use, however, is inadmissible in inflammations of the chest.

Pharm. Uses. Water is used in a vast number of preparations, either as a menstruum, or as a means for promoting chemical action by its solvent power.

Off. Prep. Aqua Destillata. B.

ARALIA NUDICAULIS. *U. S. Secondary.*

False Sarsaparilla.

The root of Aralia nudicaulis. *U. S.*

Aralia. *Sex. Syst.* Pentandria Pentagynia.—*Nat. Ord.* Araliaceæ.

Gen. Ch. Flowers umbelled. *Calyx* five-toothed, superior. *Petals* five. *Stigma* sessile, subglobose. *Berry* five-celled, five-seeded. *Torrey.*

Aralia nudicaulis. Willd. *Sp. Plant.* i. 1521; Rafinesque, *Med. Flor.* i. 53.

False sarsaparilla, wild sarsaparilla, or *small spikenard,* as this plant is variously called, is an indigenous perennial, with one leaf and one flower-stem, springing together from the root, or from a very short stalk, and seldom rising two feet in height. The leaf, which stands upon a long footstalk, is twice ternate, or once and quinate, with oblong-oval, acuminate leaflets, rounded at the base, serrate on the margin, and smooth on both surfaces. The scape or flower-stem is naked, shorter than the leaf, and terminated by three small umbels, each consisting of from twelve to thirty small yellowish or greenish flowers. The fruit consists of small round berries, about as large as those of the common elder. The plant grows throughout the United States, from Canada to the Carolinas, inhabiting shady and rocky woods, and delighting in a rich soil. It flowers in May and June.

The root, which is the officinal portion, is horizontal, creeping, sometimes several feet in length, about as thick as the little finger, more or less twisted, of a yellowish-brown colour externally, of a fragrant odour, and a warm, aromatic, sweetish taste. It has not been analyzed.

Medical Properties and Uses. False sarsaparilla is a gentle stimulant and diaphoretic, and is thought to have an alterative influence, analogous to that of

the root from which it derived its name. It is used in domestic practice, and, by some practitioners in the country, in rheumatic, syphilitic, and cutaneous affections, in the same manner and dose as genuine sarsaparilla. A strong decoction has proved useful as a stimulant to old ulcers.

The root of *Aralia racemosa*, or *American spikenard*, though not officinal, is used for the same purposes as A. nudicaulis, which it is said to resemble in medical properties. Dr. Peck strongly recommends the root of *Aralia hispida*, called in Massachusetts *dwarf elder*, as a diuretic in dropsy. He uses it in the form of decoction, and finds it pleasanter to the taste and more acceptable to the stomach than most other medicines of the same class. (*Am. Journ. of Med. Sci.*, xix. 117.) W.

ARALIA SPINOSA. *U.S. Secondary.*

Aralia Bark.

The bark of Aralia spinosa. *U. S.*

ARALIA. See ARALIA NUDICAULIS.

Aralia spinosa. Willd. *Sp. plant.* i. 1520. This is an indigenous arborescent shrub, variously called *angelica-tree toothache-tree*, and *prickly ash*. The last name, however, should be dropped; as it belongs properly to *Xanthoxylum fraxineum*, and if retained might lead to confusion. The stem is erect, simple, from eight to twelve feet high, armed with numerous prickles, and furnished near the top with very large bipinnate or tripinnate leaves, which are also prickly, and are composed of oval, pointed, slightly serrate leaflets. It terminates in an ample panicle, very much branched, and bearing numerous small hemispherical umbels, in each of which are about thirty white flowers.

This species of Aralia is found most abundantly and of the largest growth in the Southern States, where it is said sometimes to attain a height of from thirty to sixty feet. It grows also in the Western States, and as far north as New York. It is sometimes cultivated in the gardens of the North as a curious or ornamental plant. It flourishes in low, fertile woods, and flowers in August and September. The bark, root, and berries are medicinal; but the first only is directed by the Pharmacopœia.

The bark, as in the shops, is usually in small quills or half quills, from two or three lines to half an inch in diameter, thin, fibrous, grayish externally, and armed with prickles or the remains of them, yellowish within, of an odour somewhat aromatic, and a bitterish taste, which becomes slightly acrid on chewing, and leaves a lasting sense of pungency upon the tongue. It yields its virtues to boiling water.

Medical Properties and Uses. The virtues of *Aralia spinosa* are those of a stimulant diaphoretic. According to Elliot, an infusion of the recent bark of the root is emetic and cathartic. The remedy is used in chronic rheumatism and cutaneous eruptions; and in some parts of the South has been employed in syphilis. Pursh states that a vinous or spirituous infusion of the berries is remarkable for relieving rheumatic pains; and a similar tincture is said to be employed in Virginia with advantage in violent colic. The pungency of this tincture has also been found useful in relieving toothache. The bark is most conveniently administered in decoction. W.

ARGENTUM. *U.S.*

Silver.

Off. Syn. ARGENTUM PURIFICATUM. *Refined Silver.* Pure metallic silver. *Br.*

Argent, *Fr.*; Silber, *Germ.*; Argento, *Ital.*; Plata, *Span.*

Silver is occasionally found in the metallic state, sometimes crystallized, at other times combined with gold, antimony, arsenic, or mercury; but usually it

occurs in the state of sulphuret, either pure, or mixed with other sulphurets, as those of copper, lead, and antimony. It is sometimes found as a chloride.

The most productive mines of silver are found on this continent, being those of Mexico and Peru; the richest in Europe are those of Norway, Hungary, and Transylvania. Mines have been opened and profitably worked in California and Nevada, and there can be little doubt that vast deposits of silver ores exist in the mountainous regions of our country, extending northward from Arizona and New Mexico. The principal ore is the sulphuret. The mineral containing silver, which is most disseminated, is argentiferous galena, which is sulphuret of lead, containing a little sulphuret of silver. Argentiferous galena exists in several localities in the United States. A mine of silver was opened, about the year 1841, in Davidson county, N. C. The ore is an argentiferous carbonate of lead, yielding about one-third of its weight of lead, from which from 100 to 400 ounces of silver are extracted per ton. (Eckfeldt and Du Bois. *Manual of Coins.*) Native silver is associated, in small quantities, with the native copper of the Lake Superior region; and a little of it has come into the market. The two metals, though more or less mixed, are yet quite distinct, seldom being alloyed to any considerable extent.

Extraction. Silver is extracted from its ores by two principal processes, *amalgamation* and *cupellation*. At Freyberg, in Saxony, the ore, which is principally the sulphuret, is mixed with a tenth of chloride of sodium, and roasted in a reverberatory furnace. The sulphur becomes acidified, and combines with sodium and oxygen, so as to form sulphate of soda, while the chlorine forms a chloride with the silver. The roasted mass is then reduced to very fine powder, mixed with half its weight of mercury, one-third of its weight of water, and about a seventeenth of iron in flat pieces, and subjected for sixteen or eighteen hours, to constant agitation in barrels turned by machinery. The chlorine combines with the iron, and remains in solution as chloride of iron; while the silver forms an amalgam with the mercury. The amalgam is then subjected to pressure in leathern bags, through the pores of which the excess of mercury passes, a solid amalgam being left behind. This is then subjected to heat in a distillatory apparatus, by means of which the mercury is separated from the silver, which is left in a porous mass. In Peru and Mexico the process is similar to that above given, common salt and mercury being used; but slaked lime and sulphuret of iron are also employed, with an effect which is not very obvious.

When argentiferous galenas are worked for the silver they contain, they are first reduced, and the argentiferous lead obtained is fused on a large, oval, shallow vessel called a *test*, and exposed to the blast of a bellows, whereby the lead is oxidized, half vitrified, and driven off the test in scales, in the form of *litharge*. The operation being continued on successive portions of argentiferous lead, the whole of the lead is separated, and the silver, not being oxidizable, accumulates on the test as a brilliant fused mass, until its amount is sufficient to be removed. The time required for the separation is much abridged by the process of Mr. Pattinson, of Newcastle, England. This consists in allowing the melted alloy to cool slowly, and separating the crystals which first form, consisting mainly of lead, by means of a perforated ladle. The residue is a very fusible alloy of lead and silver, in which the latter metal is in large proportion, and from which it can be easily separated by cupellation or other means. (*Brande* and *Taylor.*)

Properties. Silver is a white metal, very brilliant, tenacious, malleable, and ductile. In malleability and ductility, it is inferior only to gold. It is harder than gold, but softer than copper. Its equivalent number is 108, symbol Ag, and sp. gr. about 10·4. It forms but one well characterized oxide, which is a protoxide. Exposed to a full red heat, it enters into fusion, and exhibits a brilliant appearance. It is not oxidized in the air, but contracts a superficial tarnish of sulphuret of silver by the action of sulphuretted hydrogen in the atmosphere; from which it may be freed by washing it with a strong solution of cyanide of potassium, and, as soon as it becomes bright, washing it with water and drying it. (*Chem. News*, Jan. 5, 1866, p. 12.) It is entirely soluble

in diluted nitric acid. If any gold be present, it will remain undissolved as a dark-coloured powder. From the nitric solution, the whole of the silver may be thrown down by chloride of sodium, as a white precipitate of chloride of silver, characterized by being completely soluble in ammonia. If the remaining solution contain copper or lead, it will be precipitated or discoloured by sulphuretted hydrogen. "If ammonia be added in excess to a solution of the metal in nitric acid, the resulting fluid exhibits neither colour nor turbidity" (*Br.*); proving the absence of copper, lead, and other metals.

Pharm. Uses. The only officinal preparations containing silver are the *oxide*, *nitrate*, and *cyanide*. The *chloride* will be noticed in the *third part* of this work.

ARMORACIÆ RADIX. *Br.*

Horse-radish Root.

The fresh root of Cochlearia Armoracia. *Br.*

Armoracia, Br. 1864; Raifort sauvage, *Fr.;* Meerrettig, *Germ.;* Rafano rusticano, *Ital.;* Rabano rusticano, *Span.*

Cochlearia. *Sex. Syst.* Tetradynamia Siliculosa. — *Nat. Ord.* Brassicaceæ or Cruciferæ.

Gen. Ch. Silicula emarginate, turgid, scabrous, with gibbous, obtuse valves. *Willd.*

Cochlearia Armoracia. Willd. *Sp. Plant.* iii. 451; Woodv. *Med. Bot.* p. 400, t. 145. The root of this plant is perennial, sending up numerous very large leaves, from the midst of which a round, smooth, erect, branching stem rises two or three feet in height. The radical leaves are lance-shaped, waved, scalloped on the edges, sometimes pinnatifid, and stand upon strong footstalks. Those of the stem are much smaller, without footstalks, sometimes divided at the edges, sometimes almost entire. The flowers are numerous, white, peduncled, and form thick terminal clusters. The calyx has four ovate, deciduous leaves, and the corolla an equal number of obovate petals, twice as long as the calyx, and inserted by narrow claws. The pod is small, elliptical, crowned with the persistent stigma, and divided into two cells, each containing from four to six seeds.

The horse-radish is a native of western Europe, growing wild on the sides of ditches, and in other moist situations. It is cultivated for culinary purposes in most civilized countries, and is said to have become naturalized in some parts of the United States. Its flowers appear in June.

The root, which is officinal in its fresh state, is long, conical at top, then nearly cylindrical for some inches, at last tapering, whitish externally, very white within, fleshy, of a strong pungent odour when scraped or bruised, and of a hot, biting, somewhat sweetish and sometimes bitterish taste. Its virtues are imparted to water and alcohol. They depend upon a *volatile oil*, which is dissipated by drying; the root becoming at first sweetish, and ultimately insipid and quite inert. Its acrimony is also destroyed by boiling. The oil may be obtained by distillation with water. It is colourless or pale-yellow, heavier than water, very volatile, excessively pungent, acrid, and corrosive, exciting inflammation and even vesication when applied to the skin. Hubatka considers it as identical with the volatile oil of mustard. (*Journ. de Pharm.*, 3e sér., v. 42.) According to Gutret, only six parts of it are obtained from 10,000 of the root. Besides this principle, the fresh root contains, according to the same chemist, a bitter resin in minute quantity, sugar, extractive, gum, starch, albumen, acetic acid, acetate and sulphate of lime, water, and lignin. From observations made by F. L. Winckler, it may be inferred that *myronic acid* exists in the root combined with potassa, and that it is from the reaction between this acid, *myrosine*, also existing in the root, and water, that the volatile oil is produced, in the same manner as oil of mustard from mustard seed. (See *Sinapis.*) Horse-radish, when distilled with alcohol, yields none of the oil. (*Journ. für Prakt. Pharm.*, xviii. 89.) The root may be kept for some time without material injury, if buried in sand in a cool place.

It is said that if, to the powder of the dried root, which has become apparently inert, the emulsion of white mustard seed containing myrosine be added, it reacquires its original irritant properties; so that it is the myrosine and not the myronate of potassa which is injured by drying. Hence, the powdered root may be added with advantage to mustard in preparing cataplasms, pediluvia, &c. (*Journ. de Pharm. et de Chim.*, xxvii. 268.)

Medical Properties and Uses. Horse-radish is highly stimulant, exciting the stomach when swallowed, and promoting the secretions, especially that of urine Externally it is rubefacient. Its chief use is as a condiment to promote appetite and invigorate digestion; but it is also occasionally employed as a medicine, particularly in dropsy attended with enfeebled digestion and general debility. It has, moreover, been recommended in palsy and chronic rheumatism, both as an internal and external remedy; and in scorbutic affections is highly esteemed. Cullen found advantage in cases of hoarseness, from the use of a syrup prepared from an infusion of horse-radish and sugar, and slowly swallowed in the quantity of one or two teaspoonfuls, repeated occasionally. The root may be given in the dose of half a drachm or more, grated, or cut into small pieces.

Gen. Ch. Calyx with equal leaflets, in a double row. *Seed-down* hairy, sessile. *Seeds* of the disk and ray furnished with seed-down. *Receptacle* hairy. *Hayne.*

Arnica montana. Willd. *Sp. Plant.* iii. 2106; Woodv. *Med. Bot.* p. 41, t. 17. This is a perennial, herbaceous plant, having a woody, brownish, horizontal root, from one to three inches long, and two or three lines thick, ending abruptly, and sending forth numerous slender fibres of the same colour. The stem is about a foot high, cylindrical, striated, hairy, and terminating in one, two, or three peduncles, each bearing a flower. The radical leaves are ovate, entire, ciliated, and obtuse; those of the stem, which usually consist of two opposite pairs, are lance-shaped. Both are of a bright-green colour, and somewhat pubescent on their upper surface. The flowers are very large, and of a fine orange-yellow colour. The calyx is greenish, imbricated, with lanceolate scales. The ray consists of about fourteen ligulate florets, twice as long as the calyx, striated, three-toothed, and hairy at the base; the disk, of tubular florets, with a five-lobed margin.

This plant is a native of the mountainous districts of Europe and Siberia, and is found, according to Nuttall, in the northern regions of this continent, west of the Mississippi. It has been introduced into England, and might no doubt be cultivated in this country. Its transference from the secondary to the primary catalogue, in the present edition of the U. S. Pharmacopœia, indicates that it is more used with us than formerly The flowers, leaves, and root are employed; but the flowers are usually preferred.

Properties. The whole plant, when fresh, has a strong, disagreeable odour, which is apt to excite sneezing, and is diminished by drying. The taste is acrid, bitterish, and durable. The dried root is cylindrical, contorted, and marked by scars from the insertion of the leaves. Water extracts its virtues. Chevallier and Lassaigne discovered, in the flowers, gallic acid, gum, albumen, yellow colouring matter, an odorous resin, and a bitter principle which they considered identical with *cytisin*, discovered by them in the seeds of the laburnum tree (*Cytisus Laburnum*), which are possessed of poisonous properties. (See *Lond.*

Med. Times and Gaz., Nov. 1856, p. 446.) Cytisin is yellow, of a bitter and nauseous taste, deliquescent, readily soluble in water and diluted alcohol, but with difficulty in strong alcohol, and insoluble in ether. In the dose of five grains it is powerfully emetic and cathartic; and it has been supposed to be the active principle of the plant. The flowers also contain a small proportion of a blue volatile oil. Pfaff obtained from the root a volatile oil, an acrid resin, extractive, gum, and lignin. Mr. Wm. Bastick, of London, has separated an organic alkali from the flowers, and names it *arnicina*. It is solid, slightly bitter, but not acrid, of the odour of castor, slightly soluble in water, and much more soluble in alcohol and ether. (*Pharm. Journ. and Trans.*, x. 389.)* The alkaloid, however, appears to have been previously obtained by M. Lebourdais by the charcoal process. (See *Am. Journ. of Pharm.*, xxiii. p. 243.)

Medical Properties and Uses. Leopard's-bane is a stimulant, directed with peculiar energy to the brain and whole nervous system, as manifested by the resulting headache, spasmodic contractions of the limbs, and difficulty of respiration. It acts also as an irritant to the stomach and bowels, often producing an emetic and cathartic effect, and is said by Bergius to be diuretic, diaphoretic, and emmenagogue. It is capable of acting as a poison in overdoses, causing burning in the stomach, violent abdominal pains, intense headache, and great nervous disturbance. A case of tetanic spasm of one side, and ultimate death under its use, is on record; but there is reason to doubt whether arnica was the real cause of the fatal issue. (*Ann. de Thérap.*, 1854, p. 46.) It is much used by the Germans, who prescribe the flowers and root with advantage in amaurosis, paralysis, and other nervous affections. It is said to prove useful in that disordered condition which succeeds concussion of the brain from falls, blows, &c.; and from this circumstance has received the title of *panacea lapsorum*. It has also been recommended in chronic catarrh of the old, intermittent fever and its sequelæ, dysentery, diarrhœa, nephritis, gout, rheumatism, passive hemorrhages, dropsy, chlorosis, amenorrhœa, and various other complaints, in most of which it seems to have been empirically prescribed. It is peculiarly useful in diseases attended with a debilitated or typhoid state of the system. Dr. T. C. Miller has found it a very valuable remedy in enteric or typhoid fever. (*Penins. Med. Journ.*, Sept. 1859, p. 382.) The powdered flowers and leaves are employed as a sternutatory; and the inhabitants of Savoy and the Vosges are said to substitute them for tobacco. They may be given in substance or infusion. The dose of the powder is from five to twenty grains frequently repeated. The infusion may be prepared by digesting an ounce in a pint of water, of which from half a fluidounce to a fluidounce may be given every two or three hours. It should always be strained through linen, in order to separate the fine fibres, which might irritate the throat. The poisonous properties of the plant are said to be best counteracted by the free use of vinegar or other dilute vegetable acid; but this is very doubtful; and, at all events, the stomach should be first thoroughly emptied. A tincture prepared from the flowers has come into use in this country as a domestic remedy in sprains, bruises, &c., and is now among the U. S. officinals. It is employed externally.

Off. Prep. of the Flowers. Extractum Arnicæ Alcoholicum, *U. S.*; Tinctura Arnicæ, *U. S.*

Off. Prep. of the Root. Tinctura Arnicæ, *Br.* W

* Mr. Bastick obtained the alkaloid by the following process. The flowers were macerated with alcohol acidulated with sulphuric acid; the tincture was filtered, and treated with lime until it evinced an alkaline reaction; the liquid was then filtered, and the filtrate treated with sulphuric acid in slight excess; the acid solution was filtered and concentrated by evaporation; to the residue a little water was added, the liquid was evaporated until all the alcohol was driven off, and was then again filtered; the filtered liquor was saturated with carbonate of potassa, and, after filtration, was mixed with a considerable excess of that salt; finally, the liquid was agitated with successive portions of ether until this fluid ceased to dissolve anything, and the ethereal solution obtained was left to spontaneous evaporation. Arnicina remained. (*Note to the ninth edition.*)

ARSENICUM. *U.S.*

Arsenic.

Arsenic, *Fr.;* Arsenik, *Germ.;* Arsenico, *Ital., Span.*

This metal was introduced into the U. S. and Dublin Pharmacopœias of 1850, for the purpose of being used to form the iodide of arsenic, and the solution of iodide of arsenic and mercury, two new officinals of those works. It has been retained in the Materia Medica of the U. S. Pharmacopœia, but was rejected by the compilers of the British. The Dublin College gave the following formula.

"Take of White Oxide of Arsenic of Commerce two drachms [*Dub. weight*]. Place the Oxide at the sealed end of a hard German glass tube, of about half an inch in diameter and eighteen inches long, and, having covered it with about eight inches of dry and coarsely pulverized charcoal, and raised the portion of the tube containing the charcoal to a red heat, let a few ignited coals be placed beneath the Oxide, so as to effect its slow sublimation. When this has been accomplished, the metallic arsenic will be found attached to the interior of the tube at its distant or cool extremity.

"In conducting this process, the furnace used in the performance of an organic analysis should be employed, and the fuel should be ignited charcoal. It will be proper also to connect the open extremity of the tube with a flue, for the purpose of preventing the possible escape into the apartment of arsenical vapours; and, with the view of keeping it from being plugged by the metal, to introduce occasionally into it, as the sublimation proceeds, an iron wire through a cork, fixed (but not air-tight) in its open extremity."

In the above process, the white oxide (arsenious acid) is reduced by the agency of ignited charcoal, which attracts the oxygen of the acid, and revives the metal. On the large scale, metallic arsenic is generally obtained by heating arsenical pyrites ($FeAs,FeS_2$) in earthen tubes; when the metal sublimes, and two eqs of protosulphuret of iron are left.

Properties. Arsenic is a brittle, crystalline metal, of a steel-gray colour, and possessing much brilliancy when recently broken or sublimed. Exposed to the air, its surface becomes dull and blackish. Its texture is granular, and sometimes a little scaly. Rubbed on the hands, it communicates a peculiar odour; but it is devoid of taste. Its sp. gr. is about 5·8. When heated to about 356°, it sublimes without fusing, giving rise to white vapours having a garlicky odour. Its equivalent number is 75. It forms two combinations with oxygen, both having acid properties, called arsenious and arsenic acids, and three with sulphur, namely, bisulphuret of arsenic or realgar; tersulphuret or orpiment, corresponding in composition with arsenious acid; and quintosulphuret, corresponding with arsenic acid. (See *Acidum Arseniosum;* also *realgar* and *orpiment* in the *third part* of this work.) *Arsenic acid* is obtained by distilling a mixture of twelve parts of nitric and one of muriatic acid off from four parts of arsenious acid, until the whole acquires the consistence of a thin syrup. The liquid is then poured into a porcelain dish, and evaporated at a moderate heat. Suddenly the arsenic acid, in the anhydrous state, concretes into an opaque white mass, which should be transferred, while warm, to a well-stopped bottle. Arsenic acid is white, solid, deliquescent, and soluble in six parts of cold and two of boiling water. It forms several hydrates, corresponding to those of phosphoric acid, to which it bears a close analogy. With nitrate of silver it gives a brick-red precipitate of arseniate of silver. As a poison it is even more virulent than arsenious acid. It consists of one eq. of arsenic and five of oxygen (AsO_5).

Arsenic is much diffused. Besides being present in a great many minerals, it has been detected, in minute proportion, in the earth of graveyards by Orfila; in certain soils and mineral waters by M. Walchner; in the ashes of various plants by M. Stein; and in various kinds of mineral coal, as also in the incrustation formed in the boiler of a sea-going steamer, by M. Daubrée.

ARUM. *U.S. Secondary.*

Indian Turnip.

The cormus of Arum triphyllum. *U.S.*

ARUM. *Sex. Syst.* Moncœcia Polyandria.—*Nat. Ord.* Araceæ.

Gen. Ch. Spathe one-leafed, cowled. *Spadix* naked above, female below, stamineous in the middle. *Willd.*

The root or cormus of *Arum maculatum* is occasionally used as a medicine in Europe, and formerly held a place in the Dublin Pharmacopœia. Its properties so closely resemble those of our *A. triphyllum*, that the substitution of the latter in our Pharmacopœia was obviously proper, independently of the consideration that the root is efficient only in the recent state. Its constituents, according to Enz, are a neuter acrid volatile principle soluble in ether, starch, gum, mucilage, sugar, lignin, albumen, saponin, fixed oil, resin, and phosphate of lime; the fresh cormus containing 58·4 per cent. of water, 5·2 of lignin, and 27·2 of starch. (See *Am. Journ. of Pharm.*, xxxi. 352.) In overdoses it is capable of producing fatal effects, through the violent inflammation caused by it in the mouth, fauces, œsophagus, and stomach. A fatal case, occurring in a child three years old, is recorded in the *Annuaire de Thérapeutique* (A.D. 1862, p. 16), in which, besides the effects mentioned, profound torpor occurred at the end of three hours, followed by intense febrile reaction, and subsequent prostration. It is no doubt the acrid volatile principle to which these effects are to be ascribed. The root of *A. esculentum*, which abounds in starch, is much used by the natives of the Sandwich and other islands of the Pacific, as an article of food, having been previously deprived of its acrimony by heat.

Arum triphyllum. Willd. *Sp. Plant.* iv. 480; Bigelow, *Am. Med. Bot.* i. 52. The *dragon-root, Indian turnip*, or *wake-robin*, as this plant is variously called, has a perennial root or cormus, which, early in spring, sends up a large, ovate, acuminate, variously coloured spathe, convoluted at bottom, flattened and bent over at top like a hood, and supported by an erect, round, green or purplish scape. Within the spathe is a club-shaped spadix, green, purple, black, or variegated, rounded at the end, and contracted near the base, where it is surrounded by the stamens or germs in the diœcious plants, and by both in the monœcious, the female organs being below the male. The spathe and upper portions of the spadix gradually decay, while the germs are converted into a compact bunch of shining scarlet berries. The leaves, usually one or two in number, and upon long sheathing footstalks, are composed of three ovate acuminate leaflets, paler on their under than their upper surface, and becoming glaucous as the plant advances. There are three varieties of this species, distinguished by the colour of the spathe, which in one is green, in another dark-

purple, and in a third white. The plant is a native of North and South America, and is common in all parts of the United States, growing in damp woods, in swamps, along ditches, and in other moist shady places. All parts of it are highly acrid, but the root only is officinal.

This is roundish, flattened, an inch or two in diameter, covered with a brown, loose, wrinkled epidermis, and internally white, fleshy, and solid. In the recent state, it has a peculiar odour, and is violently acrid, producing, when chewed, an insupportable burning and biting sensation in the mouth and throat, which continues for a long time, and leaves an unpleasant soreness behind. According to Dr. Bigelow, its action does not readily extend through the cuticle, as the bruised root may lie upon the skin till it becomes dry, without producing pain or redness. The acrid principle is extremely volatile, and is entirely driven off by heat. It is not imparted to water, alcohol, or olive oil, but is probably soluble in ether, as may be inferred from the experiments of Enz, before referred to, on *A. maculatum*. The root loses nearly all its acrimony by drying, and in a short time becomes quite inert. It was found by Mr. D. S. Jones, besides the acrid principle, and from 10 to 17 per cent. of starch, to contain albumen, gum, sugar, extractive, lignin, and salts of potassa and lime. (*Am. Journ. of Pharm.*, xv. 83.) The starch may be obtained from it as white and delicate as from the potato. In Europe, the dried root of *A. maculatum* is said sometimes to be employed by the country people, in periods of great scarcity, as a substitute for bread; and an amylaceous substance is prepared from it, in small quantities, in the Isle of Portland, on the south coast of England, and called *Portland arrow-root*, or *Portland sago*. The Indian turnip may be preserved fresh for a year, if buried in sand.

Medical Properties and Uses. Arum in its recent state is a powerful local irritant, possessing the property of stimulating the secretions, particularly those of the skin and lungs. It has been advantageously given in asthma, pertussis, chronic catarrh, chronic rheumatism, and various affections connected with a cachectic state of the system. As immediately taken from the ground, it is too acrid for use. The recently dried root, which retains a portion of the acrimony, but not sufficient to prevent its convenient administration, is usually preferred. It may be given in the dose of ten grains, mixed with gum arabic, sugar, and water, in the form of emulsion, repeated two or three times a day, and gradually increased to half a drachm or more. The powder, made into a paste with honey or syrup, and placed in small quantities upon the tongue, so as to be gradually diffused over the mouth and throat, is said to have proved useful in the aphthous sore-mouth of children. W.

ASARUM. *U. S. Secondary.*

Wild Ginger. Canada Snakeroot.

The root of Asarum Canadense. *U. S.*

Asarum. *Sex. Syst.* Dodecandria Monogynia.—*Nat. Ord.* Aristolochiaceæ. *Gen. Ch. Calyx* three or four cleft, sitting on the germen. *Corolla* none. *Capsule* coriaceous, crowned. *Willd.*

Asarum Canadense. Willd. *Sp. Plant.* ii. 838; Bigelow, *Am. Med. Bot.* i. 149; Barton, *Med. Bot.* ii. 85. This species of Asarum very closely resembles *A. Europæum* or asarabacca, in appearance and botanical character. It has a long, creeping, jointed, fleshy, yellowish root or rhizoma, furnished with radicles of a similar colour. The stem is very short, dividing, before it emerges from the ground, into two long round hairy leafstalks, each of which bears a broad kidney-shaped leaf, pubescent on both surfaces, of a rich shining light-green above, veined and pale or bluish beneath. A single flower stands in the fork of the stem, upon a hairy pendulous peduncle. The flower is often concealed by the loose soil or decayed vegetable matter; so that the leaves with their petioles are the only parts that appear. There is no corolla. The calyx is very woolly, divided into three broad, concave, acuminate segments, with the ends reflexed,

of a deep brownish-purple colour on the inside, and of a dull-purple inclining to greenish externally. The filaments, which are twelve in number, and of unequal length, stand upon the germ, and rise with a slender point above the anthers attached to them. Near the divisions of the calyx are three filamentous bodies, which may be considered as nectaries. The pistil consists of a somewhat hexagonal germ, and a conical grooved style, surmounted by six revolute stigmas. The capsule is six-celled, coriaceous, and crowned with the adhering calyx.

Canada snakeroot, or *wild ginger*, is an indigenous plant, inhabiting woods and shady places from Canada to the Carolinas. Its flowering period is from April to July. All parts of the plant have a grateful aromatic odour, which is most powerful in the root. This is the officinal portion.

As we have seen it in the shops, it is in long more or less contorted pieces, from the thickness of a straw to that of a goose-quill, brownish and wrinkled externally, whitish within, hard and brittle, and frequently furnished with short fibres. Its taste is agreeably aromatic and slightly bitter, said to be intermediate between that of ginger and serpentaria, but in our opinion bearing a closer resemblance to that of cardamom. The taste of the petioles, which usually accompany the root, is more bitter and less aromatic.

Among its constituents, according to Dr. Bigelow, are a light-coloured, pungent, and fragrant volatile oil, a reddish bitter resinous matter, starch, and gum; in addition to which Mr. Rushton found fatty matter, chlorophyll, and salts of potassa, lime, and iron. Mr. Procter found the resin to be acrid as well as bitter, and without aromatic properties. The root imparts its virtues to alcohol, and less perfectly to water.

Medical Properties and Uses. Canada snakeroot is an aromatic stimulant tonic, with diaphoretic properties, applicable to similar cases with serpentaria, which it resembles in its effects. It is said to be sometimes used by the country people as a substitute for ginger. Dr. J. R. Black, of Indiana, has found it to be diuretic, and has used it with extraordinary success in two cases of dropsy with albuminous urine. He gave it in decoction, made with four ounces of the root and two pints of water, in the dose of a fluidounce every four hours, till its effect was produced. (*N. Y. Journ. of Med.*, xxxii. 289.) From the close botanical analogy of the plant with the European Asarum, it might be supposed, like that, to possess emetic and cathartic properties; but such does not appear to be the case, at least with the dried root. It would form an elegant adjuvant to tonic infusions and decoctions. It may be given in powder or tincture. The dose in substance is twenty or thirty grains. W.

ASCLEPIAS. *U. S. Secondary.*

Butterfly-weed.

The root of Asclepias tuberosa. *U. S.*

Syn. Asclepias Tuberosa. *U. S.* 1850.

Asclepias. *Sex. Syst.* Pentandria Digynia.—*Nat. Ord.* Asclepiadaceæ.

Gen. Ch. Calyx small, five-parted. *Corolla* rotate, five-parted, mostly reflexed. *Staminal crown* (or nectary) simple, five leaved; leaflets opposite the anthers, with a subulate averted process at the base. *Stigmas* with the five angles (corpuscles) opening by longitudinal chinks. *Pollinia* five distinct pairs. *Torrey.*

Several species of Asclepias, besides A. tuberosa, have been employed medicinally; and two of these, *A. Syriaca* and *A. incarnata*, were recognised in the Secondary Catalogue of the U. S. Pharmacopœia, from which, however, they were discharged, perhaps not altogether judiciously, at the late revision of that work. They will be noticed particularly in the third part of the Dispensatory.

Asclepias tuberosa. Willd. *Sp. Plant.* i. 1273; Bigelow, *Am. Med. Bot.* ii. 59; Barton, *Med. Bot.* i. 239. The root of the butterfly-weed or *pleurisy-root* is perennial, and gives origin to numerous stems, which are erect, ascending, or procumbent, round, hairy, of a green or reddish colour, branching at the top, and

about three feet in height. The leaves are scattered, oblong-lanceolate, very hairy, of a rich, deep-green colour on their upper surface, paler beneath, and supported usually on short footstalks They differ, however, somewhat in shape according to the variety of the plant. In the variety with decumbent stems, they are almost linear, and in another variety cordate. The flowers are of a beautiful reddish-orange colour, and disposed in terminal or lateral corymbose umbels. The fruit is an erect lanceolate follicle, with flat ovate seeds connected to a longitudinal receptacle by long silky hairs.

This plant differs from other species of Asclepias in not emitting a milky juice when wounded. It is indigenous, growing throughout the United States from Massachusetts to Georgia, and as far west as Texas, and, when in full bloom, in June and July, having a splendid appearance. It is most abundant in the Southern States. The root is the only part used in medicine.

This is large, irregularly tuberous, branched, often somewhat fusiform, fleshy, externally brown, internally white and striated, and, in the recent state, of a sub-acrid, nauseous taste. When dried it is easily pulverized; and its taste is bitter, but not otherwise unpleasant. Mr. E. Rhoads discovered in it a peculiar principle, which he obtained by treating the cold infusion with tannic acid, mixing the precipitate, previously washed and expressed, with litharge, drying the mixture and exhausting it with hot alcohol, and finally decolorizing and evaporating the alcoholic liquor. The product was a yellowish-white powder, having the taste of the root, soluble in ether, and much less readily so in water, from which it was precipitated by tannic acid. Mr. Rhoads also found evidence of the existence in the root of tannic and gallic acids, albumen, pectin, gum, starch, a resin soluble and another insoluble in ether, fixed oil, a volatile odorous fatty matter, and various salts, besides from 30 to 35 per cent. of lignin. (*Am. Journ. of Pharm.*, xxxiii. 492.)

Medical Properties and Uses. The root of Asclepias tuberosa is diaphoretic and expectorant, without being stimulant. In large doses it is often also cathartic. Dr. Pawling, of Norristown, Pa., found it always, when freely given, to diminish the volume and activity of the pulse, while it produced copious diaphoresis (*Am. Journ. of Pharm.*, xxxiii. 496); and Dr. Goodrake, of Clinton, Illin., considers it, from his experience, slightly sedative and astringent. (*Trans. of Illinois State Med. Soc.*, A.D. 1857.) In the Southern States it has long been employed by regular practitioners in catarrh, pneumonia, pleurisy, consumption, and other pectoral affections; and appears to be decidedly useful, if applied in the early stage, or, after sufficient depletion, when the complaint is already formed. Its popular name of *pleurisy-root* expresses the estimation in which it is held as a remedy in that disease. It has also been useful in diarrhœa, dysentery, and acute and chronic rheumatism. Dr. Lockwood speaks highly of its efficacy in promoting the eruption in exanthematous fevers. (*Buffalo Med. Journ.*, March, 1848.) Much testimony might be advanced in proof of its possessing considerable diaphoretic powers. It is said to be gently tonic, and has been popularly used in pains of the stomach from flatulence and indigestion.

From twenty grains to a drachm of the root in powder may be given several times a day; but as a diaphoretic it is best administered in decoction or infusion, made in the proportion of an ounce to a quart of water, and given in the dose of a teacupful every two or three hours till it operates.* W.

Narthex Assafœtida. Falconer, *Royle's Mat. Med.*, Am. ed., p. 407.—*Ferula Assafœtida.* Willd. *Sp. Plant.* i 1413; Kœmpfer. *Amœnitat. Exotic.* 535, t. 536. This plant was first described by Kœmpfer, who wrote from actual observation. By him and others after him it was considered as belonging to the genus Ferula; but Dr. Falconer, from a careful examination of the plant in its native site, as well as of specimens cultivated in the Saharunpore Botanic Garden, came to the conclusion that it belongs to a distinct genus, which he denominated Narthex, and which is now generally admitted. The root is perennial, fleshy, tapering, simple or divided, a foot or more in length, about three inches thick at top, where it is invested above the soil with numerous small fibres, dark-gray and transversely corrugated on the outside, internally white, and abounding in an excessively fetid, opaque, milky juice. The leaves, which spring from the root, are numerous, large and spreading, nearly two feet long, light-green above, paler beneath, and of a leathery texture. They are three-parted, with bipinnatifid segments, and oblong-lanceolate, obtuse, entire or variously sinuate, decurrent lobes, forming a narrow winged channel on the divisions of the petiole. From the midst of the leaves rises a luxuriant, herbaceous stem, from six to nine feet high, two inches in diameter at the base, simple, erect, round, smooth, striated, solid, and terminating in a large head of compound umbels, with from ten to twenty rays, each surmounted by a roundish partial umbel. The flowers are pale-yellow, and the fruit oval, thin, flat, foliaceous, and reddish-brown. The plant is said to differ, in its leaves and product, in different situations.

It is a native of Persia, Affghanistan, and other neighbouring regions; and flourishes abundantly in the mountainous provinces of Laar and Chorassan, where its juice is collected. Burns, in his travels into Bokhara, states that the young plant is eaten with relish by the people, and that sheep crop it greedily. Some have erroneously supposed that certain species of Ferula contribute to the production of the assafetida of commerce; and *F. Persica* was admitted among its probable sources in the last edition of the Edinburgh Pharmacopœia. This plant grows also in Persia, and has a strong odour of the drug.*

The oldest plants are most productive, and those under four years old are not considered worth cutting. At the season when the leaves begin to fade, the earth is removed from about the top of the root, and the leaves and stem, being twisted off near their base, are thrown with other vegetable matters over the root, in order to protect it from the sun. After some time the summit of the root is cut off transversely, and, the juice which exudes having been scraped off, another thin slice is removed, in order to obtain a fresh surface for exudation. This process is repeated at intervals till the root ceases to afford juice, and perishes. During the whole period of collection, which occupies nearly six weeks, the solar heat is as much as possible excluded. The juice collected from numerous plants is put together, and allowed to harden in the sun. The fruit is said to be sent to India, where it is highly esteemed as a medicine.

Assafetida is brought to this country either from India, whither it is conveyed from Bushire, and down the Indus, or by the route of Great Britain. It some-

three pints of alcohol and a pint and a half of water, packing the mixture into a conical glass percolator, pouring on it the remainder of the menstruum, reserving the twelve fluidounces which first pass, evaporating the residue of the filtered liquor by means of a water-bath to four fluidounces, mixing this with the reserved liquor, and filtering at the end of twenty-four hours. This preparation was found effective by Dr. Pawling, in the dose of a fluidrachm every four hours. (*Note to the twelfth edition.*)

* The assafetida plant has been introduced into the European conservatories. On a visit by the author to the Edinburgh Botanical Garden, in September, 1860, in company with Drs. Christison and Balfour, the latter the Superintendent of the garden, an assafetida plant was shown to him which had flowered and borne fruit, but not until it was 14 years old. (*Note to the twelfth edition.*)

times comes in mats, but more frequently in cases, the former containing eighty or ninety, the latter from two hundred to four hundred pounds. It is sometimes also imported in casks.

Properties. As found in the shops, assafetida is in irregular masses, softish when not long exposed, of a yellowish or reddish-brown colour externally, exhibiting when broken an irregular, whitish, somewhat shining surface, which soon becomes red on exposure, and ultimately passes into a dull yellowish-brown. This change of colour is characteristic of assafetida, and is ascribed to the influence of air and light upon its resinous ingredient. The masses appear as if composed of distinct portions agglutinated together, sometimes of white, almost pearly tears, embedded in a darker, softer, and more fetid paste. Occasionally the *tears* are separate, though rarely in the commerce of this country.* They are roundish, oval, or irregular, and generally flattened, from the size of a pea to that of a large almond, sometimes larger, yellowish or brownish externally and white within, and not unlike ammoniac tears, for which they might be mistaken except for their odour, which, however, is weaker than that of the masses.

The odour of assafetida is alliaceous, extremely fetid, and tenacious; the taste, bitter, acrid, and durable. The effect of time and exposure is to render it more hard and brittle, and to diminish the intensity of its smell and taste, particularly the former. Kœmpfer assures us that one drachm of the fresh juice diffuses a more powerful odour, through a close room, than one hundred pounds of the drug as usually kept in the stores. Assafetida softens by heat without melting, and is of difficult pulverization.† Its sp. gr. is 1·327. (*Berzelius.*) It is inflammable, burning with a clear, lively flame. It yields all its virtues to alcohol, and forms a clear tincture, which becomes milky on the addition of water. Macerated in water it produces a turbid red solution, and, triturated with that fluid, gives a white or pink-coloured milky emulsion of considerable permanence. In 100 parts, Pelletier found 65 parts of resin, 19·44 of gum, 11·66 of bassorin, 3·60 of volatile oil, with traces of supermalate of lime. Brandes obtained 4·6 parts of volatile oil, 47·25 of a bitter resin soluble in ether, 1·6 of a tasteless resin insoluble in ether, 1·0 of extractive, 19·4 of gum containing traces of potassa and lime united with sulphuric, phosphoric, acetic, and malic acids, 6·4 of bassorin, 6·2 of sulphate of lime, 3·5 of carbonate of lime, 0·4 of oxide of iron and alumina, 0·4 of malate of lime with resin, 6·0 of water, and 4·6 of impurities consisting chiefly of sand and woody fibre. The odour of the gum-resin depends on the *volatile oil*, which may be procured by distillation with water or alcohol. It is lighter than water, colourless when first distilled, but becoming yellow with age, of an exceedingly offensive odour, and of a taste at first flat, but afterwards bitter and acrid. It contains, according to Stenhouse, from 15·75 to 23 per cent. of sulphur. Hlasiwetz considers it a mixture, in variable proportions, of the sulphuret and bisulphuret of a compound radical, consisting of carbon and hydrogen ($C_{12}H_{11}$). A persulphide (persulphuret) of allyl, which is sublimed when oil of mustard is heated with persulphide (persulphuret) of potassium, is said by Wertheim to have an extremely intense odour of assafetida; a fact which justifies the supposition that it may be identical with the oil of that gum-resin. (*Gmelin*, ix. 377.) The oil boils at about 280°, but suffers decom-

* From the account given by Dr. Bellew, who was officially present in the assafetida region, and had the opportunity of making personal observation, the tears are produced by the concretion of the juice which issues by drops from circular incisions at the top of the root, before this has been removed, while the lumps are from the juice which exudes from the cut surface after the removal of the top. (*Pharm. Journ. and Trans.*, May, 1864.) —*Note to the thirteenth edition.*

† In the pharmaceutical preparation of assafetida, it is sometimes very desirable to reduce it to powder. Mr. B. S. Proctor has found that this, and other gum-resins, when incorporated with from 4 to 10 per cent. of magnesia, by first softening them by means of a water-bath, and then stirring them with the earth, become readily pulverizable; and the powder is without the tendency to agglutination which it has when procured without this preliminary preparation. (*Lond. Chem. and Druggist*, April 13, 1863.)—*Note to the twelfth edition.*

position, yielding sulphuretted hydrogen. When long exposed to the air it becomes slightly acid, and acquires a somewhat different odour. (*Chem. Gaz.*, no. 178, p. 108.) The volatile oil and bitter resin are the active principles.

Impurities and Adulterations. Assafetida is probably not often purposely adulterated; but it frequently comes of inferior quality, and mixed with various impurities, such as sand and stones. Portions which are very soft, dark-brown or blackish, with few or no tears, and indisposed to assume a red colour when freshly broken, should be rejected. We have been informed that a case seldom comes without more or less of this inferior assafetida, and of many it forms the larger portion. It is sold chiefly for horses A factitious substance, made of garlic juice and white pitch with a little assafetida, has occurred in commerce.*

Assafetida is sometimes kept in the powdered state; but this is objectionable; as the drug is thus necessarily weakened by the loss of volatile oil, and is besides rendered more liable to adulteration.

Medical Properties and Uses. The effects of assafetida on the system are those of a moderate stimulant, powerful antispasmodic, efficient expectorant, and feeble laxative. Some consider it also emmenagogue and anthelmintic. Its volatile oil is undoubtedly absorbed; as its peculiar odour may be detected in the breath and the secretions. As an antispasmodic simply, it is employed in the treatment of hysteria, hypochondriasis, convulsions of various kinds, spasm of the stomach and bowels unconnected with inflammation, and in numerous other nervous disorders of a merely functional character. From the union of expectorant with antispasmodic powers, it is highly useful in spasmodic pectoral affections, such as hooping-cough and asthma, and in certain infantile coughs and catarrhs, complicated with nervous disorder, or with a disposition of the system to sink. In catarrhus senilis; in the secondary stages of peripneumonia notha, croup, measles, and catarrh; in pulmonary consumption; in fact, in all cases of disease of the chest in which there is want of due nervous energy, and in which inflammation is absent or has been sufficiently subdued, assafetida may be occasionally prescribed with advantage. In the form of enema, it is useful in cases of inordinate accumulation of air in the bowels, and, in the same form, is most conveniently administered in the hysteric paroxysm, and other kinds of convulsion. Its laxative tendency is generally advantageous, but must sometimes be counteracted by opium. It may often be usefully combined with cathartics in constipation with flatulence.

It appears to have been known in the East from very early ages, and, notwithstanding its repulsive odour, is at present much used in India and Persia as a condiment. Persons soon habituate themselves to its smell, which they even learn to associate pleasantly with the agreeable effects experienced from its internal use. Children with hooping-cough sometimes become fond of it.

The medium dose is ten grains, which may be given in pill or emulsion. (See *Mistura Assafœtidæ.*) The tincture is officinal, and is much used. When given by injection, the gum-resin should be triturated with warm water. From half a drachm to two drachms may be administered at once in this way. It may also sometimes be conveniently given in the form of a suppository.† As assafetida

* The statement made in the text that assafetida is probably not often purposely adulterated applies only to the drug after it has entered the market. From the accounts given by Dr. Bellew it appears that, at the place of its production, the drug is generally adulterated; the pure juice being mixed, to the extent of from one-fifth to one-third, usually with the flour of wheat or barley, or powdered gypsum. It is only the juice proceeding from the centre of the root top of the newly sprouting plant that is never adulterated; and this is much more costly than the common kind. (*Pharm. J. and Trans.*, May, 1864.)—*Note to the thirteenth edition.*

† Mr. R. F. Fairthorne recommends that, in the preparation of the suppository, an ethereal fluid extract should first be made, that 9 drachms of this, after having been deprived of its ether by evaporation over a water-bath, should be incorporated, while still hot, with 12 drachms of cacao butter, and that the liquid mixture should be poured into moulds; the whole being divided into 24 suppositories, each of which will be equivalent to about 5 grains of the gum-resin. (*Am. Journ. of Pharm.*, March, 1868, p. 115.) —*Note to the thirteenth edition.*

is not apt to affect the brain injuriously, it may be given very freely when not contraindicated by the existence of inflammatory action.

CITRUS. *Sex. Syst.* Polyadelphia Icosandria.—*Nat. Ord.* Aurantiaceæ.

Gen. Ch. Calyx five-cleft. *Petals* five, oblong. *Anthers* twenty, the filaments united into different parcels. *Berry* nine-celled. *Willd.*

This very interesting genus is composed of small evergreen trees, with ovate or oval-lanceolate, and shining leaves, odoriferous flowers, and fruits which usually combine beauty of colour with a fragrant odour and grateful taste. They are all natives of warm climates. Though the species are not numerous, great diversity exists in the character of the fruit; and many varieties, founded upon this circumstance, are noticed by writers. In the splendid work on the natural history of the *Citrus* by Risso and Poiteau, 169 varieties are described under the eight following heads:—1. sweet oranges, 2. bitter and sour oranges, 3. bergamots, 4. limes, 5. shaddocks, 6. lumes, 7. lemons, and 8. citrons. Of these it is difficult to decide which have just claims to the rank of distinct species, and which must be considered merely as varieties. Those employed in medicine may be arranged in two sets of which the orange, *C. Aurantium*, and the lemon, *C. Medica*, are respectively the types; the former characterized by a winged, the latter by a naked or nearly naked petiole. The form and character of the fruit, though not entirely constant, serve as the basis of subdivisions. *C. Decumana*, which yields the *shaddock*, agrees with *C. Aurantium* in the form of its petiole.

Citrus Aurantium. Willd. *Sp. Plant.* iii. 1427; Woodv. *Med. Bot.* p. 532, t. 188. The orange-tree grows to the height of about fifteen feet. Its stem is rounded, much branched, and covered with a smooth, shining, greenish-brown bark. In the wild state, and before inoculation, it is often furnished with axillary spines. The leaves are ovate, pointed, entire, smooth, and of a shining pale-green colour When held between the eye and the light, they exhibit numerous small transparent vesicles, filled with volatile oil; and, when rubbed between the fingers, are highly fragrant. Their footstalks are about an inch long, and have wings or lateral appendages. The flowers, which have a delightful odour, are large, white, and attached by short peduncles, singly or in clusters, to the smallest branches. The calyx is saucer-shaped, with pointed teeth. The petals are oblong, concave, white, and beset with numerous small glands. The filaments are united at their base in three or more distinct portions, and support yellow anthers. The germen is roundish, and bears a cylindrical style, terminated by a

globular stigma. The fruit is a spherical berry, often somewhat flattened at its base and apex, rough, of a yellow or orange colour, and divided internally into nine vertical cells, each containing from two to four seeds, surrounded by a pulpy matter. The rind of the fruit consists of a thin exterior layer, abounding in vesicles filled with a fragrant volatile oil, and of an interior one, which is thick, white, fungous, insipid, and inodorous. There are two varieties of *C. Aurantium*, considered by some as distinct species. They differ chiefly in the fruit, which in one is sweet, in the other sour and bitterish. The first retains the original title, the second is called *Citrus vulgaris* by De Candolle, and *C. Bigaradia* by Risso. The Seville orange is the product of the latter.*

This beautiful evergreen, in which the fruit is mingled, in every stage of its growth, with the blossoms and foliage, has been applied to numerous purposes of utility and ornament. A native of China and India, it was introduced into Europe at a very early period, was transplanted to America soon after its first settlement, and is now found in every civilized country where the climate is favourable. In colder countries, it is one of the most cherished ornaments of the hot-house, though in this situation its beauties are not fully devoloped, and its fruit does not attain perfection. It flourishes in the most southern portions of our own country, especially near St. Augustine in Florida, where very fine oranges are produced. The tree also grows in the gardens about New Orleans, but is sometimes destroyed by frosty winters. The fruit is brought to us chiefly from the south of Europe and the West Indies. The Havana oranges have the sweetest and most agreeable flavour.

Various parts of the plant are used in medicine. The leaves, which are bitter and aromatic, are employed in some places in the form of infusion as a gently stimulant diaphoretic. They yield by distillation with water a volatile oil, which is said to be often mixed by the distillers with the oils obtained from the flowers and unripe fruit. In regard to polarized light, it has a rotatory power to the left, which is considerably weakened by the prolonged action of heat. (Chautard, *Journ. de Pharm.*, 3e sér., xliv. 28.) The fresh flowers impart to water distilled from them their peculiar fragrance; and the preparation thus obtained is much esteemed in the south of Europe for antispasmodic virtues. (See *Aqua Aurantii Florum*, among the *Preparations*.) The dried flowers are used on the continent of Europe as a gentle nervous stimulant, in the form of infusion, which may be made in the proportion of two drachms to the pint of boiling water, and taken in the dose of a teacupful. The flowers should be dried in the shade, at a temperature between 75° and 95° F. (*Annuaire de Thérap.*, A. D. 1861, p. 59.)

An oil is also obtained from the flowers by distillation which is called *neroli* in France, and is much used in perfumery, and in the composition of *liqueurs*. It is an ingredient of the famous Cologne water. That obtained from the flowers of the Seville or bitter orange (*C. vulgaris*) is deemed the sweetest. It was introduced into the Edinburgh Pharmacopœia, with the title of *Aurantii Oleum*, to serve for the preparation of orange-flower water. Soubeiran considers this oil rather as a product of the distillation than as pre-existing in the flowers. The fact may thus be explained, that orange-flower water, made by dissolving even the finest neroli in water, has not the precise odour of that procured by distillation from the flowers. Pure neroli has a rotating power to the right, in this respect differing from the oil of the leaves. (*Chautard.*)

The fruit is applied to several purposes. Small unripe oranges, about the size of a cherry or less, previously dried, and rendered smooth by a turning lathe, are

* A variety of the orange, called the Mandarin Orange (*Citrus Bigaradia Sinensis* or *C. Bigaradia myrtifolia*), which is probably a native of China, but cultivated largely in Sicily and the south of Italy, bears a fruit much smaller than the common orange, round but flattened above and below, with a smooth, thin, delicate rind, and a very sweet delicious pulp. A volatile oil is obtained from the rind by expression, of a yellow colour, a very bland agreeable odour, different from that of the orange or lemon, and a not unpleasant taste, like that of the rind. When freed from colouring matter by distillation, it was found by M. S. de Luca to be a pure carbohydrogen, with the formula $C_{20}H_{16}$. (*Journ. de Pharm.*, 3e sér., xxxiii. 52.)—*Note to the twelfth edition.*

sometimes employed to maintain the discharge from issues. They are preferred to peas on account of their agreeable odour, and by some are thought to swell less with the moisture; but this is denied by others, and it is asserted that they require to be renewed at the end of twenty-four hours. These fruits are sometimes kept in the shops under the name of *orange berries*. They are of a grayish or greenish-brown colour, fragrant odour, and bitter taste, and are said to be used for flavouring cordials. A volatile oil is obtained from them by distillation, known to the French by the name of *essence de petit grain*, and employed for similar purposes with that of the flowers. The oil, however, which now goes by this name, is said to be distilled from the leaves, and those of the bitter orange yield the best. The oils from the unripe and the ripe fruit have a rotating power to the right, the latter much greater than the former; and this property might serve to distinguish them from the oil of the leaves.* Several of the oils from the Aurantiaceæ deposit a crystalline substance, differing from camphor. (*Chautard.*) The juice of the Seville orange is sour and bitterish, and forms with water a refreshing and grateful drink in febrile diseases. It is employed in the same manner as lemon-juice, which it resembles in containing citric acid, though in much smaller proportion. The sweet orange is more pleasant to the taste, and is extensively used as a light refrigerant article of diet in inflammatory diseases, care being taken to reject the membranous portion. The rind both of the sweet and bitter varieties is directed by the U. S. Pharmacopœia, the bitter only by the British. With the latter, the outer portion is that considered officinal; as the inner is destitute of activity, and by its affinity for moisture renders the peel liable to become mouldy. The best mode of separating the outer rind, when its desiccation and preservation are desired, is to pare it from the orange in narrow strips with a sharp knife, as we pare an apple. When the object is to apply the fresh rind to certain pharmaceutic purposes, as to the preparation of the *confection of orange peel*, it is best separated by a grater. The dried peel, sold in the shops, is usually that of the Seville orange, and is brought chiefly from the Mediterranean.

Properties. Orange peel has a grateful aromatic odour, and a warm bitter taste, which depend upon the volatile oil contained in its vesicles. The rind of the Seville orange is much more bitter than that of the other variety. Both yield their sensible properties to water and alcohol. The oil may be obtained by expression from the fresh grated rind, or by distillation with water. It is imported into the United States in tinned copper cans. It has properties resembling those of the oil of lemons, but spoils more rapidly on exposure to the air, acquiring a terebinthinate odour. The perfumers use it in the preparation of Cologne water, and for other purposes; and it is also employed by the confectioners. According to Dr. Imbert-Gourbeyre, they who are much exposed to the inhalation of the oil of bitter oranges are apt to be affected with cutaneous eruptions, and various nervous disorders; as headache, tinnitus aurium, oppression of the chest, gastralgia, want of sleep, and even muscular spasm. He thinks that the oils of the Aurantiaceæ have much resemblance to camphor in their effects. (*Chem. Pharm. Cent. Blatt*, Feb. 1854, p. 128.)

Medical Properties and Uses. Bitter orange peel is a mild tonic, carminative, and stomachic; the sweet is simply aromatic; but neither is much used alone. They are chiefly employed to communicate a pleasant flavour to other medicines, to correct their nauseating properties, and to assist their stimulant impression upon the stomach. They are a frequent and useful addition to bitter infusions and decoctions, as those of gentian, quassia, columbo, and especially Peruvian

* Prof. Procter, while in Italy, was informed that the oils of oranges and lemons were prepared in Calabria and Sicily in three ways: 1. by scraping off the exterior part of the rind and submitting it to expression; 2. by putting the scrapings into hot water, depressing the pulp beneath, and skimming off the oil as it rises; 3. by distillation. Prof. Procter also states, on the authority of Mr. John A. Dix, of New York, that the best Sicily orange oil is procured by dexterous compression, within a cask, of the fresh rind by the hand, the oil being driven out in jets. (*Am. Journ. of Pharm.*, Jan. 1868, p. 27.)—*Note to the thirteenth edition.*

bark. It is obviously improper to subject orange peel to long boiling; as the volatile oil, on which its virtues chiefly depend, is thus driven off. The dose in substance is from half a drachm to a drachm three times a day. Large quantities are sometimes productive of mischief, especially in children, in whom violent colic and even convulsions are sometimes induced by it. We have known the case of a child, in which death resulted from eating the rind of an orange.

When orange peel is used simply for its agreeable flavour, the rind of the sweet orange is preferable; as a tonic, that of the Seville orange.

AVENÆ FARINA. *U. S.*

Oatmeal.

The meal prepared from the seeds of Avena sativa. *U. S.*

Farine d'avoine, *Fr.;* Hafermehl, *Germ.;* Farina dell'avena, *Ital.;* Harina de avena, *Span.*

AVENA. *Sex. Syst.* Triandria Digynia. — *Nat. Ord.* Graminaceæ.

Gen. Ch. Calyx two-valved, many-flowered, with a twisted awn on the back. *Willd.*

Avena sativa. Willd. *Sp. Plant.* i. 446. The common oat is so well known that a minute description would be superfluous. It is specifically distinguished by its "loose panicle, its two-seeded glumes, and its smooth seeds, one of which is awned." It was known to the ancients, and is now cultivated in all civilized countries; but its original locality has not been satisfactorily ascertained It grows wild in Sicily, and is said to have been seen by Anson in the Island of Juan Fernandez on the coast of Chili.

This grain, though cultivated chiefly for horses, is very nourishing, and is largely consumed as food by the inhabitants of Scotland, the North of Ireland, Brittany, and some other countries. A decoction is said to possess decided diuretic properties, and to be useful in dropsy. (*Lond. Med. Times and Gaz.*, Sept 1854. p. 263.) The seeds deprived of their husks are called *groats*, but are little used in this country. It is only the meal, prepared by grinding the seeds, that is kept in our shops.

Oatmeal contains, according to Vogel, in 100 parts, 59 of starch, 4·30 of a grayish substance resembling rather coagulated albumen than gluten, 8·25 of sugar and a bitter principle, 2·50 of gum, 2 of fixed oil, and 23·95 of fibrous matter including loss. An elaborate analysis of oats deprived of the husk, made by Professor J. P. Norton, of Yale College, gave as the average of four varieties of the grain, 65·11 per cent. of starch, 2·24 of sugar, 2·23 of gum, 6·55 of oil, 16·51 of a nitrogenous body analogous to casein, though differing from it in some respects, 1·42 of albumen, 1·68 of gluten, 2·17 of epidermis, and 2·09 of alkaline salts, with allowance for loss and error. Professor Norton thinks there may have been some error in the proportion of the nitrogenous compounds, in consequence of the difficulty of separating them from starch; and concludes, from the quantity of nitrogen obtained by ultimate analysis, that these compounds must amount to at least 8 per cent. (*Am. Journ. of Sci. and Arts*, 2d ser., iii. 330.) Oatmeal has no smell, is very slightly but not unpleasantly bitter, and yields most of its nutritive matter with facility to boiling water.

Gruel made with oatmeal affords a nutritious, bland, and easily digested aliment, admirably adapted to inflammatory diseases; and, from its somewhat laxative tendency, preferable in certain cases to the purely mucilaginous or amylaceous preparations. It is often administered after brisk cathartics, in order

to render them easier, and at the same time more efficient in their action. It is sometimes also used in the form of enema; and the meal, boiled with water into a thick paste, forms an excellent emollient cataplasm. *Oatmeal gruel* may be prepared by boiling an ounce of the meal with three pints of water to a quart, straining the decoction, allowing it to stand till it cools, and then pouring off the clear liquor from the sediment. Sugar and lemon-juice may be added to improve its flavour; and raisins are not unfrequently boiled with the meal and water for the same purpose. W.

AZEDARACH. *U. S. Secondary.*

Azedarach.

The bark of the root of Melia Azedarach. *U. S.*

Melia. *Sex. Syst.* Decandria Monogynia. — *Nat. Ord.* Meliaceæ.

Gen. Ch. Calyx five-toothed. *Petals* five. *Nectary* cylindrical, toothed, bearing the *anthers* in the throat. *Drupe* with a five-celled nut. *Willd.*

Melia Azedarach. Willd. *Sp. Plant.* ii. 558; Michaux, *N. Am. Sylv.* iii. 4. This is a beautiful tree, thirty or forty feet high, with a trunk fifteen or twenty inches in diameter. When alone, it attains less elevation, and spreads out into a capacious summit. Its leaves are large and doubly pinnate, consisting of smooth, acuminate, denticulate, dark-green leaflets, disposed in pairs with an odd one at the end. The flowers are of a lilac colour, delightfully fragrant, and in beautiful axillary clusters near the ends of the branches. The fruit is a round drupe, about as large as a cherry, and yellowish when ripe.

This species of Melia is variously called *pride of India*, *pride of China*, and *common bead-tree*. It is a native of Syria, Persia, and the north of India, and is cultivated as an ornament in different parts of the world. It is abundant in our Southern States, where it adorns the streets of cities, and the environs of dwellings, and has even become naturalized. North of Virginia it does not flourish, though small trees may sometimes be seen in sheltered situations. It flowers early in the spring. The fruit is sweetish, and, though said by some to be poisonous, is eaten by children without inconvenience, and is reputed to be powerfully vermifuge. But the bark of the root is chiefly employed. It is preferred recent, and is scarcely to be found in the shops at the North. It has a bitter, nauseous taste, and yields its virtues to boiling water.

Medical Properties and Uses. This bark is cathartic and emetic, and in large doses is said to produce narcotic effects similar to those of spigelia, especially if gathered at the season when the sap is mounting. It is considered in the Southern States an efficient anthelmintic, and appears to enjoy, in some places, an equal degree of confidence with the pinkroot. It is thought also to be useful in those infantile remittents which resemble verminose fevers, without being dependent on the presence of worms. The form of decoction is usually preferred. A quart of water is boiled with four ounces of the fresh bark to a pint, of which the dose for a child is a tablespoonful every two or three hours, till it affects the stomach or bowels. Another plan is to give a dose morning and evening for several successive days, and then to administer an active cathartic. W.

BALSAMUM PERUVIANUM. *U. S., Br.*

Balsam of Peru.

The prepared juice of Myrospermum Peruiferum (*De Candolle*). *U. S.* A balsam obtained from Myroxylon Pereiræ, *Klotzsch. Br.*

Baume de Peru, *Fr.;* Peruvianischer Balsam, *Germ.;* Balsamo del Peru, *Ital.;* Balsamo negro, *Span.*

Myrospermum. *Sex. Syst.* Decandria Monogynia. — *Nat. Ord.* Leguminosæ. *De Cand.*

Gen. Ch. Calyx campanulate, five-toothed, persistent. *Petals* five, the upper

one largest. *Stamens* ten, free. *Ovary* stipitate, oblong, membranous, with from two to six ovules; the style originating near the apex, filiform, lateral. *Legume* with the stalk naked at the base, broadly winged above, samaroid, indehiscent, one-celled, one or two seeded, laterally somewhat pointed by the style. *Seed* covered over with balsamic juice. *Cotyledons* thick, flat. *De Candolle.*

Most botanists agree in uniting the genera *Myroxylon* and *Toluifera* of Linnæus, and *Myrospermum* of Jacquin, into one, and follow De Candolle in adopting the last-mentioned title. Klotzsch, of Berlin, however, asserts the distinctness of the genera *Myroxylon* and *Myrospermum*, and attaches the Peru balsam tree to the former. (*Bonplandia*, Sept. 15, 1857, p. 274.) Besides the officinal species, there are others which possess medical virtues, and have been more or less employed. The pod of *M. frutescens* (Jacq.), growing in Trinidad, is popularly used in that island as a carminative, and externally, in the form of tincture, as a lotion in rheumatic pains; and a small quantity of balsamic juice is obtained by incisions in the stem, not distinguishable from balsam of Tolu. (*Pharm. Journ. and Trans.*, Sept. 1862, p. 108.) Another species is known in Paraguay under the name of *quino-quino*, the bark of which is used, in powder and decoction, as a remedy in wounds and ulcers; and from the trunk of which a juice is obtained, which in its concrete state closely resembles dried balsam of Peru. (*Ibid.*, Oct. 1862, p. 183.) In relation to the particular species which yields the balsam now under consideration, there has been much uncertainty. After the death of Linnæus, specimens of a plant were sent to the younger Linnæus by Mutis, from New Granada, which was said by this botanist to yield the balsam of Peru. A description of the plant was published in the *Supplementum Plantarum* with the name of *Myroxylon Peruiferum;* and pharmacologists have generally referred the balsam to it. But considerable doubt has existed as to the identity of the species; nor have these doubts been satisfactorily settled up to the present time. Specimens of a plant were received by Dr. Pereira from Central America, which, there is no reason to doubt, is the real source of Peruvian balsam. Upon comparing these with the specimen of Mutis's plant, preserved in the Herbarium of the Linnæan Society, he found a sufficiently close resemblance in the leaves; but unfortunately this specimen is not perfect, and a certain conclusion did not seem to be attainable. A species of Myrospermum was described by Ruiz, in his Quinologia, as the true Peruvian balsam plant, which he believed to be identical with Myroxylon Peruiferum of Linn., and named accordingly. But this identity is denied by Kunth and De Candolle, who consider Ruiz's plant to be the *Myrospermum pubescens.* (*Prodrom.* ii. 95.) Lambert, in his *Illustrations of the genus Cinchona*, translated the description of Ruiz, and gave a figure of the plant (p. 97); but, according to Dr. Pereira, he drew the figure from Pavon's specimens contained in the British Museum, which were not those of Ruiz's plant, and were marked in Pavon's own handwriting *Myroxylon balsamiferum.* With this figure the real plant corresponds most closely; and it would appear, therefore, not to be the *M. Peruiferum* of Ruiz, the *M. pubescens* of Kunth and De Candolle. More recently, Prof. Carson, of the University of Pennsylvania, received from Central America a specimen, in leaf and flower, of the true Peruvian balsam tree, which he described and figured in the *Am. Journ. of Pharm* for July, 1860 (p. 297). From a comparison of this specimen with the description of Pereira's plant, and with that by Willdenow, in the 4th edition of the Species Plantarum, of the M. Peruiferum of the younger Linnæus, he concluded that the three plants were identical, and that the balsam is in fact, as originally supposed, the product of the Myroxylon Peruiferum of Linn., the Myrospermum Peruiferum of Kunth and De Candolle. In the uncertainty which exists upon this subject, we shall give a brief account of the plant described and figured by Pereira, with the designation of "Myrospermum of *Sonsonate*," leaving its proper botanical place to be determined by further observation.

The Myrospermum of Sonsonate, for which Dr. Royle proposes the name of *Myrospermum Pereiræ*, in honour of the late Dr. Pereira (*Manual of Mat. Med.*,

2d ed., p. 414), the *Myroxylon Pereiræ* of Klotzsch (*Br.*), is a handsome tree with a straight, round, lofty stem, a smooth ash-coloured bark, and spreading branches at the top. The leaves are alternate, petiolate, and unequally pinnate. The leaflets are from five to eleven, shortly petiolate, oblong, oval-oblong, or ovate, about three inches long by somewhat less than an inch and a half in breadth, rounded at the base, and contracting abruptly at top into an emarginate point. When held up to the light, they exhibit, in lines parallel with the primary veins, beautiful rounded and linear pellucid spots. The common and partial petioles and midribs are smooth to the naked eye, but, when examined with a microscope, are found to be furnished with short hairs. The fruit, including the winged footstalks, varies from two to four inches in length. At its peduncular extremity it is rounded or slightly tapering; at the top enlarged, rounded, and swollen, with a small point at the side. The mesocarp, or main investment of the fruit, is fibrous, and contains in distinct receptacles a balsamic juice, which is most abundant in two long receptacles or vittæ, one upon each side. A gum-resin exudes spontaneously in small quantities from the trunk of the tree, which, though containing, besides gum and resin, a small proportion of volatile oil, is wholly distinct from the proper balsam, and yields no cinnamic acid. (Attfield, *Pharm. Journ.*, Dec. 1863, p. 248.)

This tree grows in Central America, in the State of Saint Salvador, upon the Pacific Coast. Dr. Charles Dorat, in a letter to Professor Carson, states that it is never found at a greater height on the mountains than one thousand feet, that it begins to be productive after five years, and continues to yield for thirty years or more, and that the aroma of its flowers is perceived at the distance of one hundred yards. (*Am. Journ. of Pharm.*, xxxii. 303.) The balsam is collected from it exclusively by the aborigines, within a small district denominated the Balsam Coast, extending from Acajutla to Port Libertad. Incisions are made into the bark, which is slightly burned, so as to cause the juice to flow. Previous to the incisions, according to Dr. Dorat, the bark is beaten on four sides of the trunk, so as to separate it from the wood without breaking it; intermediate strips being left sound, in order not to destroy the life of the tree. Cuts are then made in the bruised bark, and the exuding balsam set on fire. Fifteen days after this operation the juice begins to flow freely. It is received on cotton or woollen rags inserted into the apertures, which, after saturation, are removed and replaced by others. When sufficient is collected, the rags are boiled in water in large jars, and the liquid allowed to stand; whereupon the water rises to the top, and is poured off, leaving the balsam, which is put into calabashes or bladders. (*Pharm. Journ. and Trans.*, xi. 205.)* It is then taken for sale to the neighbouring town of Sonsonate, where it is purified by subsidence and straining, and put into jars for exportation. The annual average produce is said to be about 25,000 pounds.

Seeds of the Peru balsam tree, sent to Ceylon and the W. India islands of Jamaica and Trinidad, have proved fruitful, and young plants derived from them are growing vigorously; so that at no great distance in the future commerce will cease to depend for its supplies upon Central America. (*Pharm. Journ. and Trans.*, 2d ser., vi. 441, Feb. 1865.)

A substance called *white balsam* is procured from the fruit by expression. This has been confounded by some with the balsam of Tolu, but is wholly distinct. It is of a semifluid or soft-solid consistence, somewhat granular, and, on standing, separates into a white resinous crystalline deposit, and a superior translucent more fluid portion. The smell, though quite distinct from that of the balsam of Tolu and Peru, is not disagreeable. Dr. Stenhouse has obtained from it a peculiar resinous body, readily crystallizable, and remarkably indif-

* In a communication to the *Pharmaceutical Journal* (Dec. 1863, p. 241), Mr. Daniel Hanbury published an extract of a letter from Dr. Dorat, giving an account of a somewhat modified process for collecting the balsam. After the bruising of the bark as described in the text, fire is applied to the beaten bark, which becomes charred, and, after eight days, falls off in places, or is removed; and the rags are spread on the bare wood, and allowed to remain till saturated. They are then treated as above stated. (*Note to the twelfth edition.*)

ferent in its chemical affinities, which he denominates *myroxocarpin*. (*Pharm. Journ. and Trans.*, x. 290.) Dr. Dorat, however, denies that the white balsam is produced by the same tree, or in the same vicinity.

Another substance obtained from the same tree, and much used in Central America, is a tincture of the fruit, made by digesting it in rum. It is called *balsamito* by the inhabitants, and is said to be stimulant, anthelmintic, and diuretic. It is also used as an external application to gangrenous or indolent ulcers, and as a wash to the face to remove freckles. According to Dr. Dorat, the balsamito is not the tincture, but an alcoholic extract of the young fruit. Neither this nor the white balsam reaches the markets of this country.

The balsam of Peru was named from its place of exportation; and it was long thought to be a product of Peru. It is now shipped partly from the Pacific Coast, and partly from the Balize or other ports on the Atlantic side, whither it is brought across the country. It was Guibourt who first made known the fact of its exclusive production in Central America. As imported it is usually in tin canisters, with a whitish scum upon its surface, and more or less deposit, which is dissolved with the aid of heat.

The balsam is said to be adulterated in Europe with castor oil, copaiba, &c. (*Pharm. Journ. and Trans.*, xii. 549); and a factitious substance has been sold in this country for the genuine balsam, prepared by dissolving balsam of Tolu in alcohol. This may be distinguished by taking fire readily, and burning with a blue flame. (*N. Y. Journ. of Pharm.*, i. 133.) It would, moreover, undergo diminution in volume when mixed with water, which is not the case with the genuine balsam. (*Br.*) A method of detecting castor oil, proposed by Dr. Wagner, is to expose a small portion of the suspected balsam to distillation until somewhat more than one-half has passed, to shake the distillate with baryta-water, to remove by means of a pipette the layer of oil floating on the surface, and to shake this with a concentrated solution of bisulphite of soda. If castor oil be present, the liquid will immediately become a crystalline mass. (*Am. Journ. of Pharm.*, xxx. 570, from *Annal. der Chem. und Pharm.*)

Properties. Balsam of Peru is viscid like syrup or honey, of a dark reddish-brown colour, a fragrant odour, and a warm bitterish taste, leaving when swallowed a burning or prickling sensation in the throat. Its sp. gr. is from 1·14 to 1·16. When exposed to flame it takes fire, diffusing a white smoke and fragrant odour. Containing resin, volatile oil, and either benzoic or cinnamic acid, it is properly considered a balsam, though probably somewhat altered by heat. Alcohol entirely dissolves it, taking up one part in five. (*Br.*) Boiling water extracts the acid. From 1000 parts of the balsam, Stolze obtained 24 parts of a brown nearly insoluble resinous matter, 207 of resin readily soluble, 690 of oil, 64 of benzoic acid, 6 of extractive matter, and a small proportion of water. The oil he considers to be of a peculiar nature, differing from the volatile, the fixed, and the empyreumatic oils. Frémy gives the following views of the composition of the balsam. The acid is *cinnamic* and not benzoic acid. The oily substance is named by him *cinnamein*. It is decomposed by caustic potassa into cinnamic acid, which unites with the alkali, and a light oily fluid called *peruvin*. The resin is a hydrate of cinnamein, and increases at the expense of the latter principle as the balsam hardens. Cinnamein often holds in solution a crystalline substance called *metacinnamein*, isomeric with hydruret of *cinnamyl*, and by its oxidation producing cinnamic acid. When none exists in the balsam, it is presumed to have been wholly converted into that acid.

Medical Properties and Uses. This balsam is a warm stimulating tonic and expectorant, and has been recommended in chronic catarrhs, certain forms of asthma, phthisis, and other pectoral complaints attended with debility. It has also been used in gonorrhœa, leucorrhœa, amenorrhœa, chronic rheumatism, and palsy. At present, however, it is little employed by American physicians. As an external application it has been found beneficial in chronic indolent ulcers. The dose is half a fluidrachm. It is best administered diffused in water by means of sugar and the yolk of eggs or gum arabic. W.

BALSAMUM TOLUTANUM. *U. S., Br.*

Balsam of Tolu.

The juice of Myrospermum Toluiferum (*De Candolle*). *U. S.* A balsam obtained from Myroxylon Toluifera. *Br.*

Baume de Tolu, *Fr.;* Tolubalsam, *Germ.;* Balsamo del Tolu, *Ital.;* Balsamo de Tolu, *Span.*

MYROSPERMUM. See BALSAMUM PERUVIANUM.

For a long time the tree from which this balsam is derived retained the name of *Toluifera Balsamum*, given to it by Linnæus; but it is now admitted that the genus *Toluifera* was formed upon insufficient grounds; and botanists agree in referring the Tolu balsam tree to the genus *Myroxylon*, or, as it was afterwards named, *Myrospermum*. Ruiz, one of the authors of the Flora Peruviana, considered it identical with *Myroxylon Peruiferum;* but M. Achille Richard determined that it was a distinct species, and gave it the appropriate specific name of *Toluiferum*, which is now recognised by the Pharmacopœias. Sprengel and Humboldt also consider it a distinct species of Myroxylon. According to Richard, who had an opportunity of examining specimens brought from South America by Humboldt, the leaflets of *M. Peruiferum* are thick, coriaceous, acute, blunt at the apex, and all equal in size; while those of *M. Toluiferum* are thin, membranous, obovate, with a lengthened and acuminate apex, and the terminal one is longest. *M. Peruiferum* is found in Peru and the southern parts of New Granada; *M. Toluiferum* grows in New Granada, and abounds especially in the neighbourhood of Tolu. The wood of the latter species, according to Humboldt, is of a deep-red colour, has a delightful balsamic odour, and is much used for building. Mr. John Weir, who visited the country of the Tolu balsam tree, found it growing abundantly in the mountainous region on the Magdalena river, near the towns of Plato and Las Mercedes, but at a considerable distance from the stream. The average height of the trees is seventy feet, the trunk sometimes more than two feet in diameter at a yard from the ground, and the height to the first branches 40 feet, so that it was necessary to fell the tree in order to obtain the leaves and fruit. (*Pharm. Journ. and Trans.*, July, 1864, p. 61.)

The balsam is procured by making incisions in the trunk quite through the bark. The juice is received in small calabash cups, which are inserted in slight excavations beneath the point of two vertical incisions meeting at the lower end; and Mr. Weir has seen as many as twenty cups at a time on one tree. The collectors go from tree to tree emptying the cups into flasks of raw hide. In these skin vessels the juice is taken to the different ports on the river, where it is transferred to tin cans. (Weir, *Ibid.*) It is brought from Carthagena in calabashes or baked earthen jars, or in tin or glass vessels. G. L. Ulex gives as a test of the purity of the balsam, that, if heated in sulphuric acid, it dissolves without disengagement of sulphurous acid, and yields a cherry-red liquid. (*Archiv. der Pharm.*, Jan. 1853.)

Properties. As first imported, balsam of Tolu has a soft, tenacious consistence, which varies considerably with the temperature. By age it becomes hard and brittle like resin. It is shining, translucent, of a reddish or yellowish-brown colour, a highly fragrant odour, and a warm, somewhat sweetish and pungent, but not disagreeable taste. Exposed to heat, it melts, inflames, and diffuses an agreeable odour while burning. It is entirely dissolved by alcohol and the volatile oils. Boiling water extracts its acid. Distilled with water it affords a small proportion of volatile oil; and, if the heat be continued, an acid matter sublimes. Mr. Hatchett states that, when dissolved in the smallest quantity of solution of of potassa, it loses its own characteristic odour, and acquires that of the clove pink. Its ingredients are resin, cinnamic acid, and volatile oil, the proportions of which vary in different specimens. The acid was formerly thought to be benzoic; but was proved by Frémy to be the cinnamic. The existence of the former acid in the balsam was denied by that chemist; and, though Deville

subsequently obtained benzoic acid from it, yet, according to Kopp, this did not pre-exist in the balsam, but resulted from changes produced in the resin by heat, or the reaction of strong alkaline solutions. The pure volatile oil is a carbohydrogen ($C_{10}H_8$), which is denominated by Kopp *tolene*. According to the same chemist, the resinous matter is of two kinds, one very soluble in alcohol, the other but slightly so. (*Journ. de Pharm.*, 3e sér., xi. 426.) Guibourt observed that the balsam contains more acid, and is less odorous in the solid form; and thinks that the acid is increased at the expense of the oil. Trommsdorff obtained 88 per cent. of resin, 12 of acid, and only 0·2 of volatile oil. According to Mr. Heaver, the balsam yields by distillation about one-eighth of its weight of pure cinnamic acid. The acid distils over in the form of a heavy oil, which condenses into a white crystalline mass. It may be freed from empyreumatic oil by pressure in bibulous paper, and subsequent solution in boiling water, which deposits it in minute colourless crystals, upon cooling. (*Am. Journ. of Pharm.*, xv. 77.) According to Frémy, this balsam is closely analogous in constitution to the balsam of Peru, being composed of cinnamein, cinnamic acid, and resin.

Medical Properties and Uses. Balsam of Tolu is a stimulant tonic, with a peculiar tendency to the pulmonary organs. It is given with some advantage in chronic catarrh and other pectoral complaints, in which a gently stimulating expectorant is demanded; but should not be prescribed until after the reduction of inflammatory action. Independently of its medical virtues, its agreeable flavour renders it a popular ingredient in expectorant mixtures. Old and obstinate coughs are said to be sometimes greatly relieved by the inhalation of the vapour, proceeding from an ethereal solution of this balsam. From ten to thirty grains may be given at a dose, and frequently repeated. The best form of administration is that of emulsion, made by triturating the balsam with mucilage of gum arabic and loaf sugar, and afterwards with water.

BARIUM.

Barium.

This is the metallic radical of the earth baryta, and the basis of two officinal compounds. It was first obtained in 1808 by Sir H. Davy, who describes it as a difficultly fusible metal, of a dark-gray colour, effervescing violently with water, and considerably heavier than sulphuric acid. Its eq. is 68·7, and symbol Ba. When exposed to the air, it instantly becomes covered with a crust of baryta, and when gently heated, burns with a deep-red light. The only officinal compounds of barium are the chloride, and the carbonate of the protoxide (baryta).

Baryta may be obtained from the native carbonate by intense ignition with carbonaceous matter; or from the native sulphate, by ignition with charcoal, which converts it into sulphuret of barium, subsequent solution of the sulphuret in nitric acid, and strong ignition of the nitrate formed to dissipate the acid. As thus obtained, it is an anhydrous solid, caustic, alkaline, difficultly fusible, and of a grayish-white colour. Its sp. gr. is about 4. It acts on the animal economy as a poison. When sprinkled with water it slakes like lime, becomes hot, and is reduced to the state of a white pulverulent hydrate, containing one eq. of water. The same hydrate is formed in mass, when the anhydrous earth is made into a paste with water, and exposed to a red heat in a platinum crucible. The excess of water is expelled, and the hydrate, undergoing fusion, may be poured out and allowed to congeal. Baryta dissolves in water, and forms the reagent called *baryta-water*. A boiling saturated solution, as it cools, yields crystals of baryta, containing much water of crystallization.

An economical process for obtaining baryta in crystals has been published by Dr. Mohr, of Coblentz. It consists in adding to a boiling solution of caustic soda an equivalent quantity of chloride of barium and nitrate of baryta. In consequence of the usual impurities in caustic soda, a precipitate is formed of some

carbonate and sulphate of baryta, which is easily separated by subsidence from the solution of caustic baryta, kept hot. This, when clear, is drawn off by a syphon, and put in a suitable covered vessel to cool and crystallize; when the whole liquid is often converted into a mass of acicular crystals. (*Pharm. Journ. and Trans.*, Dec. 1856.)

Baryta consists of one eq. of barium 68·7, and one of oxygen 8 = 76·7. Its symbol is, therefore, BaO. B.

BARYTÆ CARBONAS. *U.S.*

Carbonate of Baryta.

Carbonate de baryte, *Fr.;* Kohlensaurer Baryt, *Germ.;* Barite carbonate, *Ital.;* Carbonato de barito, *Span.*

The officinal carbonate of baryta is the native carbonate, a rare mineral, discovered in 1783 by Dr. Withering, in honour of whom it is called *Witherite.* It is found in Sweden and Scotland, but most abundantly in the lead mines of the north of England. It occurs usually in grayish, or pale yellowish-gray, fibrous masses, but sometimes crystallized. Its sp. gr. varies from 4·2 to 4·4. It is generally translucent, but sometimes opaque. It effervesces with acids, and, before the blowpipe, melts into a white enamel without losing its carbonic acid. It consists of one eq. of acid 22, and one of baryta 76·7 = 98·7. It is distinguished from the carbonate of strontia, with which it is most liable to be confounded, by its greater specific gravity, and by the absence of a reddish flame upon the burning of alcohol impregnated with its muriatic solution If strontia be present, the reddish flame will detect it.

When pure, carbonate of baryta is entirely soluble in muriatic acid. Any sulphate of baryta present is left undissolved. If neither ammonia nor sulphuretted hydrogen produces discoloration or a precipitate in the muriatic solution, the absence of alumina, iron, copper, and lead is shown. Lime may be detected by adding an excess of sulphuric acid, which will throw down the baryta as a sulphate, and afterwards testing the clear liquid with carbonate of soda, which, if lime be present, will produce a precipitate of carbonate of lime.

Carbonate of baryta acts as a poison on the animal economy. Its only officinal use is to prepare chloride of barium.

Off. Prep. Barii Chloridum, *U.S.* B.

BARYTÆ SULPHAS.

Sulphate of Baryta.

Heavy spar, Baroselenite; Sulfate de baryte, *Fr.;* Schwefelsaurer Baryt, *Germ.;* Barite sulfata, *Ital.*

The native sulphate of baryta is used in pharmacy with the same view as the native carbonate; namely, to obtain chloride of barium. The U. S. Pharmacopœia directs for this purpose the carbonate; but, as the sulphate may be used more economically, and is, in fact, generally employed in the preparation of chloride of barium, we retain it here, though not recognised as officinal.

Sulphate of baryta is a heavy, lamellar, brittle mineral, varying in sp. gr. from 4·4 to 4·6. It is generally translucent, but sometimes transparent or opaque, and its ordinary colour is white or flesh-red. When crystallized, it is usually in very flat rhombic prisms. Before the blowpipe it strongly decrepitates, and melts into a white enamel, which, in the course of ten or twelve hours, falls to powder. It is thus partially converted into sulphate of barium, and, if applied to the tongue, will give a taste like that of putrid eggs, arising from the formation of sulphuretted hydrogen. It consists of one eq. of acid 40, and one of baryta 76·7 = 116·7.

This salt, on account of its great insolubility, is not poisonous. Ground to fine powder, it is sometimes mixed with white lead, but impairs the quality of that pigment. The artificial sulphate of baryta, under the name of *permanent white* or *blanefix*, is much used in the arts as a water colour. It is made from

both the native sulphate and native carbonate. It forms a dazzling white colour, unalterable by light, heat, air, or sulphuretted hydrogen. It is used by the manufacturers of paper hangings, and for mixing with other colours, the tone of which it does not impair. (*Chem. Gaz.*, Feb. 1, 1857.) B.

BELÆ FRUCTUS. *Br.*

Bael Fruit.

The dried half-ripe fruit of Ægle Marmelos. *Br.*

This is a newly introduced officinal of the British Pharmacopœia, little known as yet in Great Britain, and scarcely at all in the United States; and probably sanctioned by the British Council out of complaisance to practitioners in the E. Indies, who are said to have used it with advantage. It is the unripe fruit of the *Ægle Marmelos* of De Candolle, belonging to the *Aurantiaceæ*, and with the following generic character. "*Flowers* bi-sexual. *Petals* 4-5, patent. *Stamens* 30-40, with distinct filaments, and linear-oblong anthers. *Ovary* 8-15 celled, with numerous ovules in each cell. *Style* very short and thick. *Stigma* capitate. *Fruit* baccate, with a hard rind, 8-15 celled, the cells 6-10 seeded. *Seed* with a woolly coat, covered with a slimy liquid." (*Wight & Arnott.*)

This species of Ægle, sometimes called the *Bengal quince*, is a rather large tree, with an erect stem, and few and irregular branches, covered with an ash-coloured bark, and furnished in general with strong, very sharp, axillary thorns, single or in pairs. The leaves are ternate, with oblong-lanceolate, crenulated, slightly dotted leaflets, of which the terminal is largest. The flowers are large, white, and in small, terminal or axillary panicles. The fruit is a berry, of about the size of a large orange, somewhat spherical, but flattened at the base, and depressed at the insertion of the stem, with a hard smooth shell, and from 10 to 15 cells, containing besides the seeds a large quantity of exceedingly tenacious mucilage, which, when dried, is hard and transparent. The tree is a native of Hindostan and of further India. It is figured in the *Pharm. Journ. and Trans.* (Octob. 1850, p. 166), from which we have taken the foregoing account.

Several parts of the tree are used in India. The ripe fruit is described as fragrant, and of a delicious flavour; and a sort of sherbet prepared from it is deemed useful in febrile affections. The mucilage about the seeds is applied to various purposes in the arts, in connection with its viscid properties. The rind is used in dyeing. The flowers are deemed refrigerant by the native physicians. The fresh leaves yield by expression a bitterish and somewhat pungent juice, which, diluted with water, is occasionally used in the early stage of catarrhal and other fevers. The bark of the stem and root is thought to possess febrifuge properties. But it is the unripe or half-ripe fruit which is chiefly employed, and is the part recognised by the British Pharmacopœia.

Properties. The dried fruit is imported into England in vertical slices, or in broken pieces consisting of a part of the rind with the adherent pulp and seeds. The "rind is about a line and a half thick, covered with a smooth pale-brown or grayish epidermis, and internally, as well as the dried pulp, brownish-orange, or cherry-red." (*Br.*) When moistened, the pulp becomes mucilaginous. The fruit is astringent to the taste, and yields its virtues to water by maceration or decoction. It was found by Mr. Pollock to contain tannic acid, a concrete essential oil, and a vegetable acid. (*Med. Times and Gaz.*, Feb. 1864, p. 199.)

The difficulty of obtaining bael in England, is said of late to have led to the substitution for it of mangosteen, the fruit of *Garcinia Mangostana*. This is in irregular fragments of the rind, without any adhering pulp. The pieces are convex, three or four lines or more in thickness, externally covered with a smooth, deep reddish-brown, easily separable coating, and internally pale reddish-brown or reddish-yellow, smooth, but with projecting vertical lines. (Prof. Bentley, *Pharm. Journ. and Trans.*, May, 1867, p. 654.)

Medical Properties and Uses. Bael, as the medicine is called in India, or

bela, as it has been officinally named, is said to possess astringent properties which render it useful in diarrhœa, dysentery with debility of the mucous membrane, and other diseases of the bowels with relaxation, which it relieves without inducing constipation. It is much used by some practitioners in India, generally in the form of decoction, made by slowly boiling down a pint of water with two ounces of the dried fruit to four fluidounces. Of this one or two fluid ounces are given in acute cases every two or three hours, in chronic cases two or three times a day. A liquid extract is directed in the Br. Pharmacopœia, the dose of which may be one or two fluidrachms. Mr. Waring, of the East India medical service, recommends an extract in the dose of half a drachm or a drachm. (*Med. Times and Gaz.*)

ATROPA. *Sex. Syst.* Pentandria Monogynia.—*Nat. Ord.* Solanaceæ.

Gen. Ch. Corolla bell-shaped. *Stamens* distant. *Berry* globular, two-celled. *Willd.*

Atropa Belladonna. Willd. *Sp. Plant.* i. 1017; Woodv. *Med. Bot.* p. 230, t. 82; Carson, *Illust. of Med. Bot.* ii. 19, pl. lxv. The belladonna, or *deadly nightshade*, is an herbaceous perennial, with a fleshy creeping root, from which rise several erect, round, purplish, branching stems, to the height of about three feet. The leaves, which are attached by short footstalks to the stem, are in pairs of unequal size, oval, pointed, entire, of a dusky green on their upper surface, and paler beneath. The flowers are large, bell-shaped, pendent, of a dull-reddish colour, with solitary peduncles, rising from the axils of the leaves. The fruit is a roundish berry with a longitudinal furrow on each side, at first green, afterwards red, ultimately deep purple, bearing considerable resemblance to a cherry, and containing, in two distinct cells, numerous seeds, and a sweetish violet-coloured juice. The calyx adheres to the base of the fruit.

The plant is a native of Europe, where it grows in shady places, along walls, and amidst rubbish, flowering in June and July, and ripening its fruit in September. It grows vigorously under cultivation in this country, and retains all its activity, as shown by the observations of Mr. Alfred Jones. (*Am. Journ. of Pharm.*, xxiv. 106.) All parts of it are active. The leaves and roots are directed by the United States and British Pharmacopœias; the latter including the young branches, which are probably not less efficient. The leaves should be collected in June or July, when the plant is in flower, the roots in the autumn or early in the spring, and from plants three years old or more. Leaves which have been kept long should not be used, as they undergo change through absorption of atmospheric moisture, emitting ammonia, and probably losing a portion of their active nitrogenous matter. (See *Am. Journ. of Pharm.*, xxvii. 455.)

Properties. The *dried leaves* are of a dull-greenish colour, with a very faint,

narcotic odour, and a sweetish, subacrid, slightly nauseous taste. The *root* is long, round, from one to several inches in thickness, branched and fibrous, externally when dried of a reddish-brown colour, internally whitish, of little odour, and a feeble sweetish taste. As to the relative strength of these two parts, M. Hirtz, of Strasburg, has inferred from his experiments that the root yields an extract five times stronger than that obtained from the leaves; but, to determine accurately the point referred to, another element in the calculation is necessary; the relative quantity, namely, of the extracts from the two sources; and this is uncertain. (*Annuaire de Thérap.*, A.D. 1862, p. 22.) Both the leaves and root, as well as all other parts of the plant, impart their active properties to water and alcohol. Brandes rendered it probable that these properties reside in a peculiar alkaline principle, which he supposed to exist in the plant combined with an excess of malic acid, and appropriately named *atropia*. Besides malate of atropia, Brandes found in the dried herb two azotized principles, a green resin (chlorophyll), wax, gum, starch, albumen, lignin, and various salts. The alkaline principle was afterwards detected by M. Runge; and the fact of its existence was established beyond question by Geiger and Hesse, who obtained it from an extract prepared from the stems and leaves of the plant. It was first, however, procured in a state of purity by Mein, a German apothecary, who extracted it from the root. Lübekind has described, under the name of *belladonnin*, a volatile alkaline principle, wholly distinct from atropia, which he obtained from belladonna; but it yet remains to be seen whether this was not a product of the process. (See *Am. Journ. of Pharm.*, xiii. 127.) For the mode of preparing atropia and its properties, see the article ATROPIA in the second part of this work.

The imported belladonna, especially that from Germany, is occasionally adulterated. Prof. J. M. Maisch, in a communication to the *American Journal of Pharmacy* (xxxiv. 126), states that, in different packages of the German drug, he has met with the leaves of Digitalis purpurea, Solanum nigrum and villosum, and Verbascum Thapsus, the leaves, stem, and capsules of Hyoscyamus niger, and various other impurities, not to speak of the flowers and fruit and immature leaves of the belladonna plant itself. The apothecary can have no difficulty in detecting these adulterations, if acquainted with the characters of the genuine leaves. One of the most distinctive of these is the unequal size of the two leaves constituting each pair. But the plant is so easily cultivated, and grows so vigorously in this country, that all the demand for it might be readily supplied from our own gardens, without the need of recourse to Europe, were a little attention paid to the subject.

Medical Properties and Uses. The action of belladonna is that of a powerful narcotic, possessing also diaphoretic and diuretic properties, and somewhat disposed to operate upon the bowels. Among its first obvious effects, when taken in the usual dose, and continued for some time, are dryness and stricture of the fauces and neighbouring parts, with slight uneasiness and giddiness of the head, and more or less dimness of vision. In medicinal doses, it may also occasion dilatation of the pupil, decided frontal headache, slight delirium, colicky pains and purging, and a scarlet efflorescence on the skin; but this last effect is rare. The practitioner should watch for these symptoms as signs of the activity of the medicine, and should gradually increase the dose till some one of them is experienced in a slight degree, unless the object at which he aims should be previously attained; but so soon as they occur, the dose should be diminished, or the use of the narcotic suspended for a time.

In large quantities, belladonna produces the most deleterious effects. It is in fact a powerful poison; and many instances are recorded in which it has been taken with fatal consequences. All parts of the plant are poisonous. It is not uncommon, in countries where it grows wild, for children to pick and eat the berries, allured by their fine colour and sweet taste. Soon after the poison has been swallowed, its peculiar influence is experienced in dryness of the mouth and fauces, burning in the throat and stomach, great thirst, difficult deglutition, nausea and ineffectual retching, loss of vision, vertigo, and intoxication or de

lirium, with violent gestures and sometimes fits of laughter, and followed by coma. The pupil is dilated and insensible to light, the face red and tumid, the mouth and jaws spasmodically affected, the stomach and bowels insusceptible of impressions, in fact the whole nervous system prostrated and paralyzed. A feeble pulse, cold extremities, subsultus tendinum, deep coma or delirium, and sometimes convulsions precede death. Dissection discloses appearances of inflammation in the stomach and intestines; and it is said that the body soon begins to putrefy, swells, and becomes covered with livid spots, while dark blood flows from the mouth, nose, and ears. To obviate the poisonous influence of belladonna, the most effectual method is to evacuate the stomach as speedily as possible, by means of emetics or the stomach-pump, and afterwards to cleanse the bowels by purgatives and enemata. The shocks of an electro-magnetic battery have been found useful in the comatose state. (*N. Y. Journ. of Med.*, N. S., v. 172.) The infusion of galls may be serviceable as an antidote; and, if the experiments of M. Runge can be relied on, lime-water or the alkaline solutions would render the poisonous matter remaining in the stomach inert. Bouchardat recommends the iodureted solution of iodide of potassium; and a case is recorded in which it seems to have been useful. (*Ann. de Thérap.*, 1854, p. 14.)*

Dr. Garrod, of London, infers from his experiments that the caustic alkalies have the effect of destroying the activity of the poisonous principle of belladonna, and, consequently, that solution of potassa should never be used, even though very dilute, in prescriptions with this medicine, but may be employed with the hope of some benefit as an antidote, though its influence in this respect would be much limited by the necessity of giving it in small quantities, in consequence of its caustic properties.

It has been satisfactorily ascertained that the physiological effects of opium are to some extent antagonistic to those of belladonna; and that the preparations of the former may be advantageously employed in poisoning by the latter; especially where there is great nervous excitement. But, in the present state of medical experience on the subject, it would be unsafe to rely on this expedient, to the exclusion of other measures, and especially of a thorough preliminary evacuation of the stomach.

Belladonna has been used as a medicine from early times. The leaves were first employed externally to discuss scirrhous tumours, and heal cancerous and other ill-conditioned ulcers; and were afterwards administered internally for the same purpose. Much evidence of their usefulness in these affections is on record, and even Dr. Cullen spoke in their favour; but this application of the medicine has fallen into disuse. It is now more esteemed in nervous diseases. It has been highly recommended in hooping-cough, in the advanced stages of which it is undoubtedly sometimes beneficial. In neuralgia it is one of the most effectual remedies in our possession; and it may be employed to give relief in other painful affections. Hufeland recommends it in the convulsions dependent on scrofulous irritation. It has been prescribed also in nervous colic, strangulated hernia, chorea, epilepsy, hydrophobia, tetanus, mania, delirium tremens, paralysis, amaurosis, incontinence of urine, rheumatism, gout, dysmenorrhœa, obstinate intermittents, scarlatina, dropsy, and jaundice; and, in such of these affections as have their seat chiefly in the nervous system, it may sometimes do good. Bretonneau has employed it usefully in the treatment of constipation. It has been recommended as an antaphrodisiac, and is said to have been effect-

* There has been some difference of opinion as to the effect of belladonna on certain of the lower animals. Dr. W. Ogle states, as the result of his experiments on rabbits, 1. that a middle aged rabbit may live for at least 6 days exclusively on belladonna; 2. that the animal will tolerate enormous doses of atropia, whether swallowed or injected into the areolar tissue, and that this tolerance is not owing to the non-absorption of the alkaloid; 3. that the tolerance increases with the age; 4. but that dilatation of the pupil is produced at least as readily in the old as in the young. (*Am. Journ. of Med. Sci.*, July, 1867, p. 249.) These conclusions are important, as qualifying materially any inference from experiments on these animals as to the effects of belladonna on the human system. (*Note to the thirteenth edition.*)

ually employed in several cases of strangulated hernia. It has acquired considerable credit as a preventive of scarlatina; an application of the remedy first suggested by the author of the *homœopathic* doctrine; but its efficiency in this way is at best doubtful. Much has been said of it as an antidote to the poisonous effects of opium; and there is no doubt that some of the symptoms are relieved by its use; but it should not be relied on to the exclusion of measures for evacuating the stomach; nor should it be so administered that its greatest stimulant and depressing influences on the brain should coincide with the similar influences of opium.

Applied to the eye, belladonna has the property of dilating the pupil exceedingly, and for this purpose it is employed by oculists previously to the operation for cataract. Dilatation usually comes on in about an hour, is at its greatest height in three or four hours, and continues often for one or two days, or even longer. In cases of partial opacity of the crystalline lens, confined to the centre of that body, vision is temporarily improved by a similar use of the remedy; and it may also be beneficially employed, when, from inflammation of the iris, there is danger of a permanent closure of the pupil. For these purposes, a strong infusion of the plant, or a solution of the extract, may be dropped into the eye, or a little of the extract itself rubbed upon the eyelids. The same application has been recommended in morbid sensibility of the eye. The extract, rubbed upon the areola of the breast, has been found quickly to arrest the secretion of milk; and, upon the abdomen, to relieve the vomiting of pregnancy, and other irritations sympathetic with the gravid uterus. Applied, in the form of a large plaster, above the pubes, it has been found very useful in relieving dysenteric tenesmus, and, as a dressing to a blistered surface over the abdomen, has been known to effect a cure in epidemic cholera; but in such a case much care would be required to prevent its poisonous effects. (*Ann. de Thérap.*, A.D. 1860, p. 49.) The decoction or extract, applied to the neck of the uterus, is asserted to have hastened tedious labour dependent on rigidity of the os tincæ; and spasmodic stricture of the urethra, neck of the bladder, and sphincter ani, anal fissures, and painful uterine affections, have been relieved by the local use of the extract, either smeared upon bougies, or administered by injection. In the latter mode it has relieved strangulated hernia It is asserted also to be useful in paraphimosis. The inhalation of the vapour from a decoction of the leaves or extract has been recommended in spasmodic asthma. For this purpose, two drachms of the leaves, or fifteen grains of the aqueous extract are employed to the pint of water. Relief is said to have been obtained in phthisis by smoking the leaves, infused when fresh in a strong solution of opium, and then dried.

Belladonna may be given in substance, infusion, or extract. The dose of the powdered leaves is for children from the eighth to the fourth of a grain, for adults one or two grains, repeated daily, or twice a day, and gradually increased till the characteristic effects are experienced. An infusion may be prepared by adding a scruple of the dried leaves to ten fluidounces of boiling water, of which from one to two fluidounces is the dose for an adult. The extract is generally preferred in the United States. (See *Extractum Belladonnæ.*)

From its quicker action, more uniform strength, and greater cleanliness, *atropia* has been largely substituted for extract of belladonna for local use; and it is also much employed internally. (See *Atropia* in Part II.)

BENZOINUM. *U.S., Br.*

Benzoin.

The concrete juice of Styrax Benzoin. *U. S.* A balsamic resin obtained from Styrax Benzoin. *Br.*

Benjoin, *Fr.;* Benzoe, *Germ.;* Belzoino, *Ital.;* Benjui, *Span.*

The botanical source of benzoin was long uncertain. At one time it was

generally supposed in Europe to be derived from the *Laurus Benzoin* of this country. This error was corrected by Linnæus, who, however, committed another, in ascribing the drug to *Croton Benzoë*, a shrub which he afterwards described under the name of *Terminalia Benzoin*. Mr. Dryander was the first who ascertained the true benzoin-tree to be a *Styrax*; and his description, published in the 77th vol. of the London Philosophical Transactions, has been copied by most subsequent writers.

Styrax. *Sex. Syst.* Decandria Monogynia.—*Nat. Ord.* Styraceæ.

Gen. Ch. Calyx inferior. *Corolla* funnel-shaped. *Drupe* two-seeded. *Willd.*

Styrax Benzoin. Willd. *Sp. Plant.* ii. 623; Woodv. *Med. Bot.* p. 294, t. 102. This is a tall tree of quick growth, sending off many strong round branches, covered with a whitish downy bark. Its leaves are alternate, entire, oblong, pointed, smooth above, and downy beneath. The flowers are in compound, axillary clusters, nearly as long as the leaves, and usually hang, all on the same side, upon short slender pedicels.

The benzoin, or *benjamin-tree*, is a native of Sumatra, Java, Borneo, Laos, and Siam. By wounding the bark near the origin of the lower branches, a juice exudes, which hardens upon exposure, and forms the *benzoin* of commerce. A tree is deemed of a proper age to be wounded at six years, when its trunk is about seven or eight inches in diameter. The operation is performed annually, and the product on each occasion from one tree never exceeds three pounds. The juice which first flows is the purest, and affords the whitest and most fragrant benzoin. It is exported chiefly from Bangkok in Siam, and Acheen in Sumatra, and comes into the western markets in large masses packed in chests and casks, and showing externally the impression of the reed mats in which they were originally contained.

Two kinds of benzoin are distinguishable in the market; one consisting chiefly of whitish tears united by a reddish-brown connecting medium, the other of brown or blackish masses, without tears. The first is the most valuable, and has been called *benzoë amygdaloides*, from the resemblance of the white grains to fragments of blanched almonds; the second is sometimes called *benzoë in sortis*—benzoin in sorts—and usually contains numerous impurities. Between these two kinds there is every gradation. We have seen specimens consisting exclusively of yellowish-white homogeneous fragments, which when broken presented a smooth, white, shining surface. These were no doubt identical in constitution with the tears of the larger masses.

A factitious substance has been sold in our markets for benzoin, consisting of chips of wood agglutinated by a resinous substance, with no benzoic acid, and only a trace of the cinnamic. (J. M. Maisch, *Am. Journ. of Pharm.*, xxxv. 494.)

Properties. Benzoin has a fragrant odour, with very little taste; but, when chewed for some time, leaves a sense of irritation in the mouth and fauces. It breaks with a resinous fracture, and presents a mottled surface of white and brown or reddish-brown; the white spots being smooth and shining, while the remainder, though sometimes shining and even translucent, is usually more or less rough and porous, and often exhibits impurities. In the inferior kinds, the white spots are very few, or entirely wanting. Benzoin is easily pulverized, and, in the process of being powdered, is apt to excite sneezing. Its sp. gr. is from 1·063 to 1·092. When heated it melts, and emits thick, white, pungent fumes, which excite cough when inhaled, and consist chiefly of benzoic acid. It is wholly soluble, with the exception of impurities, in alcohol, and is precipitated by water from the solution, rendering the liquor milky. It imparts to boiling water a notable proportion of benzoic acid. Lime-water and the alkaline solutions partially dissolve it, forming benzoates, from which the acid may be precipitated by the addition of other acids. Its chief constituents are resin and benzoic acid; and it therefore belongs to the balsams. The white tears and the brownish connecting medium are said by Stolze to contain nearly the same proportion of acid, which, according to Bucholz, is 12·5 per cent., to Stolze, 19·8 per cent. In a more recent examination by Kopp, the white tears were found

to contain from 8 to 10 per cent. of acid, and the brown 15 per cent. (*Journ. de Pharm.*, 3e sér., iv. 46.) The resin is of three kinds, one extracted from the balsam with the benzoic acid by a boiling solution of carbonate of potassa in excess, another dissolved by ether from the residue, and the third affected by neither of these solvents. Besides benzoic acid and resin, the balsam contains a minute proportion of extractive, and traces of volatile oil. Benzoin retards the oxidation of fatty matters, and thus tends to prevent rancidity.

It appears from recent researches that benzoin, besides its own characteristic acid, often also contains the cinnamic, which is found more especially in the white tears. Indeed, Hermann Aschoff obtained from some benzoin of Sumatra a pure cinnamic acid, without any benzoic; and Messrs. Kolbe and Lautermann, upon examining a specimen of the tears, discovered what they at first supposed to be a peculiar acid, but which, on further investigation, proved to be a mixture of the cinnamic and benzoic acids. Aschoff recommends the following method of detecting cinnamic acid. Boil the benzoin with milk of lime, filter, decompose with muriatic acid, and add either bichromate of potassa with sulphuric acid, or permanganate of potassa, when, if cinnamic acid be present, the odour of oil of bitter almonds will be perceived. (*Annal. der Chem. und Pharm.*, cxix. 136.) The two acids which, when they occur together in benzoin, are said to be always mixed in the same proportion, may be at least partially separated by simple crystallization; their melting points being very different, that of benzoic acid 249° F., and that of the mixed acid, consisting of one part of the cinnamic and two of the benzoic, only 78° F. (*Pharm. Journ.*, Aug. 1863, p. 77.)

Medical Properties and Uses. Benzoin is stimulant and expectorant, and was formerly employed in pectoral affections; but, except as an ingredient of the compound tincture of benzoin, it has fallen into disuse. Trousseau and Pidoux recommend strongly its inhalation in chronic laryngitis. Either the air of the chamber may be impregnated with its vapour by placing a small portion upon some live coals, or the patient may inhale the vapour of boiling water to which the balsam has been added. It is employed in pharmacy for the preparation of benzoic acid (see *Acidum Benzoicum*); and the milky liquor resulting from the addition of water to its alcoholic solution is sometimes used as a cosmetic, under the impression that it renders the skin soft. A tincture has been strongly recommended in fissures of the anus. In the East Indies the balsam is burnt by the Hindoos as a perfume in their temples.*

Berberis. *Sex. Syst.* Hexandria Monogynia.—*Nat. Ord.* Berberaceæ. *Lindley.*

* A styptic liquid, prepared by a Roman pharmaceutist named *Pagliari*, and kept secret for a time, has acquired some reputation among the French army surgeons. It is made by boiling, for six hours, eight ounces of tincture of benzoin (containing about two ounces of the balsam), a pound of alum, and ten pounds of water, in a glazed earthen vessel, stirring constantly, and supplying the loss with hot water. The liquor is then strained and kept in stopped bottles. It is limpid, styptic, of an aromatic smell, and said to have the property of causing an instantaneous coagulation of the blood. (See *Am. Journ. of Med. Sci.*, N. S., xxv. 199.)—*Note to the tenth edition.*

M. Meyer, believing that the long boiling in the foregoing process is injurious, if in no other way, by dissipating the benzoic acid, proposes to dispense with it, and has substituted the following formula, which furnishes a product always identical. Take tears of benzoin, 6 grammes (about ʒiss), alcohol at 90° C. 15 grammes; dissolve and add of water 300 grammes, alum 30 grammes; mix and boil till the liquid becomes clear. The liquid should mark 6° on the hydrometer. (*Journ. de Pharm. et de Chim.*, 4e sér., v. 123.)

Fumigating pastiles are made from 16 parts of benzoin, 4 of balsam of Tolu, 4 of yellow

Gen. Ch. Sepals 6, with interior scales. *Petals* 6, with 2 glands at the base. *Stamens* 6, without denticulations. *Pericarp* fleshy, oblong, 2 to 3 seeded. *Seeds* erect, oblong, with a crustaceous skin. *Lindley.*

The plants belonging to this genus are shrubs, with the inner bark and wood yellow, and with leaves and berries of a sour taste. Besides the officinal Berberis vulgaris, there are other species of which the products have been medicinally employed. The *Lycium*, or λυκιον of the ancients, highly valued as a local application in affections of the eye and eyelids, and used for various other purposes, is supposed to be the medicine still used in India for the same affections, under the name of *rusot* or *ruswut*. This, according to Dr. Royle, is an extract from the wood or roots of different species of Berberis, as *B. Lycium*, *B. aristata*, &c., growing in Upper India, especially near Lahore. Combined with opium and alum, it is much used, and with great asserted benefit, in both incipient and chronic ophthalmia. It has been employed also by European practitioners for the same purpose, and especially by Mr. Walker, of Edinburgh, who found it very efficient. The preparation used by him consisted of equal parts of lycium and burnt alum, with half the quantity of opium, and was applied, mixed with lemon-juice to the consistence of cream, over the eyelids and eyebrows. (J. V. Simpson, *Pharm. Journ.*, xiii. 415.) More recently the remedy has been used by Mr. L. W. Stewart, Surgeon in the Madras army, with highly favourable results, in the treatment of intermittent, remittent, and typhoid fevers, diarrhœa, and dyspepsia. (*Pharm. Journ. and Trans.*, Dec. 1865, p. 303.)

Berberis vulgaris. Gray's *Manual of Botany*, p. 19; Woodv. *Med. Bot.* p. 618, t. 219. This is a native of Europe, but grows wild in waste grounds in the eastern parts of New England, and is sometimes cultivated in gardens on account of its berries. It is a spreading shrub, from 4 to 6 feet or more in height, with thorny branches, a light-gray bark, and a fine yellow wood. The leaves are somewhat obovate, with ciliated teeth on their edges, and upon the young shoots three-parted and spiny. The flowers, which are in drooping many-flowered racemes, have yellow entire petals, and are succeeded by oblong scarlet berries. It is a vulgar error to suppose that the vicinity of this plant is injurious to wheat. Under the name of *Berberis Canadensis*, Pursh described an American plant, which grows in hilly districts, from the borders of Canada to the Carolinas, and which is characterized, according to Gray, by its repandly-toothed leaves, with the teeth less bristly-pointed, by its few-flowered racemes, its petals notched at the apex, and its oval berries. By Dr. Hooker, however, it is considered a variety of B. vulgaris, from which it differs only in the points mentioned. It is from 1 to 3 feet high.

Properties. The *berries*, which grow in loose bunches, are oblong, and of a red colour, have a grateful, sour, astringent taste, and contain malic and citric acids. They are refrigerant, astringent, and antiscorbutic, and are used in Europe, in the form of drink, in febrile diseases and diarrhœas. An agreeable syrup is prepared from the juice; and the berries are sometimes preserved for the table. The *root* and *inner bark* have been used for dyeing yellow. The *bark of the root* is the officinal portion. This is grayish on the outside, yellow within, very bitter, and stains the saliva when chewed. Brandes found in 100 parts of the root 6·63 of bitter, yellow extractive, 1 55 of brown colouring matter, 0·35 of gum, 0·20 of starch, 0·10 of cerin, 0·07 of stearin, 0·03 of chlorophyll, 0·55 of a subresin, 55·40 of lignin, and 35·00 of water. The active properties reside in the extractive matter of Brandes, which, however, has subsequently been found to owe its virtues, as well as colouring properties, to a peculiar crystallizable principle, possessed of alkaline properties, and named *berberin*, or more properly *berberina*. This alkaloid appears to have been first discovered, in 1826, in a species of Xanthoxylum, by Chevallier and Pelletan, who, from its colour and

saunders, 1 of labdanum, 48 of charcoal, 2 of nitre, 1 of tragacanth, 2 of gum arabic, and 12 of cinnamon-water, by reducing the solid ingredients to powder, and mixing the whole into a plastic mass, which is to be formed into cones, flattened at the base, and dried first in the air, and then in a stove. (Soubeiran, *Trait. de Pharm.*, 3e ed., i. 463.)

taste, named it *xanthopicrite*. Buchner and Herberger, in 1835, found it in Berberis vulgaris, and named it berberin; but none of these chemists were aware of its alkaline properties. Indeed, the substance obtained by them, at least the berberin of Buchner, must have been a native salt of the proper alkaloid, which was not, therefore, procured in a pure state. Subsequently Fleitmann demonstrated its basic character, and published an account of several of its salts. It is not confined to the barberry, but has been found, by various chemists, in several other plants, particularly those combining bitterness and a yellow colour, as in various products of Cocculus palmatus, Hydrastis Canadensis, Xanthorrhiza apiifolia, Coptis Teeta, Xanthoxylum Clava Herculis, Coscinium fenestratum, and others belonging to the natural families of *Berberaceæ*, *Menispermaceæ*, and *Ranunculaceæ*. Indeed, few if any of the known alkaloids are so widely diffused as this appears to be in the vegetable kingdom.*

Berberina may be obtained most readily from its sulphate. Prof. Procter has given the following process for preparing it, based upon a suggestion of Mr. Merrill, of Cincinnati. The coarsely powdered root is to be exhausted by repeated decoction with boiling water, and the mixed liquids, after filtration, are to be evaporated to a soft extract. This is to be digested several times with stronger alcohol, in the proportion of a pint to half a pound of the root, until exhausted, one-fourth of its bulk of water is to be added to the tincture, and five-sixths of the alcohol to be distilled off. To the residue, while still hot, sulphuric acid is to be added in excess, and the liquid allowed to cool. The sulphate of berberin is deposited in crystals, and, having been purified by recrystallization, is to be decomposed by the addition, in excess, to its solution in boiling water, of freshly precipitated protoxide of lead, the solution being kept hot until the decomposition is completed. This may be known by the absence of a precipitate when acetate of lead is added to a drop of the clear liquid. The liquid is then to be filtered, and set aside to crystallize. Thus obtained, berberina is in the form of a yellow powder, which, under the microscope, appears to consist of groups of minute acicular crystals. It has a bitter taste, is soluble in about 100 parts of cold water, still less soluble in cold alcohol, freely soluble in both these liquids when hot, and insoluble in ether. It forms salts of difficult solubility with muriatic and sulphuric acids, and is distinguished by being copiously precipitated by the former acid from its cold watery solution in the form of crystals of the muriate. It is freely dissolved by acetic acid, which forms with it a readily soluble salt. (*Am. Journ. of Pharm.*, Jan. 1864, p. 10.) Its formula is, according to Fleitmann, $C_{42}H_{18}NO_9$, but, on the more recent authority of Perrins, $C_{40}H_{17}NO_8$. (*Pharm. Journ.*, April, 1863, p. 464.) The *muriate of berberina*, which is the salt that has attracted most notice, may be readily obtained by using muriatic instead of sulphuric acid in the above process, and purifying the precipitate by solution in hot alcohol, and subsequent refrigeration. It is in fine acicular crystals, of a bright-yellow colour, and intensely bitter taste, very slightly soluble in cold water, to which, however, it imparts a deep-yellow colour, slightly soluble also in cold alcohol, but dissolved in large proportion by both liquids when hot. By concentrated nitric acid both this salt and its base are decomposed, with the production of a dark-red colour, and the escape of nitrous fumes.

Besides berberina, another alkaloid has been discovered in the root of the barberry, for which the name of *vinetina*, derived from the French name of the plant, has been proposed. *Oxycanthin* and *berbina* are other, though less appropriate names, which have been applied to this principle. To procure it, the mother-liquor of berberina is precipitated by carbonate of soda, the precipitate treated with dilute muriatic acid, and the liquid filtered, and precipitated by ammonia. The impure alkaloid thus obtained may be purified by washing with water, drying, exhausting with ether, evaporating, dissolving the residue in dilute muriatic acid, and finally precipitating by ammonia. Vinetina is a white amorphous powder, crystallizable from its alcoholic and ethereal solutions,

* For a list of all plants from which it has been obtained, see a paper by J. Dyson Perrins, contained in the *Am. Journ. of Pharm* (Sept. 1863, p. 456).

purely bitter, fusible unchanged at 283° F., insoluble or but slightly soluble in water, sparingly dissolved by cold but freely by hot alcohol and ether, and freely soluble in alcohol. It forms soluble salts with the acids, and its muriate is white. When deprived of one eq. of water at 212°, it has the formula $C_{32}H_{23}NO_{11}$. (*Am. Journ. of Pharm.*, xxxiii. 455.)

Medical Properties. Barberry is in small doses tonic, in larger cathartic, and was formerly given in jaundice, in which, though probably originally employed on account of its yellow colour, it may be useful, when the influence of a gentle tonic and laxative is required. It may be used in the form of decoction. There can be little doubt that its alkaloid berberina, from its extensive diffusion in plants used in medicine, is possessed of valuable remedial properties, and capable of advantageous application in many diseases. It would be desirable to test thoroughly its antiperiodic properties. It may be used in the form of the muriate, of which the dose is stated at from one to ten grains, according to the effect desired. Should it come into extensive use, it would be more conveniently obtained from the root of our native Hydrastis Canadensis, which yields it very copiously. W.

BISMUTHUM. *U. S., Br.*

Bismuth.

A crystalline metal. As met with in commerce it is generally impure. *Br.* Etain de glace, Bismuth, *Fr.;* Wissmuth, *Germ.;* Bismutto, *Ital.;* Bismut, *Span.*

Bismuth occurs usually in the metallic state, occasionally as a sulphuret, and rarely as an oxide. It is found principally in Saxony. It occurs also in Cornwall, and has been found at Monroe, in Connecticut. It has recently been discovered largely in South Australia, whence a quantity of it has been sent into commerce. (*Pharm. Journ. and Trans.*, Aug. 1867, p. 95.) It is obtained almost entirely from native bismuth, which is heated by means of wood or charcoal, whereby the metal is fused and separated from its gangue. Nearly all the bismuth of commerce comes from Saxony.

Bismuth was first distinguished as a metal by Agricola in 1520. Before that period it was confounded with lead. It is a brittle, pulverizable, brilliant metal, of a crystalline texture, and of a white colour with a slight reddish tint. Its crystals are in the form of cubes. It undergoes but a slight tarnish in the air. Its sp. gr. is 9·8, melting point 507° (*Brande and Taylor*), eq. number 213, and symbol Bi. When impure bismuth solidifies after fusion, globules of the metal, nearly pure, are thrown up from the mass. This takes place when the metal contains as much as 50 per cent. of impurity. The same phenomenon does not occur when pure bismuth is melted. (*R. Schneider.*) At a high temperature, in close vessels, bismuth volatilizes, and may be distilled over. When heated in the open air to a full red heat, it takes fire, and burns with a faint blue flame, forming an oxide of a yellow colour. This is the *teroxide*, and consists of one eq. of bismuth 213, and three of oxygen 24 = 237. There is another compound of bismuth and oxygen, consisting of one eq. of the former and five eqs. of the latter, which, having acid properties, is called *bismuthic acid*, BiO_5. It is obtained in the form of a hydrate by boiling nitrate of bismuth in solution of potassa, washing the precipitate, and mixing it while moist with solution of potassa into which chlorine is passed. A mixture of teroxide and bismuthic acid is precipitated, from which the former is separated by digestion with nitric acid. The hydrated acid remaining, when washed and dried, is in the form of a red powder, which gives up its water at 266°, and at a higher heat loses oxygen. Bismuth is acted on feebly by muriatic acid, but violently by nitric acid, which dissolves it with a copious extrication of red fumes. Sulphuric acid, when cold, has no action on it, but at a boiling heat effects its solution with the extrication of sulphurous acid. As it occurs in commerce, it is generally contaminated with other metals, among which is arsenic in minute quantity, and sometimes a very small proportion of thallium. It may be purified from all contaminating metals

by dissolving the bismuth of commerce in diluted nitric acid, precipitating the clear solution by adding it to water, and reducing the white powder thus obtained with black flux. The same precipitate is obtained by adding ammonia to the nitric solution; and, if the supernatant liquor is blue, the presence of copper is indicated. If the precipitate is yellowish, iron is present.

Pharmaceutical Uses, &c. Bismuth is not used in medicine in an uncombined state, but is employed pharmaceutically to obtain the subcarbonate and subnitrate of bismuth, the only medicinal preparations formed from this metal. In the arts it is used to form a white paint for the complexion, called *pearl white;* and as an ingredient of the best pewter.

BRAYERA. *U. S. Secondary*

Koosso.

The flowers and unripe fruit of Brayera anthelmintica. *U. S.*

Off. Syn. CUSSO. *Kousso.* The flowers and tops of Brayera anthelmintica. *Br.*

BRAYERA. *Nat. Ord.* Rosaceæ.

Gen. Ch. "*Calyx* with the tube bibracteolate at the base, turbinate; throat internally constricted by a membranous ring: the limb with two series of segments, each five in number, the outer much larger. *Petals* five, inserted in the throat of the calyx, small, linear. *Stamens* from 15 to 20, inserted with the petals. *Filaments* free, unequal. *Anthers* bilocular, dehiscing longitudinally. *Carpels* two at the bottom of the calyx, free, unilocular, containing one or two pendulous ovules. *Styles* terminal, exserted from the throat of the calyx, thickened upward. *Stigmas* subpeltate, dilated, crenate, oblong." The flowers are said to be diœcious; though the male have well-developed carpels.

Brayera anthelmintica. Kunth; De Cand. *Prodrom.* ii. 580; Pereira, *Mat. Med.*, 3d ed., ii. 1818.—*Hagenia Abyssinica.* Lamarck.—*Banksia Abyssinica.* Bruce. This is a tree about 20 feet high, growing on the table-land of Abyssinia, at an elevation of not less than six or seven thousand feet. The branches exhibit circular cicatrices, left by the fallen leaves. These are crowded near the ends of the branches, large, pinnate, sheathing at the base, with opposite, lanceolate, serrate leaflets, villose at the margin, and nerved beneath. The flowers are tinged with purple, pedicelled, with an involucre of four roundish, oblong, obtuse, membranous bractes, and are arranged in fours, upon hairy, flexuous, bracteate peduncles, with alternate branches. They are small and of a greenish colour, becoming purple. These and the unripe fruit are the parts of the plant employed. The petals are apt to be wanting in the dried flowers. They are brought from Abyssinia packed in boxes. The Abyssinian name of the medicine has been variously spelled by European writers kosso, kousso, cusso, cosso, &c.; but that at the head of this article is deemed the most appropriate English title, as it indicates the proper pronunciation of the word.

Properties. The dried flowers are in unbroken though compressed clusters. The general colour of the mass is greenish-yellow. As the medicine, from its high price, is apt to be adulterated, it should be procured in the unpowdered state, in which the botanical characters of the flower will sufficiently test its genuineness. It has a fragrant balsamic odour; and the taste, little perceptible at first, becomes in a short time somewhat acrid and disagreeable. Analyzed by Wittstein, it was found to contain, in 100 parts, 1·44 of fatty matter and chlorophyll, 2·02 of wax, 6·25 of bitter acrid resin, 0·77 of tasteless resin, 1·08 of sugar, 7·22 of gum, 24·40 of tannic acid, 40·97 of lignin, 15·71 of ashes, with 0·14 parts loss. To Clemens Willing it yielded a small quantity of volatile oil, having the odour of the flowers, much extractive, tannic acid colouring iron green, a crystallizable acid, and a resin with a bitter and astringent taste and the odour of the oil. (*Chem. Cent. Blatt*, Marz 31, 1855, p. 224.) In which of

these constituents the virtues of the medicine reside has not been determined. The claims of the *koossine* of Signor Pavesi, of Mortara, in Piedmont, to be considered the active principle, cannot be admitted until experimentally determined; and indeed it is by no means certain that it is not a complex substance. In the present state of knowledge on the subject, it appears to us premature even to give it the name of koossine, much less that of *teniine*, which has also been proposed for it, from its supposed relation to the tapeworm. (See *Journ. de Pharm.*, Avril, 1849, p. 274.)

Medical Properties. Koosso is highly valued in Abyssinia as a vermifuge. Bruce speaks of it in his travels, and gives a figure of the plant. Dr. Brayer, a French physician, practising in Constantinople, employed the medicine effectively, and published a treatise on it at Paris, so long ago as 1823. It was in his honour that Kunth adopted his generic title of the plant. Much attention has recently been attracted to this medicine; and trials made with it have proved that it has extraordinary efficacy in the destruction and expulsion of the tapeworm. Its effects, when taken internally, are not very striking. In the ordinary dose it sometimes produces heat of stomach, nausea, and even vomiting, and shows a tendency to act on the bowels, though this effect is not always produced. It appears to operate exclusively as a poison to the worms; and has been found equally effectual in both kinds of tapeworm. The high price demanded for it has tended very much to restrict the use of the remedy; but, should the demand continue, it will no doubt be supplied at a reasonable cost, as it is brought by caravans from Abyssinia into Egypt; and the monopoly which was at first the cause of its expensiveness cannot be long maintained. The medicine is taken in the morning upon an empty stomach, a light meal having been made the preceding evening. A previous evacuation of the bowels is also recommended. The flowers are given in the form of powder, mixed with half a pint of warm water; the mixture being allowed to stand for fifteen minutes, then stirred up, and taken in two or three draughts at short intervals. The medicine may be preceded and followed by lemonade. The medium dose for an adult is half an ounce, which may be diminished one-third for a child of 12 years, one-half for one of 6, and two-thirds for one of 3. Should the medicine not act on the bowels in three or four hours, a brisk cathartic should be administered. One dose is said to be sufficient to destroy the worm. Should the quantity mentioned not prove effectual, it may be increased to an ounce or more.

Off. Prep. Infusum Cusso, *Br.* W.

BROMINIUM. *U.S.*

Bromine.

Off. Syn. BROMUM. *Bromine.* A liquid non-metallic element, obtained from sea-water, and from saline springs. *Br.*

Brome, *Fr.;* Brom, *Germ.;* Bromo, *Ital.*

Bromine is an elementary body, possessing many analogies to chlorine and iodine. It was discovered in 1826 by M. Balard, of Montpellier, in the bittern of sea-salt works, in which it exists as a bromide of magnesium. Since then it has been found in the waters of the ocean, in certain marine animals and vegetables, in various aquatic plants, as the water-cress, in numerous salt springs, and, in two instances, in the mineral kingdom—in an ore of zinc, and in the cadmium of Silesia. It has also been detected by M. Mène in the coal-gas liquor of the Paris gas works. In the United States it was first obtained by Professor Silliman, who found it in the bittern of the salt works at Salina, in the State of New York. It was discovered in the salt wells, near Freeport, Pa., by Dr. David Alter, who has been engaged for several years in manufacturing it on a large scale. The bittern of the salt wells of that locality contains the bromine combined with sodium and magnesium, and affords an average product of nine drachms of bromine to the gallon; though the yield of different wells varies greatly. Bromine has been detected also in the waters of the Saratoga springs.

Minute quantities of this, as well as of chlorine and iodine, may be detected in any mixture by means of spectrum analysis. For the method employed for this purpose by Alex. Mitscherlich, see *Chem. News* (Nov. 24, 1865, p 243).

Preparation. Bromine is obtained from bittern, rich in this element, on the same principle that chlorine is procured from chloride of sodium; that is, by the action of diluted sulphuric acid and deutoxide of manganese. As manufactured near Freeport, the reaction takes place with the bromides of sodium and magnesium, with the result of forming a residue, consisting of the sulphates of soda and magnesia, mixed with sulphate of deutoxide of manganese. The distillation should be performed at a gentle heat, by means of a water-bath, into a refrigerated receiver containing water. We are informed by Dr. Thomas Magill, of Allegheny Co., Pa., that Dr. Alter first heats the bittern in an iron boiler, and then introduces it hot into the retort, thus facilitating the process.

The bittern of the salt works of Schoenbeck, in Germany, which contains only seven-tenths of one part of bromine in 1000 parts, is subjected to several successive operations, whereby the solution is reduced in bulk, and so far purified as to contain chiefly the bromide and chloride of magnesium. The chlorine is separated in the form of muriatic acid gas, by heating the liquid with sulphuric acid, at a temperature not exceeding 259°; the sulphates are crystallized out; and the bromine is evolved in the usual manner by sulphuric acid and deutoxide of manganese. The last operation, occupying six hours, is performed in a leaden still, of sufficient capacity to contain a charge of 84 pounds of the concentrated bittern, 60 or 70 pounds of weak sulphuric acid from the leaden chambers, and 40 pounds of deutoxide of manganese. The product is 4 pounds of bromine. (Moritz Herman, *Journ. de Pharm.*, Janv. 1854.)

Bromine has also been obtained from sea-weeds by carbonizing them, lixiviating the carbonaceous residue, and then separating the ingredients, among which are iodine and bromine. For the particulars of the process, see *Chem News* (July 6, 1866, p. 2).

Properties. Bromine is a volatile liquid, of a dark-red colour when viewed in mass, but hyacinth-red in thin layers. Its taste is very caustic, and its smell strong and disagreeable, having some resemblance to that of chlorine.* Its density is very nearly 3 (2·966, *Br.*). At 4° below zero it becomes a hard, brittle, crystalline solid, having a dark leaden colour, and a lustre nearly metallic. It boils at about 117°, forming a reddish vapour resembling that of nitrous acid, and of the sp. gr. 5·39. It evaporates readily, a single drop being sufficient to fill a large flask with its peculiar vapour. Shaken with solution of soda in slight excess it becomes colourless, and, if now coloured again by a little bromine, does not assume a blue colour on the addition of a cold solution of starch (*Br.*); thus showing the absence of iodine.

Bromine is sparingly soluble in water, to which it communicates an orange colour, more soluble in alcohol, and still more so in ether. By the aid, however, of bromide of potassium, it may be dissolved to any desirable extent in water. Its alcoholic and ethereal solutions lose their colour in a few days, and become acid from the generation of hydrobromic acid. It bleaches vegetable substances like chlorine, destroys the colour of sulphate of indigo, and decomposes organic matters. Its combination with starch has a yellow colour. It corrodes the skin and gives it a deep-yellow stain. Bromine is intermediate in its affinities between chlorine and iodine; since its combinations are decomposed by chlorine, while, in its turn, it decomposes those of iodine. Its eq. number is 78·4 (80, *Dumas*), and its symbol Br. It forms acids with both oxygen and hydrogen, called bromic and hydrobromic acids, which are analogous in properties and composition to the corresponding acids of chlorine and iodine. It combines also with chlorine,

* Inhaled in the form of vapour it produces intense irritation, and endangers asphyxia through spasm of the glottis. A case which had nearly proved fatal occurred under the notice of G. P. Duffield, Ph.D., of Detroit, and was apparently saved by throwing steam sufficiently cooled into the larynx. (*Am. Journ. of Pharm.*, July, 1868, p. 288.)—*Note to the thirteenth edition.*

forming chloride of bromine, which probably has the formula $BrCl_5$. This is prepared by passing chlorine through bromine, and condensing the resulting vapours at a low temperature. It is a reddish-yellow liquid, very fluid and volatile, soluble in water, and having a penetrating odour and disagreeable taste.

Commercial bromine sometimes contains as much as 6 or 8 per cent. of *bromide of carbon*, as ascertained by M. Poselger. He discovered the impurity by submitting some bromine to distillation, during the progress of which the boiling point rose to 248°. The residuary liquid at this temperature was colourless, and, when freed from a little bromine, proved to be the bromide of carbon in the form of an oily, aromatic liquid.

In testing for bromine in mineral or saline waters, the water is evaporated in order to crystallize most of the salts. The solution, after having been filtered, is placed in a narrow tube, and a few drops of strong chlorine water are added. If this addition produces an orange colour, bromine is present. The water examined, in order that the test may succeed, must be free from organic matter, and the chlorine not be added in excess. Bromine may be detected in marine vegetables by carbonizing them in a covered crucible, exhausting the charcoal, previously pulverized, with boiling distilled water, precipitating any alkaline sulphuret present in the solution by sulphate of zinc, and then adding successively a few drops of nitric acid and a portion of ether, shaking the whole together. If bromine be present, it will be set free and dissolve in the ether, to which it will communicate an orange colour. (*Dupasquier.*) According to Reynoso, a more delicate test is furnished by oxidized water, which liberates bromine from its compounds, without reacting on it when free. The mode of proceeding is as follows. Put a piece of the deutoxide of barium in a test tube, and add successively distilled water, pure muriatic acid, and ether. The materials are here present for generating oxidized water; and so soon as bubbles are seen to rise to the surface, the substance suspected to contain bromine is added, and the whole shaken together. If a bromide be present, the muriatic will give rise to hydrobromic acid; and the oxidized water, acting on this, will set free the bromine, which will dissolve in the ether, and give it a yellow tint.

Medical Properties. Bromine, from its analogy to iodine, was early tried as a remedy, and the result has demonstrated its value as a therapeutic agent. It acts like iodine as an alterative, and probably also as a stimulant to the lymphatic system, thereby promoting absorption. It has been employed in bronchocele, scrofulous tumours and ulcers, secondary and tertiary syphilis, amenorrhœa, diphtheric affections, chronic diseases of the skin, and hypertrophy of the ventricles. Magendi recommends it in cases in which iodine does not operate with sufficient activity, or has lost its effect by habit. The form in which it is employed is aqueous solution, the dose of which, containing one part of bromine to forty of distilled water, is about six drops taken several times a day.* Locally it is powerfully irritant, and in its concentrated state even caustic. When used as a wash for ulcers, from ten to forty minims may be added to a pint of water. Bromine has recently been found by Dr. Goldsmith, Surgeon of the U. S. Volunteers, extremely efficacious as a local remedy in hospital gangrene, being applied either pure or dissolved in water; and the same remedy, dissolved in water, with the aid of bromide of potassium, in the proportion of from 15 to 40 drops to the fluidounce, has produced very good effects in erysipelas. (See *Am. Med. Times*, June 20, 1863.) Of the compounds of bromine, the bromides of potassium, ammonium, iron, and mercury have been chiefly used. Some of them have been found to exercise a remarkable influence in allaying nervous irritation, and are now much employed for that purpose. See these titles respectively in the different parts of this work. The *chloride of bromine*

* This is a very small dose, originally taken from Pereira's Materia Medica; and much more has been given with impunity. M. Pourché, of Montpellier, gave six drops of bromine in three ounces of distilled water three times in 24 hours. (*Trousseau and Pidoux.*) A safe and efficient dose would probably be two or three drops, largely diluted with distilled water, and gradually increased if necessary. (*Note to the thirteenth edition.*)

has been used in cancer by Landolfi, of Naples, both externally as a caustic and internally. The caustic was usually formed of equal parts of the chlorides of bromine, zinc, gold, and antimony, made into a paste with flour. To assist the local treatment, he gave a pill, composed of the tenth of a drop of chloride of bromine, half a grain of extract of hemlock, and a grain of phellandrium seed, daily, for two months, and twice a day for two months more. (*Arch. Gén.*, Mai, 1855, p. 609.) A committee of the Paris Academy of Sciences, consisting of M. Broca and others, having practically examined the method of Landolfi in the hospitals, reported decidedly against it, not only as inefficacious, but as sometimes positively injurious. (*Gaz. Hebdom. de Méd. et Chir.*, Mai 9, 1856.)

Dr. J. Lawrence Smith, of Louisville, Ky., proposes the following as a convenient formula for a solution of bromine. Dissolve 160 grains of bromide of potassium in two fluidounces of water, add one troyounce of bromine, and, stirring diligently, pour in sufficient water to make the solution measure four fluidounces. The solution should be kept in accurately stopped bottles. This is a suitable preparation for application to hospital gangrene, and may be diluted to any desirable extent with water. (*Am. Journ. of Pharm.*, May, 1863, p. 202.)

Bromine, in an overdose, acts as an irritant poison. The best antidote, according to Mr. Alfred Smee, is ammonia. A case of poisoning by this substance, which proved fatal in seven hours and a half, is related by Dr. J. R. Snell, of Long Island, N. Y. The amount swallowed was about an ounce, and the symptoms generally were those produced by the irritant poisons: such as violent inflammation of the lips, mouth, tongue, and œsophagus, with incessant burning pain, followed, in two hours and a half, by prostration, which soon ended in death. (*New York Journ. of Med.*, Sept. 1850.)

Bromine is extensively used in the art of the daguerreotypist.

Off. Prep. Ammonii Bromidum, *Br.*; Potassii Bromidum. B.

BUCHU. *U. S.*

Buchu.

The leaves of Barosma crenata, and of other species of Barosma. *U. S.*

Off. Syn. BUCHU FOLIA. The dried leaves of Barosma betulina, Barosma crenulata, and Barosma serratifolia. *Br.*

This medicine consists of the leaves of different plants growing at the Cape of Good Hope, formerly ranked in the genus *Diosma*, but transferred by botanists to *Barosma*, so named from the strong odour of the leaves (βαρυς and οσμη). *B. crenata* (*B. betulina*, Br.), *B. crenulata*, and *B. serratifolia* are described by Lindley as medicinal species. The leaves of these and other Barosmas, and of some *Agathosmas*, are collected by the Hottentots, who value them on account of their odour, and, under the name of *bookoo* or *buchu*, rub them, in the state of powder, upon their greasy bodies.

Barosma. *Sex. Syst.* Pentandria Monogynia. — *Nat. Ord.* Rutaceæ.

Gen. Ch. Calyx five-cleft or five-parted. Disk lining the bottom of the calyx, generally with a short scarcely prominent rim. *Petals* five, with short claws. *Filaments* ten; the five opposite the petals sterile, petaloid; the other five longer, subulate. *Style* as long as the petals. *Stigma* minute, five-lobed. *Fruit* composed of five cocci, covered with glandular dots at the back. These plants are small shrubs, with opposite leaves and peduncled flowers. (*Lindley.*)

Barosma crenata. Lindley, *Flor. Med.* p. 213. — *Diosma crenata.* De Cand. *Prodrom.* i. 714; Woodv. *Med. Bot.*, 3d ed., v. 52. This is a slender shrub, with smooth, somewhat angular branches, of a purplish colour. The leaves are opposite, ovate or obovate, acute, serrated and glandular at the edge, coriaceous, and full of small pellucid dots on the under surface. The flowers are white or of a reddish tint, and stand solitarily at the end of short, lateral, leafy shoots.

Properties. The leaves, as found in the shops, are from three-quarters of an inch to an inch long, from three to five lines broad, elliptical, lanceolate-ovate

or obovate, sometimes slightly pointed, sometimes blunt at the apex, very finely notched and glandular at the edges, smooth and of a green colour on the upper surface, dotted and paler beneath, and of a firm consistence. Their odour is strong, diffusive, and somewhat aromatic; their taste bitterish, and analogous to that of mint. These properties will distinguish them from senna, with which they might be confounded upon a careless inspection. They are sometimes mixed with portions of the stalks and fruit. Cadet de Gassicourt found them to contain, in 1000 parts, 6·65 parts of a light, brownish-yellow, and highly odorous volatile oil, 211·7 of gum, 51·7 of extractive, 11 of chlorophyll, and 21·51 of resin. Water and alcohol extract their virtues, which probably depend on the volatile oil and extractive. The latter is precipitated by infusion of galls.

The foregoing description of buchu leaves applies to the drug, as first seen by the author many years ago, when the chief product imported was probably that of B. crenulata, more or less mixed with the leaves of B. crenata. The first of these has now in great measure disappeared from our market, the importations consisting either of the leaves of B. crenata or B. serratifolia, in distinct parcels. The following is a concise description of the three different kinds of leaf. The leaves of *B. crenata* (*short buchu* or *round buchu*, as it is called in commerce) are "about three-quarters of an inch long, obovate, with a recurved truncated apex, and sharp, cartilaginous, spreading teeth;" those of *B. crenulata*, of *medium size*, "are about an inch long, oval-lanceolate, obtuse, minutely crenated, and five-nerved;" those of *B. serratifolia*, or *long buchu*, "are from an inch to an inch and a half long, linear-lanceolate, tapering to each end, sharply and firmly serrated, three-nerved." (*Br.*). The last-mentioned leaves are also of more delicate structure than the others. Of the three species, the short-leaved was found by Mr. P. W. Bedford to yield an average of 1·21 per cent. of volatile oil; while the long-leaved, though more highly valued in the market, gave only 0·66 per cent., showing their great inferiority in strength. (*Proceed. of the Am. Pharm. Association*, A.D. 1863, p. 211.)

Medical Properties and Uses. Buchu is gently stimulant, with a peculiar tendency to the urinary organs, producing diuresis, and, like all similar medicines, exciting diaphoresis when circumstances favour this effect. The Hottentots have long used it in a variety of diseases. From these rude practitioners the remedy was borrowed by the resident English and Dutch physicians, by whose recommendation it was employed in Europe, and has come into general use. It is given chiefly in complaints of the urinary organs, such as gravel, chronic catarrh of the bladder, morbid irritation of the bladder and urethra, disease of the prostate, and retention or incontinence of urine from a loss of tone in the parts concerned in its evacuation. It has also been recommended in dyspepsia, chronic rheumatism, cutaneous affections, and dropsy. From twenty to thirty grains of the powder may be given two or three times a day. The leaves are also used in infusion, in the proportion of an ounce to a pint of boiling water, of which the dose is one or two fluidounces. A tincture has been employed as a stimulant embrocation in local pains. There is an officinal fluid extract, of which the dose is half a fluidrachm.

Off. Prep. Extractum Buchu Fluidum, *U.S.*; Infusum Buchu; Tinctura Buchu, *Br.* W.

CADMIUM. *U.S.*

Cadmium.

This metal was introduced into the present U.S. Pharmacopœia, because used in the preparation of sulphate of cadmium. It is associated with zinc in its ores, and, being more volatile than that metal, comes over with the first portions of it distilled in the process for obtaining it. (See *Zincum.*) The cadmium is separated by dissolving the mixed metal in dilute sulphuric acid, precipitating the sulphuret by sulphuretted hydrogen, treating the precipitate with muriatic acid, and again precipitating with carbonate of ammonia. The

carbonate of cadmium thus obtained, after being washed and dried, is mixed with charcoal, and exposed to a dull-red heat in an earthen retort, when the reduced metal distils over.

Properties. Cadmium is a white metal, resembling tin, but somewhat heavier and more tenacious. Like that metal, it crackles when bent. Its sp. gr. is 8·7, melting point about 440°, point of volatilization 480° (*Guy*), equivalent 55·8, and symbol Cd. It is little affected by the air, but, when heated, combines with an eq. of oxygen, forming a reddish-brown or orange-coloured oxide, CdO, which combines with the acids to form salts. From its saline solutions the oxide is precipitated by the alkalies in the form of a white hydrate. Cadmium also combines with chlorine, iodine, bromine, and sulphur, in equivalent proportions. It is distinguished by forming a colourless solution with nitric acid, from which sulphuretted hydrogen or hydrosulphate of ammonia precipitates a lemon-yellow sulphuret, insoluble in an excess of the reagent, or in potassa or ammonia, and not volatilized at a red heat. Potassa produces a white precipitate insoluble in an excess, and ammonia a similar precipitate soluble in an excess of the precipitant. Zinc precipitates cadmium in the metallic state. "A neutral solution of the metal in nitric acid, after having been fully precipitated by carbonate of soda in slight excess, yields a filtrate which is not affected by hydrosulphate of ammonia." (*U.S.*) This proves the absence of arsenic.

Medical Uses. According to Prof. Simpson, of Edinburgh, cadmium resembles antimony in its effects on the system. Dr. Garrod considers the metal, in this respect, more closely allied to zinc. In overdoses its salts appear to act as corrosive poisons. Three cases are recorded in which serious consequences resulted from inhaling the powdered carbonate, while used in polishing silver. The chief symptoms were constriction of the throat, embarrassed respiration, vomiting and purging, giddiness, and painful spasms. (*Annuaire de Thérap.*, A.D. 1859, p. 229.) Experiments by Dr. Wilh. Marmé demonstrate that the sulphuret of cadmium is not poisonous, but that all its compounds soluble in water or in diluted acids at the heat of the body are so; and they all operate in an analogous manner, locally as powerful irritants, and internally producing giddiness, vomiting, purging, slowness of pulse and respiration, prostration, loss of consciousness, and spasms. (*Neues Repertorium*, A.D. 1867, xvi. 303.) It is chiefly, if not exclusively, for external application that the preparations of this metal are used. Two of them have especially engaged attention; the iodide and sulphate. The latter is among the *Preparations* in the U. S. Pharmacopœia, and will be treated of in the second part of this work. (See *Cadmii Sulphas.*) The former will be noticed here.

Off. Prep. Cadmii Iodidum, *Br.;* Cadmii Sulphas, *U. S.;* Unguentum Cadmii Iodidi, *Br.* B.

CADMII IODIDUM. *Br.*

Iodide of Cadmium.

Iodide of cadmium (CdI) may be prepared by mixing iodine and filings of cadmium in a moist state. It is soluble in water and alcohol, and may be crystallized from either solution in large, white, transparent crystals, in the form of six-sided tables, of a pearly lustre. These are permanent in the air, melt at about 600° F. forming an amber-coloured liquid, and give off violet vapours at a dull-red heat. The salt is freely soluble in water and in alcohol, and the solution has an acid reaction. The Br. Pharmacopœia gives the following tests. The aqueous solution gives a yellow precipitate with sulphuretted hydrogen or sulphide of ammonium, insoluble in excess of the sulphide; and a white gelatinous precipitate with excess of solution of potash, the filtrate from which is unaffected by sulphide of ammonium. Ten grains dissolved in water gives with an excess of nitrate of silver a precipitate which, washed with water and afterwards with half an ounce of water of ammonia, and dried, weighs 12·5 grains.

Iodide of cadmium was introduced as an external remedy by Dr. A. B. Gar-

rod, of London. He has employed it, with good effects, in the form of ointment, made of one part of the iodide to eight of lard, as a local application by friction to enlarged scrofulous glands, nodes, chronic inflammations of joints, certain cutaneous diseases, and chilblains. The ointment is soft and white, readily yields its iodine for absorption, and is preferable to the corresponding ointment of iodide of lead, the use of which endangers lead poisoning. (*Pharm. Journ. and Trans.*, Nov. 1857, p. 260.) B.

Coffee.

The seed of Caffea Arabica. *U. S.*

Café, *Fr.;* Kaffee, *Germ.;* Caffè *Ital.;* Café, *Span.;* Bun, *Arabic;* Copi cotta, *Cingalese;* Kaeva, *Malay.*

Coffea. *Sex. Syst.* Pentandria Monogynia.—*Nat. Ord.* Cinchonaceæ. *Lindley.*

Gen. Ch. "*Calyx* with a small, 4-5 toothed limb. *Corolla* tubular, funnel-shaped, with a 4-5 parted spreading limb. *Stamens* 4-5, inserted in the middle of the upper part of the tube, exserted or enclosed. *Style* bifid at the apex. *Berry* umbilicate, naked, or crowned with the calyx, containing two seeds enclosed in a parchment-like putamen." *Lindley.*

Coffea Arabica. Linn Sp. 245; *Bot. Mag.*, t. 1303. The coffee-plant is a small tree, from fifteen to thirty feet in height. The branches are opposite, the lower spreading, the upper somewhat declining, and gradually diminishing in length as they ascend, so as to form a pyramidal summit, which is covered with green foliage throughout the year. The leaves are opposite, upon short footstalks, oblong-ovate, acuminate, entire, wavy, four or five inches long, smooth and shining, of a dark-green colour on their upper surface, paler beneath, and accompanied with a pair of small pointed stipules. The flowers are white, with an odour not unlike that of the jasmine, and stand in groups in the axils of the upper leaves. The calyx is very small, the corolla salverform, with a nearly cylindrical tube, and a flat border divided into five lanceolate, pointed segments. The stamens project above the tube. The fruit, which is inferior, is a roundish berry, umbilicate at top, at first green, then red, and ultimately dark purple. It is about as large as a cherry, and contains two seeds surrounded by a paper-like membrane, and enclosed in a yellowish pulpy matter. These seeds, divested of their coverings, constitute coffee.

This tree is a native of Southern Arabia and Abyssinia, and probably pervades Africa about the same parallel of latitude, as it is found growing wild at Liberia, on the western coast of the continent. It is cultivated in various parts of the world where the temperature is sufficiently elevated and uniform. Considerable attention has long been paid to its culture in its native country, particularly in Yemen, in the vicinity of Mocha, from which the demands of commerce were at first almost exclusively supplied. About the year 1690, it was introduced by the Dutch into Java, and in 1718, into their colony of Surinam. Soon after this latter period, the French succeeded in introducing it into their West India Islands, Cayenne, and the Isles of France and Bourbon; and it has subsequently made its way into the other West India Islands, various parts of tropical America, Hindostan, and Ceylon.

The tree is raised from the seeds, which are sown in a soil properly prepared, and, germinating in less than a month, produce plants which, at the end of the year, are large enough to be transplanted. These are then set out in rows at suitable distances, and in three or four years begin to bear fruit. It is customary to top the trees at this age, in order to prevent their attaining an inconvenient height, and to increase the number of the fruit-bearing branches. It is said that they continue productive for 30 or 40 years. Though almost always covered with flowers and fruit, they yield most largely at two seasons, and thus afford two harvests during the year. Various methods are employed for freeing the seeds from their coverings; but that considered the best is, by means of machinery,

to remove the fleshy portion of the fruit, leaving the seeds surrounded only by their papyraceous envelope, from which they are afterwards separated by drying, and by the action of peeling and winnowing mills.

The character of coffee varies considerably with the climate and mode of culture. Consequently, several varieties exist in commerce, named usually from the sources from which they are derived. The *Mocha Coffee*, which is in small roundish grains, takes precedence of all others. The *Java Coffee* is highly esteemed in this country; but our chief supplies are derived from the West Indies and South America. Some good coffee has been brought from Liberia. Coffee improves by age, losing a portion of its strength, and acquiring a more agreeable flavour. It is said to be much better when allowed to ripen perfectly on the tree, than as usually collected. The grains should be hard, and should readily sink in water. When soft, light, black or dark-coloured, or musty, they are inferior.

Properties. Coffee has a faint, peculiar odour, and a slightly sweetish, somewhat austere taste. An analysis by M. Payen gives for its constituents, in 100 parts, 34 of cellulose, 12 of hygroscopic water, 10 to 13 of fatty matter, 15·5 of glucose, with dextrin and a vegetable acid, 10 of legumin, 3·5 of *chlorogenate of potassa and caffein*, 3 of a nitrogenous body, 0·8 of free caffein, 0·001 of concrete volatile oil, 0·002 of fluid volatile oil, and 6·697 of mineral substances. (*Journ. de Pharm.*, 3e sér., x. 266.) Pfaff recognised, in the precipitate produced by acetate of lead with the decoction of coffee, two peculiar principles, one resembling tannin, called *caffeo-tannic acid*, and the other an acid, called by him *caffeic acid*. The latter is thought to be identical with the chlorogenic acid of Payen. When strongly heated, it emits the odour of roasted coffee, and is supposed to be the principle to which the flavour of coffee as a drink is owing. A remarkable property of caffeic acid is that, when acted on by sulphuric acid and binoxide of manganese, it is converted into kinone, being in this respect analogous to kinic acid. The *sugar* of coffee is probably neither glucose as supposed by Payen, nor cane-sugar as stated by Rochleder, but peculiar; for, when the coffee is roasted, it does not answer to Trommer's test for glucose. (*Pharm. Journ.*, xvi. 526–8.) Caffeo-tannic acid has been ascertained by Klasiwetz to be a glucoside, resolvable into glucose and a peculiar crystallizable acid, $C_{18}H_8O_8$, named by him caffeic acid (*Journ. de Pharm. et de Chim.*, Oct. 1867, p. 307), and which may be obtained from coffee, by boiling a solution of the extract with caustic potassa, treating the resulting liquid with sulphuric acid in excess, and extracting the caffeic acid with ether, which yields it somewhat impure by evaporation. (*Ibid.*, January, 1868, p. 75.) Another acid, named *viridic acid*, has been obtained by M. Cech from coffee, by bruising the grains, removing the fat by boiling etherized alcohol, and exposing the residue, moistened from time to time, to the air. In a few days the matter assumes a green colour from the formation of *viridiate of lime*, which will yield the acid to alcohol mixed with acetic acid. (*Ibid.*, Oct. 1867, p. 318.)

Caffein (*Caffeia*) was first discovered by Runge, and afterwards by Robiquet. According to Payen, it exists in coffee partly free, partly as a double salt, consisting of *chlorogenic acid*, combined with potassa and caffein. It may be obtained in the following manner. Exhaust bruised coffee by two successive portions of boiling water, unite the infusions, add acetate of lead in order to precipitate various principles accompanying the caffein, filter, decompose the excess of acetate of lead in the filtered liquor by sulphuretted hydrogen, concentrate by evaporation, and neutralize with ammonia. The caffein is deposited in crystals upon cooling, and may be purified by redissolving in water, treating with animal charcoal, and evaporating. H. J. Versmann, of Lubeck, recommends the following process as more economical. Powdered coffee, mixed with one-fifth of its weight of slaked caustic lime, is exhausted, by means of percolation, with alcohol of 0·863; the tincture is distilled to separate the alcohol; the residue is rinsed out of the still with warm water, and the supernatant oil separated; the liquid is evaporated so as to solidify on cooling; and the crystalline mass thus obtained, having been expressed and dried by pressure in bibulous

paper, is purified by solution in water with animal charcoal, and recrystallization. (*Chem. Gaz.*, Feb. 1852, p 67.) H. Leuchsenring obtains caffein by availing himself of its property of subliming unchanged by heat. He precipitates a concentrated decoction of coffee by a weak solution of acetate of lead, filters, evaporates to dryness, mixes the residue with sand, and sublimes as in Mohr's process for procuring benzoic acid. (*Am. Journ. of Pharm.*, xxxii. 25.) Still another method, proposed by Vogel, is to treat coffee, ground to powder, with benzine, which dissolves the caffein and an oily substance, to separate the benzine by distillation, to treat the residue with boiling water which dissolves the caffein, and deposits it in a crystalline form, after filtration and concentration. (*Journ. de Pharm.*, 3e sér., xxxv. 436.) The proportion of caffein in coffee may be stated at from 0·75 to 1·0 per cent. (*Pharm. Journ.*, xvi. 527.) Caffein crystallizes, by the cooling of its concentrated solution, in opaque, silky, flexible needles, by slow and spontaneous evaporation, in long transparent prisms. It has a feebly bitter and disagreeable taste, is soluble in water, alcohol, and ether, melts when exposed to heat, and at a higher temperature sublimes, without residue, in needles analogous to those formed by benzoic acid. It is precipitated from its aqueous solution by no reagent except tannic acid and solution of iodide of potassium and mercury. When this solution, made by saturating iodide of potassium with red oxide of mercury, is added to a solution of caffein, a precipitate is produced, which soon takes the form of white, shining, acicular crystals. This reaction is proposed as a test of caffein by Prof. Dellfs; for, though the same solution will precipitate the other alkaloids, the product is always amorphous. (*Chem. Gaz.*, Feb. 15, 1855.) It is stated by M. Schwazenback that, if chlorine-water with caffein is evaporated, a red residue is obtained, which becomes yellow at a higher temperature, and is restored to its original red colour by a drop of solution of ammonia. This is proposed as a delicate test of caffein. (*Journ. de Pharm.*, 3e sér., xxxix. 232.) Caffein is remarkable for containing a larger proportion of nitrogen than almost any other proximate vegetable principle, in this respect equalling some of the most highly animalized products. The present views of its composition are represented by the formula $C_{16}H_{10}N_4O_4$; and it is believed to be identical with theïn, or the peculiar principle of tea. Notwithstanding its large proportion of nitrogen, caffein is indisposed to putrefaction.

Coffee undergoes considerable change during the roasting process. It swells up very much, acquiring almost double its original volume, while it loses from 15 to 20 per cent. of its weight. (*Pharm. Cent. Blatt*, Oct. 1850, p. 687.) It acquires, at the same time, a peculiar odour entirely different from that of the unroasted grains, and a decidedly bitter taste. A volatile oil is developed during the process, and, according to Chenevix, a portion of tannin. The *caffein* does not appear to undergo material change, as, according to Garot, it may be extracted unaltered from the roasted coffee. The excellence of the flavour of roasted coffee depends much upon the manner in which the process is conducted, and the extent to which it is carried. It should be performed in a covered vessel, over a moderate fire, and the grains should be kept in constant motion. When they have acquired a chestnut-brown colour, the process should cease. If too long continued, it renders the coffee bitter and acrid, or, by reducing it to charcoal, deprives it entirely of flavour. The coffee should not be burnt long before it is used, and should not be kept in the ground state.

Medical and Economical Uses. More attention has been paid to the effects of coffee on the system in the roasted than in the crude state. Unroasted coffee has been employed by Dr. Grindel, of Russia, in intermittent fever; and the practice has been followed by others; but the success, though considerable, has not been such as to lead to the conclusion that this medicine would answer as a substitute for quinia. It was given in powder, in the dose of a scruple every hour; in decoction prepared by boiling an ounce with eighteen ounces of water down to six; or in extract in the dose of from four to eight grains.

The action of coffee is directed chiefly to the nervous system. When swallowed it produces a warming cordial impression on the stomach, quickly followed

by a diffused agreeable nervous excitement, which extends itself to the cerebral functions, giving rise to increased vigour of imagination and intellect, without any subsequent confusion or stupor such as characterizes the action of narcotic medicines. Indeed, one of its most extraordinary effects is a disposition to wakefulness, which continues for several hours after it has been taken. It is even capable of resisting, to a certain extent, the intoxicating and soporific influence of alcohol and opium, and may sometimes be advantageously employed for this purpose. It also moderately excites the circulatory system, and stimulates the digestive function. A cup of coffee, taken after a hearty meal, will often relieve the sense of oppression so apt to be experienced, and enable the stomach to perform its office with comparative facility. The exhilarating effects of coffee, united with its delicious flavour when suitably qualified by cream and sugar, have given rise to its habitual employment as an article of diet. Its use for this purpose has prevailed from time immemorial in Persia and Arabia. In 1517 it was introduced by the Turks into Constantinople, whence it was carried to France and England about the middle of the succeeding century, and has since gradually made its way into almost universal use. It cannot be supposed that a substance, capable of acting so energetically upon the system, should be entirely destitute of deleterious properties. Accordingly, if taken in large quantities, it leaves, after its first effects, a degree of nervous derangement or depression equivalent to the previous excitement; and its habitual immoderate employment is well known very greatly to injure the tone of the stomach, and frequently to occasion troublesome dyspeptic and nervous affections. This result is peculiarly apt to take place in individuals of susceptible nervous systems, and in those of sedentary habits. We have repeatedly known patients, who have long suffered with headache and vertigo, to get rid of them by abstaining from coffee.

In the treatment of disease, coffee has been less employed than might have been expected from its effects upon the system. There can be no doubt that it may be advantageously used in various nervous disorders. In a tendency to stupor or lethargy dependent on deficient energy of the brain, without congestion or inflammation, it would be found useful by stimulating the cerebral functions. In light nervous headaches, and even in sick headache not caused by the presence of offending matter in the stomach, it often proves temporarily useful. It has acquired much reputation as a palliative in the paroxysms of spasmodic asthma, and has been recommended in hooping-cough, and in hysterical affections. The Egyptians are said to have formerly employed it as a remedy in amenorrhœa. Hayne informs us that, in a case of violent spasmodic disease, attended with short breath, palpitation of the heart, and a pulse so much increased in frequency that it could scarcely be counted, immediate relief was obtained from a cup of coffee, after the most powerful antispasmodics had been used in vain for several hours. It has been given, with supposed advantage, in strangulated hernia. By the late Dr. Dewees it was highly recommended in cholera infantum. It is said also to have been used successfully in obstinate chronic diarrhœa; and the late Dr. Chapman, of Philadelphia, found it highly useful in calculous nephritis. Under the impression of its diuretic powers, it has been recommended in dropsy. We have heard of its effectual use in croup. Dr. Wallace, of Belfast, Ireland, has found it, in strong decoction, successful in many cases of cholera. (*Ann. de Thérap.*, 1867, p. 60.) In acute inflammatory affections it is contraindicated. It should be given in cases of poisoning from opium, after the evacuation of the stomach, or when from any cause such evacuation is not effected.

Roasted coffee is said to have the effect of destroying offensive and noxious effluvia from decomposing animal and vegetable substances, and therefore to be capable of beneficial application as a disinfecting and deodorizing agent. The powder of the grains should be roasted until it becomes dark-brown, and then sprinkled, or placed in plates, in the infected place.

Coffee is usually prepared in this country by boiling the roasted grains, previously ground into a coarse powder, in water for a short time, and then clarifying by the white of an egg. Some prefer the infusion, made by a process similar

to that of displacement. It has more of the aroma of the coffee than the decoction, with less of its bitterness. The proper proportion for forming the infusion for medical use is an ounce to a pint of boiling water, of which a cupful may be given warm for a dose, and repeated, if necessary. A *syrup of coffee* is prepared by Dorvault in the following manner. Treat a pound of ground roasted coffee by percolation with boiling water until two pints have passed. Evaporate eight pounds of simple syrup to six, add the infusion, and strain. Two tablespoonfuls of this syrup may be added to a cup of hot water or milk. It is also used with carbonic acid water.

Caffein, though undoubtedly one of the active principles of coffee, is not exactly identical with it in effects. Precise and reliable information as to its physiological action and therapeutic application is yet wanting. Lehmann found it, in doses of from two to ten grains, to produce great disturbance of the nervous and circulatory systems. Introduced directly into the circulation, in the lower animals, such as cats, rabbits, and dogs, in doses of three-quarters of a grain or more, by Drs. Stuhlmann and Falek, it caused death, preceded by purging, vomiting of food, tonic and clonic spasm, and prostration; but no useful reliable inference can be drawn from these results. (*Ranking's Abstract*, xxix. 286.) By Botkin it is said to diminish the frequency of the cardiac contractions, and rapidly to increase the quantity of the urine, while the desire to urinate is augmented, and heat is felt in the passage of it. Patients, however, soon become habituated to it. (*Ann. de Thérap.*, 1867, p. 60.) It has been used remedially both uncombined, and in the state of salt. Prof. H. F. Campbell, of Georgia, found it apparently very useful, given by enema, in a case of poisoning by opium, in the advanced stage, when the patient could no longer swallow. He injected twenty grains in infusion of coffee. The patient recovered; but in a second case, though some favourable effects seemed to be produced, the patient ultimately succumbed. (See *Am. J. of Med. Sci.*, July and Oct. 1860, pp. 282 and 570.) In the form of *citrate of caffein*, made by dissolving caffein in a solution of citric acid with a gentle heat, and evaporating carefully, it has been recommended, as a remedy and preventive in sick headache, in the dose of a grain every hour, before and during the paroxysm. Two or three grains during the twenty-four hours is recommended under ordinary circumstances. (*Botkin.*) The *arseniate* has been given as an antiperiodic; but the arsenic is no doubt the main therapeutic agent in this case.

The *leaves* of the coffee plant possess properties analogous to those of the fruit, and are extensively used, in the form of infusion, as a beverage, in the vicinity of Padang, in the island of Sumatra. An account of their employment was published in the *Singapore Free Press* by Mr. N. M. Ward, of Padang. Previously to this, Dr. John Gardener, of London, had proposed to introduce them into use in Europe, and is stated to have taken out a patent for the mode of preparing them. A specimen examined by Dr. Stenhouse has been found to contain caffein in larger proportion than the coffee-bean, and also caffeic acid. Mr. Ward states that, in Sumatra, the leaves are prepared for use by moderately roasting them, and then powdering them coarsely by rubbing in the hands. The powder is made into an infusion like common tea. The taste is said to be like that of tea and coffee combined. (*Pharm. Journ.*, xii. 443, and xiii. 207 and 382.)

CALAMUS. *U. S. Secondary.*

Sweet Flag.

The rhizoma of Acorus Calamus. *U. S.*

Acorus vrai, Acorus odorant, *Fr.;* Kalmuswurzel, *Germ.;* Calamo aromatico, *Ital.*, *Span.*

Acorus. *Sex. Syst.* Hexandria Monogynia. — *Nat. Ord.* Acoraceæ.

Gen. Ch. Spadix cylindrical, covered with florets. *Corolla* six-petaled, naked. *Style* none. *Capsule* three-celled. *Willd.*

Acorus Calamus. Willd. *Sp. Plant.* ii. 199; Barton, *Med. Bot.* ii. 63. The

sweet flag, or calamus, has a perennial, horizontal, jointed, somewhat compressed root (rhizome), from half an inch to an inch thick, sometimes several feet in length, sending off numerous round and yellowish or whitish radicles from its base, and bunches of brown fibres resembling coarse hair from its joints, internally white and spongy, externally whitish with a tinge of green, variegated with triangular stains of light brown and rose colour. The leaves are all radical, sheathing at the base, long, sword-shaped, smooth, green above, but, near their origin from the root, of a red colour variegated with green and white. The scape or flower-stem resembles the leaves, but is longer, and from one side, near the middle of its length, sends out a cylindrical spadix, tapering at each end, about two inches in length, and crowded with greenish-yellow flowers. These are without calyx, and have six small, concave, membranous, truncated petals. The fruit is an oblong capsule, divided into three cells, and containing numerous oval seeds.

This is an indigenous plant, growing throughout the United States, in low, wet, swampy places, and along the sides of ditches and streams, and flowering in May and June. It is also a native of Europe and Western Asia; and a variety is found in India. The European plant differs slightly from the American. The leaves as well as root have an aromatic odour; but the latter only is employed. It should be collected late in the autumn, or in the spring. After removal from the ground, the roots are washed, freed from their fibres, and dried with a moderate heat. By the process of drying they lose nearly one-half their diameter, but are improved in odour and taste.

Properties. The roots, as kept in the shops, are in pieces of various length, somewhat flattened, externally wrinkled and of a yellowish-brown colour, and presenting on their under surface numerous minute circular spots, indicating the points at which the radicles were inserted. Their texture is light and spongy, their colour internally whitish or yellowish-white, and their fracture short and rough. A variety imported from Germany consists exclusively of the interior portion of the root. The pieces are usually long, slender, irregularly quadrangular, and of a grayish-white colour.

The odour of calamus is strong and fragrant; its taste warm, bitterish, pungent, and aromatic. Its active principles are taken up by boiling water. From 100 parts of the fresh root of the European plant, Trommsdorff obtained 0·1 of volatile oil, 2·3 of soft resin, 3·3 of extractive with a little chloride of potassium, 5·5 of gum with some phosphate of potassa, 1·6 of starch analogous to inulin, 21·5 of lignin, and 65·7 of water. Sixteen ounces of the dried root afforded to Neumann about two scruples of volatile oil. The oil is at first yellow, but ultimately becomes red, and has the smell and taste of calamus. The extractive matter has an acrid and sweetish taste. The root is sometimes attacked by worms, and deteriorates by keeping. The India variety is more slender than the European, and has a stronger and more pleasant flavour.

Medical Properties and Uses. Calamus is a stimulant tonic, possessing the ordinary virtues of the aromatics. It may be taken with advantage in pain or uneasiness of the stomach or bowels arising from flatulence, and is a useful adjuvant to tonic or purgative medicines, in cases of torpor or debility of the alimentary canal. It was probably known to the ancients, and is supposed to have been the ἄκορον of the Greeks; but the *calamus aromaticus* of Dioscorides was a different product, having been derived, according to Dr. Royle, from a species of Andropogon. The medicine is at present much neglected, though well calculated to answer as a substitute for more costly aromatics. The dose in substance is from a scruple to a drachm.* An infusion, made in the propor-

* A *fluid extract of calamus* may be prepared in the same manner as fluid extract of ginger, and given in the dose of from half a fluidrachm to a fluidrachm. From this Prof. Maisch prepares a syrup by rubbing f℥i of the fluid extract with about ℥viii of sugar, exposing the mixture to a moderate heat until all the alcohol has been evaporated, then adding ℥vii of sugar, and half a pint of water, heating to 212°, and straining. (*Am. Journ. of Pharm.*, xxxii. 113.)—*Note to the twelfth edition.*

tion of an ounce of the root to a pint of boiling water, is sometimes given in the dose of a wineglassful or more. W.

CALCIUM.

Calcium.

This is the peculiar metal of lime, and consequently of all calcareous substances. It was obtained by Dr. Matthiessen, in 1855, in masses of the size of a pea, by the electrolysis, with a Bunsen battery, of chloride of calcium. It is a pale-yellow metal, remarkably glittering when freshly filed. Its fracture is jagged, becoming granular. It is malleable and very ductile. In a dry air it remains unaltered; but it soon tarnishes in a moist one. It melts at a red heat, and afterwards burns with splendour, forming lime. Its eq. number is 20, and symbol Ca. (See *Chem. Gaz.*, June 15, 1855.)

Calcium is a very abundant element in nature, existing in the mineral kingdom chiefly as a carbonate, in the form of limestone, marble, chalk, and calcareous spar; and as a phosphate and carbonate in the bones and shells of animals. It is the peculiar metal in the officinals, lime, chloride of calcium, and carbonate, phosphate, and hypochlorite of lime. B.

CALCII CHLORIDUM. *U. S., Br.*

Chloride of Calcium.

Fused chloride of calcium. *U. S.* CaCl. *Br.*

Muriate of lime, Hydrochlorate of lime; Chlorure de calcium, Hydrochlorate de chaux, *Fr.;* Chlorcalcium, Salzsaurer Kalk, *Germ.*

Chloride of calcium consists of chlorine, united with calcium, the metallic radical of lime. It may be readily formed by saturating muriatic acid with chalk or marble, evaporating to dryness, and heating to redness. The muriatic acid, by reacting with the lime, forms chloride of calcium and water, the latter of which is dissipated at a red heat. The Br. Pharmacopœia, after the neutralization of the acid with carbonate of lime, adds a little solution of chlorinated lime and slaked lime, filters, evaporates till the chloride becomes solid, and, instead of igniting the residue, dries it at about 400°.

Properties. In the fused or anhydrous state, as it is directed or understood to be in the U. S. and Br. Pharmacopœias, chloride of calcium is a colourless, slightly translucent, hard and friable solid, of an acrid, bitter, saline taste, extremely deliquescent, very soluble in water, and readily soluble in rectified spirit. On account of its avidity for water, the fused salt is used for drying gases, and for bringing alcohol to its highest degree of concentration. The crystallized salt is also very deliquescent, and has the form of colourless, transparent, striated, six-sided prisms. The crystals, on exposure to heat, first dissolve in their water of crystallization, and after this has evaporated, undergo the igneous fusion. With ice or snow they form a powerful frigorific mixture. Solution of chloride of calcium, when pure, yields no precipitate with ammonia, chloride of barium, or ferrocyanide of potassium dissolved in a large quantity of water; evincing the absence of magnesia, sulphuric acid, and iron. The salt evolves no chlorine or hypochlorous acid on the addition of hydrochloric acid, is entirely soluble in twice its weight of water, and is not precipitated by lime-water. *Br.*

Chloride of calcium exists in the water of the ocean and of many springs. It is usually associated with common salt and chloride of magnesium, from which it is separated with difficulty. It consists of one eq. of chlorine 35·5, and one of calcium 20 = 55·5. When crystallized, it contains six eqs. of water = 54.*

* Various useful applications of chloride of calcium, independently of its employment in chemical operations, have been proposed, or carried into effect, of which one is the substitution of its solution for water alone in sprinkling the streets of towns in dry weather; its affinity for moisture being such that much less sprinkling is necessary in order to obtain the desired result; another, its application to the surface of combustible substances,

Chloride of calcium is used medicinally in solution only. In this state it forms the officinal *Liquor Calcii Chloridi*, under which title its medicinal properties are given.

CALX. *U. S., Br.*

Lime.

Lime recently prepared by calcination. *U. S.* An alkaline earth, CaO, with some impurities, obtained by calcining chalk or limestone so as to expel carbonic acid. *Br.*

Quicklime; Chaux, Chaux vive, *Fr.*; Kalk, *Germ.*; Calce, *Ital.*; Calviva, *Span.*

Lime, which is ranked among the alkaline earths, is a very important pharmaceutical agent, and forms the principal ingredient in several standard preparations. It is a very abundant natural production. It is never found pure, but mostly combined with acids; as with carbonic acid in chalk, marble, calcareous spar, limestone, and shells; with sulphuric acid in the different kinds of gypsum; with phosphoric acid in the bones of animals; and with silica in a great variety of minerals.

Preparation. Lime is prepared by calcining, by a strong heat, some form of the native carbonate. The carbonic acid is thus expelled, and the lime remains behind. When the lime is intended for nice chemical operations, it should be obtained from pure white marble, or from oyster shells. For the purpose of the arts it is procured from common limestone, by calcining it in kilns of peculiar construction. When obtained in this way it is generally impure, being of a grayish colour, and containing alumina, silica, sesquioxide of iron, and occasionally a little magnesia and oxide of manganese.

The officinal lime of the United States and British Pharmacopœias is the lime of commerce, and therefore impure. It may be obtained purer by exposing pure white marble, broken into small fragments, in a covered crucible, to a full red heat for three hours, or till the residuum, when slaked and suspended in water, no longer effervesces on the addition of muriatic acid.

Properties. Lime is a grayish-white solid, having a strong caustic, alkaline taste, and the sp. gr. 2·3. It is very refractory in the fire, having been fused only by the compound blowpipe of Dr. Hare. Exposed to the air, it absorbs moisture and carbonic acid, and falls into a white powder. On account of its liability to change by being kept, lime intended for pharmaceutical purposes should be recently prepared. It acts upon vegetable colours like an alkali. Upon the addition of water, it cracks and falls into powder, with the evolution of heat, forming hydrate of lime. In this state lime dissolves freely in syrup. (See *Syrup of Lime.*) If it dissolve in muriatic acid without effervescence, the fact shows the absence of carbonic acid, and that the lime has been well calcined. If any silica be present, it will remain undissolved. If the solution give no precipitate with ammonia, the absence of iron and alumina is shown.

Lime is but sparingly soluble in water, requiring at 60° about seven hundred times its weight of that liquid for complete solution. Contrary to the general law, it is less soluble in hot than in cold water. The solution is called lime-water. (See *Liquor Calcis.*) When lime in excess is mixed with water, so as to form a thick liquid, the mixture is called *milk of lime.*

Lime is the protoxide of calcium, and consists of one eq. of calcium 20, and one of oxygen 8 = 28. (See *Calcium.*) It is distinguished from the other alkaline earths by forming a very deliquescent salt (*chloride of calcium*) by reac-

such as wood, by which they are in a considerable degree protected against fire. For the latter purpose it is recommended to add to the solution a portion of milk of lime, which prevents the unpleasant dampness which it would tend to maintain in the surfaces covered with it. (*Neues Repertorium*, xvi. 597.)—*Note to the thirteenth edition.*

tion with muriatic acid, and a sparingly soluble one with sulphuric acid. All acids, acidulous, ammoniacal, and metallic salts, borates, alkaline carbonates, and astringent vegetable infusions are incompatible with it.

Medical Properties. Lime acts externally as an escharotic, and was formerly applied to ill conditioned ulcers. The *lime ointment* of Spender is made by incorporating four parts of washed slaked lime with one part of fresh lard and three parts of olive oil, previously warmed together. Mixed with potassa, lime forms an officinal caustic. (See *Potassa cum Calce.*) As an internal remedy, it is always administered in solution. (See *Liquor Calcis.*)

CALX CHLORINATA. *U. S.*

Chlorinated Lime.

A compound resulting from the action of chlorine on hydrate of lime, and containing at least twenty-five per cent. of Chlorine. *U. S.*

Off. Syn. CALX CHLORATA. *Chlorinated Lime.* A product obtained by exposing slaked lime to the action of chlorine gas so long as the latter is absorbed. *Br.*

Chloride of lime, Hypochlorite of lime, Oxymuriate of Lime, Bleaching powder; Calcis chloridum, Calcis hypochloris, *Lat.;* Chlorure de chaux, *Fr.;* Chlorkalk, *Germ.;* Cloruro di calce, *Ital.*

This compound was originally prepared and brought into notice as a bleaching agent, in 1798, by Tennant of Glasgow. Subsequently it was found to have valuable properties as a medicine and disinfectant; and, accordingly, it has been introduced into the United States and British Pharmacopœias.

The following is an outline of the process for preparing chlorinated lime on the large scale. An oblong square chamber is constructed, generally of siliceous sandstone, the joints being secured by a cement of pitch, rosin, and dry gypsum. At one end it is furnished with an air-tight door, and on each side with a glass window, to enable the operator to inspect the process during its progress. The slaked or hydrated lime is sifted, and placed on wooden trays eight or ten feet long, two broad, and one inch deep. These are piled within the chamber to a height of five or six feet on cross-bars, by which they are kept about an inch asunder, in order to favour the circulation of the gas over the lime. The chlorine is generated in a leaden vessel nearly spherical, the lower portion of which is surrounded with an iron case, leaving an interstice two inches wide, intended to receive the steam for the purpose of producing the requisite heat. In the leaden vessel are five apertures. The first is in the centre of the top, and receives a tube which descends nearly to the bottom, and through which a vertical stirrer passes, intended to mix the materials, and furnished, at the lower end, with horizontal cross-bars of iron, or of wood sheathed with lead. The second is for the introduction of the common salt and manganese. The third admits a syphon-shaped funnel, through which the sulphuric acid is introduced. The fourth is connected with a pipe to lead off the chlorine. The fifth, which is near the bottom, receives a discharge pipe, passing through the iron case, and intended for drawing off the residuum of the operation. The pipe leading off the chlorine terminates, under water, in a leaden chest or cylinder, where the gas is washed from muriatic acid. From this intermediate vessel the chlorine finally passes, by means of a pretty large leaden pipe, through the ceiling of the chamber containing the lime. The process of impregnation generally lasts four days, this time being necessary to form a good bleaching powder. If it be hastened, heat will be generated, which will favour the production of chloride of calcium, with a proportional diminution of chloride of lime.

The proportions of the materials generally adopted are 10 cwt. of common salt, mixed with from 10 to 14 cwt. of deutoxide of manganese: to which are added, in successive portions, from 12 to 14 cwt. of strong sulphuric acid, diluted before being used until its sp. gr. is about 1·65, which is accomplished by adding about one-third of its weight of water. In manufactories in which sulphuric acid is also made, the acid intended for this process is brought to the sp gr. 1 65 only, whereby the expense of further concentration is saved.

Properties. Chlorinated lime is a dry, or but slightly moist, grayish-white, pulverulent substance, having an acrid, hot, bitter, astringent taste, and an odour resembling that of chlorine. It possesses powerful bleaching properties. When perfectly saturated with chlorine, it dissolves almost entirely in water; but, as ordinarily prepared, a large proportion is insoluble, consisting of hydrate of lime. When exposed to heat, it gives off oxygen, and some chlorine, and is converted into chloride of calcium. It is incompatible with the mineral acids, carbonic acid, and the alkaline carbonates. The acids evolve chlorine copiously, and the alkaline carbonates cause a precipitate of carbonate of lime. (See *Liquor Sodæ Chlorinatæ.*)*

Chlorinated lime is an oxidizing agent, the oxygen being derived from water, the hydrogen of which unites with the chlorine to form muriatic acid. It has a powerful action on organic matter, converting sugar, starch, cotton, linen, and similar substances into formic acid, which unites with the lime. (*W. Bastick.*) It also acts energetically on the volatile oils, including oil of turpentine, producing chloroform. (J. Chautart, *Journ. de Pharm.*, Mars, 1855.)

Composition. According to Dr. Ure, bleaching powder consists of hydrate of lime and chlorine, united in variable proportions, not correspondent to equivalent quantities. According to Brande, Grouvelle, and Phillips, the compound obtained when chlorine ceases to be absorbed consists of one eq. of chlorine and two of hydrate of lime, resolvable, by water, into one eq. of hydrated chloride of lime which dissolves, and one of hydrate of lime which is left. Dr. Thomson, however, asserts that the compound has been so much improved in quality, that good samples consist of single equivalents of lime and chlorine, and are almost entirely soluble in water. Its ultimate constituents, exclusive of the elements of water, may, therefore, be considered to be one eq. of calcium, one of oxygen, and one of chlorine. Three views may be taken of the manner in which these elements are united to form the bleaching powder. The first makes it a chloride of lime, CaO,Cl; the second, oxychloride of calcium, $Ca \begin{cases} O \\ Cl \end{cases}$; and the third hypochlorite of lime with chloride of calcium, $CaO,ClO + CaCl$, formed by doubling the equivalents of the elements present.

The simplest view of the nature of bleaching powder is that which supposes it to be a compound of chlorine and lime. The view which makes it a hypochlorite with chloride of calcium is that of Balard, and is supported by the

* Chlorinated lime is constantly becoming weaker on exposure, giving off chlorine or hypochlorous acid, probably through the influence of the atmospheric carbonic acid, which sets them free by combining with the lime. But it would seem that, even when closely confined, it sometimes at least gives off gaseous matter, as we have an account of a well-stopped bottle containing it having been broken by a violent explosion, without any peculiar exposure to heat. (See *Am. Journ. of Pharm.*, Jan. 1861, p. 72.) M. Barreswil has found that the subjection of chlorinated lime to strong pressure greatly diminishes the tendency to decomposition. It is rendered in this way as hard as a stone, and may be kept long without undergoing change. (*Chem. News*, no. 58, p. 38.)

Under the following conditions, it is stated by C. Schrader that good chlorinated lime may be prepared which will long retain its strength. 1. The lime used must be free from iron and alumina; but the hydrate may contain from 6 to 12 per cent. of moisture without injury. 2. The chlorine must be brought slowly in contact with the hydrate. 3. When the hydrate of lime is oversaturated with chlorine, decomposition speedily ensues. Hence the hydrate and the muriatic acid employed must be in due proportion, to be determined by practice. 4. To ensure complete saturation, there should be free chlorine in the apparatus at the close of the process. By attending to these precautions, it is said that a product may be obtained, with from 33 to 35 per cent. of chlorine, and losing its strength only at the rate of 3 or 4 per cent. a year. (*Ibid.*, Aug. 15, 1863, p. 78.)—*Note to the twelfth edition.*

fact that the compound smells of hypochlorous acid. But, if it contain chloride of calcium, it ought to deliquesce; unless it can be shown that the metallic chloride is in such a state of combination as to prevent this result. The second view, that it is an oxychloride, which assimilates its nature to that of the deutoxide of calcium, is held by Millon. According to this chemist, the quantity of chlorine, taken up by a metallic protoxide, is regulated by the nature of its peroxide. The peroxide of calcium is a deutoxide (CaO_2); and Millon contends that, in forming bleaching powder, the lime takes up but one eq. of chlorine, corresponding to the second eq. of oxygen in the deutoxide, thus generating the compound $Ca \begin{cases} O \\ Cl. \end{cases}$ Again, the peroxide of potassium is represented by KO_3, and Millon states that the bleaching compound which potassa (KO) forms with chlorine is $K \begin{cases} O \\ Cl_2. \end{cases}$ If further observation should show that the number of equivalents of chlorine, necessary to convert a protoxide into a bleaching compound, is always equal to the number of eqs. of oxygen required to convert it into a peroxide, the fact will go far to prove the correctness of Millon's views.

On the supposition that the bleaching powder is a hypochlorite of lime with chloride of calcium, the mode of its formation is thus explained. Two eqs. of chlorine, by uniting separately with the elements of one eq. of lime, form one eq. of chloride of calcium, and one of hypochlorous acid; the latter of which combines with an additional eq. of lime, to form hypochlorite of lime.

M. Fresenius, having submitted chlorinated lime to the action of successive portions of water, noticed that the first portions dissolved out nearly all the free chloride of calcium, with very little hypochlorite of lime, while in the subsequent operations the two salts were dissolved in regular proportion. From this fact he inferred that either the chloride of calcium and hypochlorite of lime were combined, or that water decomposed the chlorinated lime into them. His views as to the composition of the bleaching powder, deduced from this observation and from various experiments, are that it consists of hypochlorite of lime, combined with chloride of calcium $CaO,ClO+CaCl$, of free chloride of calcium $CaCl$, of hydrated lime $CaO.HO$, and of combined water. (*Chem. Gaz*, Aug. 30, 1862.)

Impurities and Tests. Chlorinated lime may contain a great excess of lime, from imperfect impregnation with the gas. This defect will be shown by the large proportion insoluble in water. If it contain much chloride of calcium, it will be quite moist, which is always a sign of inferior quality. When long and insecurely kept, it deteriorates from the gradual formation of chloride of calcium and carbonate of lime. Several methods have been proposed for determining its bleaching power, which depends solely on the proportion of loosely combined chlorine. Walter proposed to add a solution of the bleaching powder to a standard solution of sulphate of indigo, in order to ascertain its decolorizing power; but the objection to this test is that the indigo of commerce is very variable in its amount of colouring matter. Dr. Ure has proposed muriatic acid to disengage the chlorine over mercury; but this test is liable to the fallacy that it will disengage carbonic acid as well as chlorine; and it has been shown, by some unpublished experiments of Prof. Procter of this city, that the amount of disengaged gaseous matter is not in proportion to the decolorizing power. Dalton recommended, as a test, to add a solution of the bleaching powder to one of the sulphate of protoxide of iron, slightly acidulated with muriatic or sulphuric acid, until the odour of chlorine is perceived. Chlorine is not disengaged until the iron is sesquioxidized, and the stronger the bleaching powder, the sooner will this be accomplished. A more delicate way of ascertaining when all the iron is sesquioxidized, is to test a drop of the liquid with one of a solution of ferridcyanide of potassium (red prussiate of potassa). So long as any protoxide of iron remains in the liquid, this salt will occasion a blue precipitate (*Turnbull's prussian blue*), but not afterwards. This test for chlorinated lime was adopted in the U. S. Pharmacopœia of 1850, and is applied as follows. "When 40 grains of it, triturated with a fluidounce of distilled water, are well shaken with a solu-

tion of 78 grains of crystallized sulphate of protoxide of iron, and 10 drops of sulphuric acid in two fluidounces of distilled water, a liquid is formed which does not yield a blue precipitate with ferridcyanide of potassium (red prussiate of potassa)." The chlorinated lime of the U. S. Pharmacopœia is directed to contain at least 25 per cent. of chlorine. If it be to this extent chlorinated, 40 grains will contain enough chlorine to cause the sesquioxidation of all the protoxide of iron in 78 grains of crystallized sulphate of iron; but, if impregnated with chlorine to a less extent, some of the protoxide will remain unchanged, and, consequently, a blue precipitate will be formed with the ferridcyanide. According to Wittstein and Claude, however, the test of sulphate of iron is not reliable.

The following is the test given in the British Pharmacopœia. "Ten grains mixed with thirty grains of iodide of potassium, and dissolved in four fluidounces of water, produce, when acidulated with two fluidrachms of hydrochloric acid, a reddish solution, which requires for the discharge of its colour at least 850 grain-measures of *the volumetric solution of hyposulphite of soda*, corresponding to 30 per cent. of chlorine liberated by hydrochloric acid." In this process iodine is separated by the chlorine in equivalent quantity, and imparts colour to the liquid, which is removed by the hyposulphite of soda, by forming colourless compounds with the iodine; and the quantity required for this purpose measures the quantity of iodine, and consequently that of chlorine present in the chlorinated solution. (See *Hyposulphite of Soda.*)

Medical Properties and Uses. Chlorinated lime, externally applied, is a desiccant and disinfectant, and has been used with advantage in solution, as an application to ill-conditioned ulcers, burns, chilblains, and cutaneous eruptions, especially itch; as a gargle in putrid sorethroat; and as a wash for the mouth to disinfect the breath, and for ulcerated gums. Internally, it is stimulant and astringent. It has been employed by Dr. Reid in the epidemic typhoid fever of Ireland; by the same practitioner in dysentery, both by the mouth and injection, with the effect of correcting the fetor, and improving the appearance of the stools; by Cima, both internally and externally, in scrofula; and by Dr. Varlez, of Brussels, in ophthalmia. Dr. Pereira has used a weak solution very successfully in the purulent ophthalmia of infants. In the febrile cases, Dr Reid found it to render the tongue cleaner and moister, to check diarrhœa, and induce sleep. The dose internally is from three to six grains, dissolved in one or two fluidounces of water, filtered and sweetened with syrup. It should never be given in pills. As it occurs of variable quality, and must be used in solution more or less dilute, according to the particular purpose to which it is to be applied, it is impossible to give any very precise directions for its strength as an external remedy. From one to four drachms of the powder added to a pint of water, and the solution filtered, will form a liquid within the limits of strength ordinarily required. For the cure of itch, M. Derheims has recommended a much stronger solution—three ounces of the chloride to a pint of water, the solution being filtered, and applied several times a day as a lotion, or constantly by wet cloths. When applied to ulcers, their surface may be covered with lint dipped in the solution. When used as an ointment, to be rubbed upon scrofulous enlargements of the lymphatic glands, this may be made of a drachm of the chloride to an ounce of lard. Chlorinated lime is less eligible for some purposes than the solution of chlorinated soda. (See *Liquor Sodæ Chlorinatæ.*)

In consequence of its powers as a disinfectant, chlorinated lime is a very important compound in its application to medical police. It possesses the property of preventing or arresting animal and vegetable putrefaction, and, perhaps, of destroying pestilential and infectious miasms. It may be used with advantage for preserving bodies from exhaling an unpleasant odour, before interment, in the summer season. In juridical exhumations its use is indispensable; as it effectually removes the disgusting and insupportable fetor of the corpse. The mode in which it is applied, in these cases, is to envelop the body with a sheet completely wet with a solution, made by adding about a pound of the chloride to a bucketful of water. It is employed also for disinfecting dissecting rooms, privies, com-

mon sewers, docks, and other places which exhale offensive effluvia. In destroying contagion and infection, it appears to be highly useful. Hence hospitals, alms-houses, jails, ships, &c. may be purified by its means. In short, all places deemed infectious from having been the receptacle of disease, may be more or less disinfected by its use, after having undergone the ordinary cleansing.

Chlorinated lime acts exclusively by its chlorine, which, being loosely combined, is disengaged by the slightest affinities. All acids, even the carbonic, disengage it; and, as this acid is a product of animal and vegetable decomposition, noxious effluvia furnish the means, to a certain extent, of their own disinfection. But the stronger acids disengage the chlorine far more readily, and, among these, sulphuric acid is the most convenient. Accordingly, the powder may be dissolved in a very dilute solution of this acid; or a small quantity of the acid may be added to an aqueous solution ready formed, if a more copious evolution of chlorine be desired than that which takes place from the mere action of the carbonic acid of the atmosphere.

Chlorinated lime may be advantageously applied to the purpose of purifying offensive water, a property which makes it invaluable on long voyages. When used for this purpose, from one to two ounces of the chloride may be mixed with about sixty-five gallons of the water. The water must afterwards be exposed for some time to the air, and allowed to settle, before it is fit to drink.

Strong insecticide properties have been ascribed to chlorinated lime. Hence it is recommended to sprinkle it on vegetables, flowers, fruit-trees, &c., which are apt to be attacked by worms and insects.

CALUMBA. *U. S.*

Columbo.

The root of Cocculus palmatus. *U. S.*

Off. Syn. CALUMBÆ RADIX. *Calumba Root.* The root, cut transversely and dried, of Jateorrhiza Calumba, *Miers;* Cocculus palmatus, *non DC.; Steph. and Church. Med. Bot.*, plate 160. *Br.*

Colomba, *U. S.* 1850; Colombo, *Fr.;* Columbowurzel, *Germ.;* Columba, *Ital.;* Raiz de Columbo, *Span.;* Kalumbo, *Port.;* Calumb, *Mozambique.*

The columbo plant was long but imperfectly known. Flowering specimens of a plant gathered by Commerson, about the year 1770, in the garden of M. Poivre in the Isle of France, and sent to Europe with that botanist's collection, were examined by Lamarck, and described under the name of *Menispermum palmatum.* But its original locality was unknown, and it was only conjectured to be the source of columbo. In the year 1805, M. Forten, while engaged in purchasing the drug in Mozambique, obtained possession of a living offset of the root, which, being taken to Madras, and planted in the garden of Dr. Anderson, produced a male plant, which was figured and described by Dr. Berry. From the drawing thus made, the plant was referred to the natural family of the Menispermeæ; but, as the female flowers were wanting, some difficulty was experienced in fixing its precise botanical position. De Candolle, who probably had the opportunity of examining Commerson's specimens, gave its generic and specific character; but confessed that he was not acquainted with the structure of the female flower and fruit. This desideratum, however, was supplied by ample drawings sent to England by Mr. Telfair, of Mauritius, made from plants which were propagated from roots obtained by Captain Owen in 1825, while prosecuting his survey of the eastern coast of Africa. The genus *Cocculus*, in which the plant is now placed, was separated by De Candolle from *Menispermum*, and includes those species which have six stamens, while the Menispermum is limited to those with twelve or more.

More recently, Mr. J. Miers, on examination of the male and female flowers as well as of the seeds, came to the conclusion that they presented peculiarities

which justified the establishment of a new genus, which he named *Jateorrhiza*, from the medicinal properties of the root. "The plants of this genus, natives of intertropical Africa, are all climbers, distinguished by a very peculiar habit, having very large deeply-lobed leaves, upon very long petioles, and clothed with long strigose hairs; their inflorescence is in long slender racemes; the fruit is a drupe containing a putamen covered with a dense hairy coating imbedded in the fleshy mesoderm."* (*Ann. and Mag. of Nat. Hist.*, Feb. 1864.) From the statements of Mr. Miers it appears, moreover, that the species described by De Candolle under the name of Cocculus palmatus, is different from that cultivated in the Botanical Garden at Calcutta, which appears in Wallich's Catalogue under the same name of Cocculus palmatus; two species having, as appears, been confounded together. This new species is described by Mr. Miers under the name of Jateorrhiza Calumba, and is asserted by him to be the true columbo plant. The claim is admitted by Prof. Bentley, of London, and the species is recognised in the last edition of the British Pharmacopœia. But upon what grounds it is assumed to be the exclusive source of the drug has not been satisfactorily shown. Both species grow in the same neighbourhood, and both are described from specimens originating in that neighbourhood, and asserted to have been derived from plants yielding the columbo of commerce. Why, therefore, the root should be ascribed exclusively to either is not obvious. It is by no means improbable that the drug is obtained indifferently from both; and it is not, therefore, needful, while admitting the claims of the new species, to reject the old one. The French Codex, recently published, still ascribes the root to the Cocculus palmatus of De Candolle.

Cocculus. *Sex. Syst.* Dicœcia Hexandria. — *Nat. Ord.* Menispermaceæ.

Gen. Ch. Sepals and Petals ternate, usually in 2, rarely in 3 rows *Stamens* six, distinct, opposite the petals. *Drupes* berried, 1-6, generally oblique, reniform, somewhat compressed, one seeded. *Cotyledons* distant. *De Cand.*

Cocculus palmatus. De Cand., *Syst. Veg.* i. 523; Woodv *Med. Bot.*, 3d ed., v. 21.; Hooker, *Curtis's Bot. Mag.*, nos. 2970, 2971. *Jateorrhiza palmata.* Miers, *Annal. and Mag. of Nat. Hist.*, Feb. 1864, p. 183. This is a climbing plant, with a perennial root, consisting of several fasciculated, fusiform, somewhat curved, and descending tubers, as thick as an infant's arm. The stems, of which one or two proceed from the same root, are twining, simple in the male plant, branched in the female, round, hairy, and about as thick as the little finger. The leaves, which stand on rounded, glandular hairy footstalks, are alternate, distant, cordate, with three, five, or seven entire, acuminate, wavy, somewhat hairy lobes, and as many nerves, each running into one of the lobes. The flowers are small and inconspicuous, and arranged in solitary axillary racemes, which, in the male plant, are compound, in the female, simple, and in both, shorter than the leaves.

Jateorrhiza Calumba. Miers. Br. Pharm. — *Cocculus palmatus.* Wallich, non De Cand. — *Menispermum Columba.* Roxb. *Flor. Ind.* This species is characterized by "rounded, angularly striate, roughly pilose branches; broadly orbicular, sinuously lobed leaves, with rounded sinuses; the lobes being 5 in number, broadly ovate, acute, mucronately acuminate; the basal deeply divaricate and hence broadly cordate; 7 to 9 nerved, opaque above, on both sides

* The following is the generic character given by Mr. Miers of his Jateorrhiza abbreviated. "Flores dioici. Masc. *Sepala*, 6, ovata, 2-seriata, exteriora paulo minora. *Petala* 6, ovata, sepalis paulo breviora, apice truncata, lateribus introflexis stamina tegentia. *Stamina* 6, petalis opposita et subæquilonga; *filamenta*, carnosa, apice valde tumida, rugulosa punctata, subito refracta, et extrorsum antherifera; *antheræ* globoso 4 lobæ, rima horizontali 2-valvatim hiantes. Fœm. *Sepala* ut in masc. *Petala* cuneato-obovata, crassiuscula, apice emarginata, lateribus introflexis stamina volventia. *Stamina* 6, sterilia, petalis dimidio breviora. *Ovaria* 3, libera, erecta, oblonga, gibba, extus dense glanduloso-pilosa, gynæcio sub 3-gono imposita, 1-locularia; *ovulo* unico. *Stylus* brevis, crassus, subexcentricus. *Stigma* 3-partitum, laciniis 2-3 fidis, reflexis. *Drupæ* 3, abortu pauciores, ovatæ, carnosæ, 1-spermæ; *putamen* ovatum, dorso convexum, tuberculatum, pilis fibrillosis creberrime indutum, ventre læve." (*Annals and Magaz. of Nat. Hist.*, Feb. 1864, p. 132.)—*Note the thirteenth edition.*

furnished with short, adpressed, somewhat curved, reddish hairs, beneath, pale, strongly reticulate with prominent nerves and veins; the petiole somewhat slender, striate, tortuous, and roughly glandular; the racemes axillary, solitary or many; the rachis greatly elongated, striate, bristly, with elongated, smooth, divaricate, almost capillary, subflexuous, few-flowered branches; the flowers sessile, and almost without bractes." (*Miers.*)

These plants are natives of Mozambique, on the south-eastern coast of Africa, where they grow wild in great abundance in the thick forests extending from the sea many miles into the interior. They are not cultivated. The root is dug up in March, when dry weather prevails. From the base of the root numerous fusiform offsets proceed, less fibrous and woody than the parent stock. These offsets are separated and cut into transverse slices, which are dried in the shade. The old root is rejected.

Columbo is a staple export of the Portuguese from their dominions in the south-east of Africa. It is taken to India, and thence distributed. It was formerly supposed to be a product of Ceylon, and to have derived its name from Colombo, a city of that island, from which it was thought to be exported. It is possible that, when the Portuguese were in possession of Ceylon, Colombo may have been the entrepot for the drug brought from Africa, and thus have given origin to its name. Some, however, consider a more probable derivation to be from the word *calumb*, which is said to be the Mozambique name for the root. Dr. Christison has been misinformed in relation to the cultivation of the true columbo plant in this country. (*Dispensatory*, Am. ed., p. 304.)

Properties. The root, as it reaches us, is in flat circular or oval pieces, from the eighth of an inch to near an inch in thickness, and from one to two inches in diameter. Along with these are sometimes a few cylindrical pieces an inch or two in length. The cortical portion is thick, of a bright-yellow, slightly greenish colour internally, but covered with a brownish, wrinkled epidermis. The interior or medullary portion, which is readily distinguishable from the cortical, is light, spongy, yellowish, usually more or less shrunk, so that the pieces are thinnest in the centre; and is often marked with concentric circles and radiating lines. Those pieces are to be preferred which have the brightest colour, are most compact and uniform, and least worm-eaten. The odour of columbo is slightly aromatic. The taste is very bitter, that of the cortical much more so than that of the central portion, which is somewhat mucilaginous. The root is easily pulverized. The powder is greenish, becoming browner with age, and deepening when moistened. As it attracts moisture from the air, and is apt to undergo decomposition, it should be prepared in small quantities.

M. Planche analyzed columbo in 1811, and found it to contain an azotized substance, probably albumen, in large quantity, a bitter yellow substance not precipitated by metallic salts, and one-third of its weight of starch. He obtained also a small proportion of volatile oil, salts of lime and potassa, oxide of iron, and silica. Wittstock, of Berlin, afterwards isolated a peculiar crystallizable principle, which he called *colombin*. This crystallizes in beautiful transparent quadrilateral prisms, is without smell, and is extremely bitter. It is but very slightly soluble in water, alcohol, or ether, at ordinary temperatures, and yet imparts to these fluids a strongly bitter taste. It is more soluble in boiling alcohol, which deposits it upon cooling. The best solvent is dilute acetic acid. It is taken up by alkaline solutions, from which it is precipitated by acids. It has neither acid nor alkaline properties, and its alcoholic and acetic solutions are not affected by the metallic salts, or the infusion of galls. It is obtained by exhausting columbo by means of alcohol of the sp. gr. 0·835, distilling off three-quarters of the alcohol, allowing the residue to stand for some days till crystals are deposited, and lastly treating these crystals with alcohol and animal charcoal. The mother-waters still contain a considerable quantity of colombin, which may be separated by evaporating with coarsely powdered glass to dryness, exhausting the residue with ether, distilling off the ether, treating the residue with boiling acetic acid, and evaporating the solution to crystallization.

From the researches of Dr. Bödeker it appears that another bitter principle exists in columbo, which corresponds in composition and chemical relations with *berberina*, the active principle of *Berberis vulgaris*, and is assumed to be identical with that substance. It was obtained by exhausting columbo with alcohol of 0·889, distilling off the alcohol, allowing the residual liquor to stand for three days so as to deposit the colombin, evaporating the supernatant liquid together with the aqueous washings of the colombin to dryness, exhausting the residue with boiling alcohol of 0·863, treating the solution thus obtained as the former one, submitting the residue to the action of boiling water, filtering and adding muriatic acid, collecting the precipitate thus formed on a filter, drying it with bibulous paper, and finally, in order to separate adhering acid, dissolving it in alcohol, and precipitating with ether. The result was an imperfectly crystalline, bright-yellow powder, of a disagreeable, bitter taste, supposed to be *muriate of berberina*. It is stated that berberina is present in columbo in much larger proportion than colombin, and, being freely soluble in hot water and alcohol, while colombin is but slightly so, is probably more largely extracted in the ordinary liquid preparations of the root. (*Am. Journ. of Pharm.*, xx. 322.) It is thought that berberina exists in columbo combined with a peculiar acid denominated *columbic acid;* and that, while the colombin occurs in the cells of the root in a crystalline state, the columbate of berberina is deposited in the thickening layers of the cell-membranes. (*Chem. Gaz.*, vii. 150.) It is probable that the bitter yellow principle of Planche either was berberina or contained it.

There can be little doubt that both colombin and berberina contribute to the remedial effects of columbo. The virtues of the root are extracted by boiling water and by alcohol. Precipitates are produced with the infusion and tincture by infusion of galls, and solutions of acetate and subacetate of lead; but the bitterness is not affected.

Adulterations. It is said that the root of *white bryony*, tinged yellow with the tincture of columbo, has sometimes been fraudulently substituted for the genuine root; but the adulteration is too gross to deceive those acquainted with the characters of either of these drugs. American columbo, which is the root of *Frasera Walteri*, is said to have been sold in some parts of Europe for the genuine. Independently of the sensible differences between the two roots (see *Frasera*), M. Stolze of Halle states that, while the tincture of columbo remains unaffected by the sulphate or sesquichloride of iron, and gives a dirty-gray precipitate with tincture of galls, the tincture of frasera acquires a dark-green colour with the former reagent, and is not affected by the latter. (*Duncan.*) Under the name of *columbo wood*, or *false columbo*, the wood of *Coscinium fenestratum*, a plant of the family of Menispermaceæ, growing in Ceylon, has been imported into England, and offered for sale in the drug market. (*Pharm. Journ.*, x. 321, and xii. 185.)

Medical Properties and Uses. Columbo is among the most useful of the mild tonics. Without astringency, with very little stimulating power, and generally acceptable to the stomach, it answers admirably as a remedy in simple dyspepsia, and in the debility of convalescence, especially when the alimentary canal is left enfeebled. Hence, it is often prescribed in the declining stages of remittent fever, dysentery, diarrhœa, cholera morbus, and cholera infantum. The absence of irritating properties renders it also an appropriate tonic in the hectic fever of phthisis, and kindred affections. It has been highly recommended in vomiting, unconnected with inflammation of the stomach, as in the sickness of pregnant women. It is frequently administered in combination with other tonics, aromatics, mild cathartics, and antacids. The remedy which we have found most effectual in the permanent cure of a disposition to the accumulation of flatus in the bowels, is an infusion made with half an ounce of columbo, half an ounce of ginger, a drachm of senna, and a pint of boiling water, and given in the dose of a wineglassful three times a day. Columbo is much used by the natives of Mozambique in dysentery and other diseases. (*Berry.*) It was first introduced to the notice of the profession in Europe

by François Redi, in the year 1685. It is most commonly prescribed in the state of infusion. (See *Infusum Calumbæ.*) The dose of the powder is from ten to thirty grains, and may be repeated three or four times a day. It is frequently combined with powdered ginger, subcarbonate of iron, and rhubarb.

CAMPHORA. *U. S., Br.*

Camphor.

A peculiar concrete substance derived from Camphora officinarum, and purified by sublimation. *U. S.* A concrete volatile oil, obtained from the wood of Camphora officinarum; imported in the crude state from China and Japan, and purified by sublimation. *Br.*

Camphre, *Fr.;* Kampher, *Germ.;* Canfora, *Ital.;* Alcanfor, *Span.*

The name of camphor has been applied to various concrete, white, odorous, volatile products, found in different aromatic plants, and resulting probably from chemical change in their volatile oil. But commercial camphor is derived exclusively from two plants, the *Camphora officinarum* of Nees or *Laurus Camphora* of Linnæus, and the *Dryobalanops Camphora;* the former of which yields our officinal camphor, the latter a product much valued in the East, but unknown in the commerce of this country and of Europe. A considerable quantity of camphor, said to be identical with the officinal, was a few years since obtained upon the Tenasserim Coast, in further India, by subliming the tops of an annual plant, abundant in that region, and thought to be a species of Blumia. This product, however, has not been introduced into general commerce. (*Am. Journ. of Pharm.*, xvi. 56.) The Rev. Mr. Mason, an American missionary in Burmah, states, in a letter to Mr. Vaux, of Philadelphia, that the Chinese settlers informed him that the same plant abounds in China, and that camphor is procured from it there. (*Proceed. of the Acad of Nat. Sci. of Phil.*, May 13th, 1851, p. 201.) The following observations apply to the officinal camphor.

Camphora. *Sex. Syst.* Enneandria Monogynia. — *Nat. Ord.* Lauraceæ.

Gen. Ch. Flowers hermaphrodite, panicled, naked. *Calyx* six-cleft, papery, with a deciduous limb. *Fertile stamens* nine, in three rows; the inner with two-stalked, compressed glands at the base; anthers four-celled; the outer turned inwards, the inner outwards. Three *sterile stamens* shaped like the first, placed in a whorl alternating with the stamens of the second row; three others stalked, with an ovate glandular head. *Fruit* placed on the obconical base of the calyx. *Leaves* triple-nerved, glandular in the axils of the principal veins. Leaf buds scaly. (Lindley, *Flora Medica*, 332.)

Among the species composing the genus Laurus of Linn., such striking differences have been observed in the structure of the flower and fruit, that botanists have been induced to arrange them in new genera. The camphor, cinnamon, and sassafras trees have been separated from the proper laurels by Nees, and made the types of distinct genera, which have been adopted by most recent writers, and may be considered as well established.

Camphora officinarum. Nees, *Laurin.* 88; Carson, *Illust. of Med. Bot.* ii. 29, pl. lxxiv. — *Laurus Camphora.* Willd. *Sp. Plant.* ii. 478; Woodv. *Med. Bot.* p. 681, t. 236. The camphor-tree is an evergreen of considerable size, having the aspect of the linden, with a trunk straight below, but divided above into many branches, which are covered with a smooth, greenish bark. Its leaves, which stand alternately upon long footstalks, are ovate-lanceolate, entire, smooth and shining, ribbed, of a bright yellowish-green colour on their upper surface, paler on the under, and two or three inches in length. The flowers are small, white, pediceled, and collected in clusters, which are supported by long axillary peduncles. The fruit is a red berry resembling that of the cinnamon. The tree is a native of China, Japan, and other parts of eastern Asia. It has been in-

troduced into the botanical gardens of Europe, and is occasionally met with in our own conservatories.*

The leaves have when bruised the odour of camphor, which is diffused through all parts of the plant, and is obtained from the root, trunk, and branches by sublimation. The process is not precisely the same in all places. The following is said to be the one pursued in Japan. The parts mentioned, particularly the roots and smaller branches, are cut into chips, which are placed with a little water in large iron vessels, surmounted by earthen capitals, furnished with a lining of rice-straw. A moderate heat is then applied, and the camphor, volatilized by the steam, rises into the capital, where it is condensed upon the straw. In China, the comminuted plant is said to be first boiled with water until the camphor adheres to the stick used in stirring, when the strained liquor is allowed to cool; and the camphor which concretes, being alternated with layers of earth, is submitted to sublimation. In the Island of Formosa, where the camphor-tree abounds, the chips are heated in an iron pot, surmounted by another, and the product of the sublimation is introduced into large vats, with holes in the bottom, through which an oil escapes called *camphor-oil*, much used by the Chinese for medical purposes, and samples of which have been sent to Europe. The camphor, thus drained, is packed in bags and exported. (*Pharm. Journ.*, Dec. 1863, p. 280.)

Commercial History. Camphor, in the *crude* state, is brought to this country chiefly from Canton. It comes also from Batavia, Singapore, Calcutta, and frequently from London. All of it is probably derived originally from China and Japan. Two commercial varieties are found in the market. The cheapest and most abundant is the *Chinese camphor*, most of which is produced in the Island of Formosa, and thence taken to Canton. It comes in chests lined with lead, each containing about 130 pounds. It is in small grains or granular masses, of a dirty-white colour, and frequently mixed with impurities. It has occurred in commerce adulterated with muriate of ammonia. The other variety is variously called *Japan*, *Dutch*, or *tub* camphor, the first name being derived from the place of its origin, the second from the people through whom it was introduced into commerce, and the third from the recipient in which it is often contained. It has usually come from Batavia, to which port it was taken from Japan. Like the former variety, it is in grains or granular masses; but the grains are larger and of a pinkish colour, and there are fewer impurities, so that it yields a larger product when refined.

Crude camphor, as brought from the East, is never found in the shop of the apothecary. It must be refined before it can be used for medicinal purposes. The process for refining camphor was first practised in Europe by the Venetians, who probably derived it from the Chinese. It was afterwards transferred to the Dutch, who long enjoyed a monopoly of this business; and it is only within a few years that the process has been generally known. It is now practised largely in this country, and the camphor refined in our domestic establishments is equal to any formerly imported. Crude camphor is mixed with about one-fiftieth of quicklime, and exposed, in an iron vessel placed in a sand-bath, to a gradually increasing heat, by which it is melted, and ultimately converted into vapour, which condenses in a suitable recipient.† Refined in this manner, it is usually in the form of large circular cakes, one or two inches thick, slightly convex on one side and concave on the other, and perforated in the centre.

Properties. Camphor has a peculiar, strong, penetrating, fragrant odour; and

* The camphor-tree sometimes attains a great age and an enormous size. A tree seen by Kämpfer, in Japan, in 1691, with a trunk 36 feet in circumference, was in the year 1826 described by Siebold as having a circumference of 50 feet. (*Japan as it was and is*, by R. Hildreth. Boston, 1855, p. 337.) The author has seen a large tree growing in the open air at Naples, and has no doubt that it might be readily, and perhaps profitably cultivated in the southern parts of our own country, and especially in California.

† We are informed that the process is conducted in the following manner in the laboratories of Philadelphia. The vessels in which the camphor is put are of cast-iron, circular, from 12 to 15 inches or more in diameter, and 4 inches deep, with perpendicular

a bitter, pungent taste, with a slight sense of coolness. It is beautifully white and pellucid, somewhat unctuous to the touch, brittle, and yet possessed of a tenacity which renders its reduction to a fine powder very difficult, unless its cohesion be overcome by the addition of a minute proportion of alcohol, or other volatile liquid for which it has an affinity. It may be obtained in powder also by precipitating the tincture with water, or by grating and afterwards sifting it. The fracture of camphor is shining, and its texture crystalline. Its sp. gr. varies from 0·9857 to 0·996. When thrown in small fragments upon water, it assumes singular circulatory movements, which cease upon the addition of a drop of oil; and this property has been applied to the detection of grease in liquids, a very small proportion of which is sufficient to prevent the movements. Its volatility is so great that, even at ordinary temperatures, it is wholly dissipated if left exposed to the air. When it is confined in bottles, the vapour condenses on the inner surface, and, in large bottles partially filled, sometimes forms, after long standing, large and beautiful crystals. It melts at 288° F., boils at 400°, and, in close vessels, sublimes unchanged. When allowed to concrete slowly from the state of vapour, it assumes the form of hexagonal plates. It is not altered by air and light. It readily takes fire, burning with a brilliant flame, with much smoke, and without residue. Water triturated with camphor dissolves, according to Berzelius, not more than 1000th part; which, however, is sufficient to impart a decided odour and taste to the solvent. By the intervention of sugar or magnesia, a much larger proportion is dissolved. (See *Aqua Camphoræ.*) Carbonic acid increases the solvent power of water, as also does the spirit of nitrous ether. Ordinary alcohol will take up 75 per cent of its weight of camphor, which is precipitated upon the addition of water. Berzelius states that 100 parts of alcohol, of the sp. gr. 0·806, dissolve 120 parts at 50° F. It is soluble without change in ether, the volatile and fixed oils, strong acetic acid, and diluted mineral acids, and is extremely soluble in chloroform. By strong sulphuric and nitric acids it is decomposed; the former carbonizing and converting it into artificial tannin, the latter, with the aid of repeated distillation, into *camphoric acid.* Alkalies produce very little effect upon it. Resins unite with it, forming a soft tenacious mass, in which the odour of the camphor is sometimes almost extinguished, and frequently diminished; and a similar softening effect results when it is triturated with the concrete oils.* Exposed to a strong heat, in close vessels, camphor is resolved into a volatile oil and charcoal. It is closely analogous in character to the essential oils; and is thought to consist of a radical called *camphene* united with oxygen. Camphene, which is represented

sides, and a ledge at top on which the cover rests. This consists of sheet iron, with a hole through the centre about an inch in diameter, over which a small hollow cone of sheet-iron is placed loosely. The crude camphor mixed with the lime, the object of which is said to be to combine with the moisture present, which interferes with the due solidification of the camphor vapour, is placed in the iron vessels described, of which from 20 to 50 are arranged in a long sand-bath. Heat is then applied until the camphor melts, after which it is kept as nearly uniform as possible, so that the vaporization may take place regularly, without violent ebullition. The vapour condenses on the lower surface of the lid; and care is taken, by the occasional removal of the iron cone, and clearing of the opening by means of a knife, to allow the escape of any accidental excess of the vapour. They who desire to see minute details as to the mode of refining camphor practised in France, are referred to an article, by M. Emile Perret, pharmacian at Moret, in the *Journ. de Pharm. et de Chimie* (Fev. 1868, p. 124). — *Note to the ninth and thirteenth editions.*

* As this property of camphor may have a bearing, injuriously or otherwise, on pharmaceutical processes, it is desirable that the operator, as well as prescriber, should be aware of the degree of effect produced by different resinous substances which may be mixed with it. M. Planche has found that mixtures, formed by triturating powdered camphor with powdered *dragon's blood*, *guaiac*, *assafetida*, and *galbanum*, assume, and preserve indefinitely the pilular consistence; with *benzoin*, *tolu*, *ammoniac*, and *mastic*, though at first of a pilular consistence, afterwards become soft by exposure to the air; with *sagapenum* and *animé*, assume a permanently semi-liquid form; with *olibanum*, *opopanax*, *gamboge*, *euphorbium*, *bdellium*, *myrrh*, and *amber*, remain pulverulent though somewhat grumous; and with *tacamahac*, *resin of jalap*, *sandarac*, and *resinoid matter of cinchona*, preserve the form of powder indefinitely. The same experimenter observed that camphor loses its

by pure oil of turpentine, is composed of twenty eqs. of carbon and sixteen of hydrogen ($C_{20}H_{16}$). With two eqs. of oxygen it forms camphor, with eight eqs of the same element, hydrated camphoric acid, and with one eq. of hydrochloric acid, artificial camphor.* Camphor, dehydrated by means of chloride of zinc,

odour entirely, when mixed with *assafetida*, *galbanum*, *sagapenum*, *animé*, and *tolu*; retains a feeble odour with *dragon's blood*, *olibanum*, *mastic*, *benzoin*, *opopanax*, *tacamahac*, *guaiac*, and *ammoniac*; while with the other resinous substances above mentioned, it either has its odour increased, or retains it without material change. (*Journ. de Pharm.*, xxiv. 226.)

In mixing camphor with other substances in the form of powder, it is best first to pulverize the camphor with the aid of a little alcohol, then to pulverize the other substances together, and lastly to mix the two powders gently; much rubbing with the pestle having the effect of consolidating the granules of the camphor. (*Procter.*)

* *Sumatra Camphor. Borneo Camphor. Dryobalanops Camphor. Camphol.* It has long been known that a variety of camphor is produced in the islands of Sumatra and Borneo, by a forest tree, which remained until a recent period undetermined. It was at length, however, described by Colebrook, and is now recognised in systematic works as *Dryobalanops Camphora*, or *D. aromatica*. It is a very large tree, often exceeding one hundred feet in height, with a trunk six or seven feet in diameter, and ranking among the tallest and largest trees in India.* It is found in Sumatra and Borneo, and is abundant on the N. W. coast of the former island. The camphor exists in concrete masses, which occupy longitudinal cavities or fissures in the heart of the tree, from a foot to a foot and a half long, at certain distances apart. The younger trees are generally less productive than the old. The only method of ascertaining whether a tree contains camphor is by incision. A party proceeds through the forest, wounding the trees, till they find one which will answer their purpose; and hundreds may be examined before this object is attained. When discovered, the tree is felled and cut into logs, which are then split, and the camphor removed by means of sharp-pointed instruments. It is stated that the masses are sometimes as thick as a man's arm; and that the product of a middling-sized tree is nearly eleven pounds; of a large one, double that quantity. The trees which have been wounded, and left standing often produce camphor seven or eight years afterwards. Mrs. Ida Pfeiffer states, in her *Second Journey round the World* (Am. ed. p. 183), that the camphor is also found in a concrete state under the bark, and is swept down with long brooms. The Dryobalanops yields also a fragrant straw-coloured liquid, called in the East Indies *oil of camphor*, and highly valued as an external application in rheumatism and other painful affections. It is said to be found in trees too young to produce camphor, and is supposed to constitute the first stage in the development of this substance; as it occupies the cavities in the trunk which are afterwards filled with the camphor. It has been stated to hold a large portion of this principle in solution, and to yield an inferior variety by artificial concretion; but this was not true of a specimen in the possession of Dr. Christison. A specimen examined by Professor Procter deposited a small quantity of the camphor at a temperature near the zero of Fahrenheit. By the action of nitric acid, it may be combined with oxygen, and converted into camphor of the same character as that deposited by refrigeration. The whole tree is pervaded more or less by the camphor or the oil. The wood retains a fragrant smell, and, being on this account less liable to the attacks of insects, is highly esteemed for carpenter's work. The camphor wood-chests, occasionally brought to this country from the East Indies, are probably made out of the wood of the Dryobalanops.

It has been supposed that this variety of camphor is occasionally brought into the markets of Europe and America. But this is a mistake; as the whole produce of the islands is engrossed by the Chinese, by whom it is so highly valued that it commands at Canton, according to Mr. Crawford, seventy-eight times according to Mr. Reeves, one hundred times the price of ordinary camphor. A specimen in our possession, which was sent to this country from Canton as a curiosity, and kindly presented to us by Dr. Joseph Carson, is in tabular plates of the size of a finger nail or smaller, of a foliaceous crystalline texture, white, somewhat translucent, of an odour analogous to that of common camphor, and yet decidedly distinct, and less agreeable. It has also a camphorous taste. It is more compact and brittle than ordinary camphor; and, though the pieces will often float for a time when thrown on water, yet they sink when thoroughly moistened, and deprived of adhering air. According to Dr. Christison, its sp. gr. is 1009. It is easily pulverized without the addition of alcohol. It is, moreover, much less disposed to rise in vapour, and to condense on the inside of the bottle containing it. Like ordinary camphor, it is fusible, volatilizable, very slightly soluble in water, and freely soluble in alcohol and in ether Dr. Gregory considers it as the bihydrate of camphene ($C_{20}H_{18}O_2$).

---

* For a particular description of this tree, see a paper by Dr. W. H. De Vriese, of Leyden, in the *American Journal of Pharm.* (xxiv. 329), taken from Hooker's Journal of Botany. In this paper it is stated, on the authority of Dr. Junghuhn, who witnessed the process of collection, that the camphor is deposited in very small quantities in minute fissures between the fibres, from which it is scraped off by small splinters of wood, or by the nail; and the thickest and oldest trees seldom yield more than two ounces. This account as to the productiveness of the tree differs greatly from that of Colebrook, as stated in the note above. (*Note to the tenth edition.*)

is said to yield a hydrocarbon $C_{20}H_{14}$, at first considered identical with the *cymene* obtained from the oil of chamomile, but determined by Fittig and Ferber to be not identical though isomeric with that principle. (*Journ. de Pharm. et de Chim.*, 4e sér., iii. 157.)

Genuine camphor is said to be sometimes adulterated with the artificial, which may be detected by the action of ammonia upon its alcoholic solution, causing a flocculent precipitate, which does not redissolve, and the quantity of which is proportionate to that of the artificial product in any mixture of the two. (*Am. Journ. of Pharm.*, xxxiv. 189.) As a means of distinguishing natural from the artificial camphor resulting from the reaction between oil of turpentine and muriatic acid, Mr. J. W. Bailey recommends that a drop of alcohol, holding a little of the camphor to be tested in solution, be allowed to evaporate on the slide of a miscroscope. The crystals then formed produce with polarized light beautiful colours, when of natural camphor, but not when of the artificial. (*Neues Repertorium*, xvi. 763, A.D. 1867.)

Medical Properties and Uses. Camphor does not seem to have been known to the ancient Greeks and Romans. Europe probably derived it from the Arabians, by whom it was employed as a refrigerant. Much difference of opinion has prevailed as to its mode of action; some maintaining its immediate sedative influence, others considering it as a direct and decided stimulant. Its operation appears to be primarily and chiefly directed to the cerebral and nervous systems; and the circulation, though usually affected to a greater or less extent, is probably involved, for the most part, through the brain. It acts, also, to a certain extent, as a direct irritant of the mucous membranes with which it is brought into contact, and may thus in some measure secondarily excite the pulse. The effects of the medicine vary with the quantity administered. In moderate doses it produces, in health, mental exhilaration, increased heat of skin, and occasional diaphoresis. The pulse is usually increased in fulness, but little, if at all, in force or frequency. According to the experiments of certain Italian physicians, it has a tendency to the urinary and genital organs, producing a burning sensation along the urethra, and exciting voluptuous dreams (*N. Am. Med. and Surg. Journ.*, ix. 442); and these experiments have been confirmed by the observations of Dr. Reynolds in a case of poisoning by camphor (*Brit. Am. Journ. of Med.*, June, 1846). Cullen, however, states that he has employed it fifty times, even in large doses, without having ever observed any effect upon the urinary passages. By many it is believed to calm irritation of the urinary and genital apparatus, and to possess antaphrodisiac properties. In its primary operation, it allays nervous disorder, quiets restlessness, and produces a general placidity of feeling, and is thus highly useful in certain forms of disease attended with derangement of the nervous functions. In larger doses, it displays a more decided action on the brain, producing more or less giddiness and mental confusion, with a disposition to sleep; and, in morbid states of the system, relieving pain and allaying spasmodic action. In immoderate doses it occasions nausea, vomiting, anxiety, faintness, vertigo, delirium, insensibility, coma, and convulsions, which may end in death. The pulse, under these circumstances, is at first reduced in frequency and force (Alexander, *Experimental Essays*, p. 227); but, as the action advances, it sometimes happens that symptoms of strong sanguineous determination to the head become evident in the flushed countenance, inflamed and fiery eyes, and highly excited pulse. (*Quarin.*) In three cases of poisoning by camphor, reported by Schaaf, of Strasburg, the symptoms produced were violent and incessant convulsions, paleness and coolness of the surface, vomiting and frequent micturition, and finally stupor or coma. The patients were children, and the youngest, a girl of about eighteen months, died from the effects of the poison, of which she took about ten grains. (*Monthly Journ. of Med. Sci.*, Oct. 1850, p. 377.) There can be no doubt that camphor is absorbed; as its odour is observed in the breath and perspiration, and according to Dr. Reynolds, in the urine also, though the contrary has been asserted.

By its moderately stimulating powers, its diaphoretic tendency, and its influ-

ence over the nervous system, camphor is admirably adapted to the treatment of diseases of a typhoid character, which combine, with the enfeebled condition of the system, a frequent irritated pulse, a dry skin, and much nervous derangement, indicated by restlessness, watchfulness, tremors, subsultus, and low muttering delirium. With a view to its anodyne and narcotic influence, it is also used in diseases of an inflammatory character; as in our ordinary remittents, and the phlegmasiæ, particularly rheumatism, when the increased vascular action is complicated with derangement of the nervous system. In such cases, however, it should not be given until after proper depletion, and even then should be combined with such medicines as may obviate the slight stimulation it produces, and increase its tendency to the skin; as, for instance, tartarized antimony, ipecacuanha, or nitre. In a great number of spasmodic and nervous disorders, and complaints of irritation, camphor has been extensively employed. The cases of this nature to which experience has proved it to be best adapted, are dysmenorrhœa, puerperal convulsions and other nervous affections of the puerperal state, and certain forms of mania, particularly nymphomania, and that arising from the abuse of spirituous liquors. In some of these cases, advantage may be derived from combining it with opium. Camphor has also been employed internally to allay the strangury produced by cantharides.

It is much used locally as an anodyne, dissolved in alcohol, oil, or acetic acid, and frequently combined with laudanum.* In rheumatic and gouty affections, and various internal spasmodic and inflammatory complaints, it often yields relief in this way. The ardor urinæ of gonorrhœa may be alleviated by injecting an oleaginous solution of camphor into the urethra; and the tenesmus from ascarides and dysentery, by administering the same solution in the form of enema. Twenty or thirty grains of camphor, added to a poultice, and applied to the perineum, allay the chordee which is a painful attendant upon gonorrhœa. Its vapour has been inhaled into the lungs with benefit in asthma and spasmodic cough; and a lump of it held to the nose is said to relieve coryza. It has been employed for the same purpose, and for nervous headache, in the form of powder snuffed up the nostrils. It enters into the composition of certain tooth-powders; but is asserted, when employed in this way, to injure the enamel of the teeth.

Camphor may be given in substance, in the form of bolus or pill, or diffused in water by trituration with various substances. The form of pill is objectionable; as in this state the camphor is with difficulty dissolved in the gastric liquor, and, floating on the top, is apt to excite nausea, or pain and uneasiness at the upper orifice of the stomach. Orfila states that, when given in the solid form, it is capable of producing ulceration in the gastric mucous membrane.† The emulsion is almost always preferred. This is made by rubbing up the camphor with loaf sugar, gum arabic, and water; and the suspension will be rendered more complete and permanent by the addition of a little myrrh. Milk is sometimes used as a vehicle, but is objectionable, from its liability to become speedily sour. The aqueous solution is often employed where only a slight impression is desired. For this purpose, the *Aqua Camphoræ* of the U. S. Pharmacopœia is preferable to the solution made by simply pouring boiling water upon a lump of camphor, which is sometimes prescribed under the name of *camphor tea.* When chloroform is not inadmissible, an elegant preparation may be made by dissolving camphor in that liquid, in the proportion of two drachms of the

* An *ointment of camphor* may be made by heating three parts, in powder, by means of a water-bath, with twelve parts of prepared lard, and stirring the solution thoroughly when it begins to thicken on cooling. (*Pharm. Journ.*, July, 1860, p. 41.) M. Parisel recommends, as affording a better product, that the powdered camphor and the lard should be mixed, at ordinary temperatures, in a thin well-glazed earthen vessel, and allowed to stand for twelve hours, with occasional agitation. The solution of the camphor is effected without apparent liquefaction, each molecule being dissolved in the surrounding molecules of the lard. (*Journ. de Pharm.*, Mai, 1860, p. 362.)—*Note to the twelfth edition.*

† There is some difficulty in making a good pilular mass with powdered camphor. Mr. W. H. Githens states that this difficulty may be obviated by using soap and honey as excipients. (*Am. Journ. of Pharm.*, xxxiii. 206.)—*Note to the twelfth edition.*

former to a fluidrachm of the latter, and then mixing the solution with water by the intervention of the yolk of an egg.

The medium dose of camphor is from five to ten grains; but, to meet various indications, it may be diminished to a single grain, or increased to a scruple. The injurious effects of an overdose are said to be best counteracted, after clearing out the stomach, by the use of opium.

CANELLA. *U. S.*

Canella.

The bark of Canella alba. *U. S.*

Off. Syn. CANELLÆ ALBÆ CORTEX. *Canella Alba Bark.* The bark of Canella alba. *Br.*

Canelle blanche, *Fr.;* Weisser Zimmt, Canell, *Germ.;* Canella bianca, *Ital.;* Canela blanca, *Span.*

CANELLA. *Sex. Syst.* Dodecandria Monogynia.—*Nat. Ord.* Meliaceæ. *De Cand.* Canelleæ. *Lindley.*

Gen. Ch. Calyx three-lobed. *Petals* five. *Anthers* sixteen, adhering to an urceolate nectary. *Berry* one-celled with two or four seeds. *Willd.*

Canella alba. Willd. *Sp. Plant.* ii. 851; Woodv. *Med. Bot.* p. 694, t. 237; Carson, *Illust. of Med. Bot.* i. 24, pl. 16. This is the only species of the genus. It is an erect tree, rising sometimes to the height of fifty feet, branching only at the top, and covered with a whitish bark, by which it is easily distinguished from other trees in the woods where it grows. The leaves are alternate, petiolate, oblong, obtuse, entire, of a dark-green colour, thick and shining like those of the laurel, and of a similar odour. The flowers are small, of a violet-colour, and grow in clusters upon divided footstalks, at the extremities of the branches. The fruit is an oblong berry, containing one, two, or three black shining seeds.

Canella alba is a native of Jamaica and other West India islands. The bark of the branches, which is the part employed in medicine, having been removed by an iron instrument, is deprived of its epidermis, and dried in the shade. It comes to us in pieces partially or completely quilled, occasionally somewhat twisted, of various sizes, from a few inches to two feet in length, from half a line to two or even three lines in thickness, and, in the quill, from half an inch to an inch and a half in diameter.

Properties. Canella is of a pale orange-yellow colour externally, yellowish-white on the inner surface, with an aromatic odour somewhat resembling that of cloves, and a warm, bitterish, very pungent taste. It is brittle, breaking with a short fracture, and yielding, when pulverized, a yellowish-white powder. Boiling water extracts nearly one-fourth of its weight; but the infusion, though bitter, has comparatively little of the warmth and pungency of the bark. It yields all its virtues to alcohol, forming a bright-yellow tincture, which is rendered milky by the addition of water. By distillation with water it affords a large proportion of a yellow or reddish, fragrant, and very acrid volatile oil. It contains, moreover, according to the analysis of MM. Petroz and Robinet, mannite, a peculiar very bitter extractive, resin, gum, starch, albumen, and various saline substances. Meyers and Reiche obtained twelve drachms of the volatile oil from ten pounds of the bark. They found it to consist of two distinct oils, one lighter and the other heavier than water. According to the same chemists, the bark contains 8 per cent. of mannite, and yields 6 per cent. of ashes. (See *Am. Journ. of Pharm.*, xvi. 75.) Canella has been sometimes con-

founded with Winter's bark, from which, however, it differs both in sensible properties and composition. (See *Wintera.*)

Medical Properties and Uses. Canella is possessed of the ordinary properties of the aromatics, acting as a local stimulant and gentle tonic, and producing upon the stomach a warming cordial effect, which renders it useful as an addition to tonic or purgative medicines, in debilitated states of the digestive organs. It is scarcely ever prescribed except in combination. In the West Indies it is employed by the negroes as a condiment, and has some reputation as an antiscorbutic.

CANNA. *U. S.*

Canna.

The fecula from the rhizoma of an undetermined species of Canna. *U. S.*

CANNA. *Sex. Syst.* Monandria Monogynia.—*Nat. Ord.* Marantaceæ.

Gen. Ch. Corolla unequal, scarcely lip-shaped in any segment. *Stamens* petaloid, one with half an anther on the edge. *Style* straight, flat, nearly free. *Ovary* three-celled, many-seeded, granular. *Fruit* membranous, three-valved, with a deciduous granular surface. *Lindley.*

It is yet somewhat uncertain from what species of Canna the fecula commonly known by the French name *tous les mois*, and officinally designated *canna*, is derived, though it is generally believed to be C. edulis. The tubers of *Canna Achiras* (Gillies), growing in Central and South America, are said to be used as food in Peru and Chili (Lindley, *Med. and Econom. Bot.* p. 50); and a root or rhizoma, closely resembling turmeric, and used by the native Africans at Sierra Leone for dyeing yellow, was found by Dr. Wm. F. Daniell to be the product of a species of Canna, believed to be the *C. speciosa* of Roscoe. (*Pharm Journ.*, Nov. 1859, p. 258.)

Canna edulis. Lindley, *Flor. Med.* p. 569, figured in *Fl. Med. and Econ.* of the same author, p. 49. This is a tuberous plant, with erect, smooth, purplish stems, from four to six feet high, and invested with sheathing leaves, which are ovate-oblong, tapering towards each end, smooth, and of a deep glaucous green, with purplish edges. The flowers are few, and in compact racemes, of a red and yellow colour. The plant is a native of the West Indies, and is cultivated in the islands of St. Kitts, Trinidad, and perhaps others. The tubers, which are said to be three times larger than the fist, are first rasped, by means of a machine, into a pulp, from which the starch is extracted in the usual manner, by washing and straining, and, after the washings have been allowed to stand, so as to deposit the fecula, decanting the clear liquid. (Pereira, *Mat. Med.*)

Properties. Canna starch is in the form of a light, beautifully white powder, of a shining appearance, very unlike the ordinary forms of fecula. Its granules are said to be larger than those of any other variety of starch in use, being from the 300th to the 200th of an inch in length. Under the microscope they appear ovate or oblong, with numerous regular unequally distant rings; and the circular hylum, which is sometimes double, is usually situated at the smaller extremity. (*Pereira.*) This fecula has the ordinary chemical properties of starch, and forms, when prepared with boiling water, a nutritious and wholesome food for infants and invalids. It may be prepared in the same manner as *arrow-root*, and is said to form even a stiffer jelly with boiling water. (See *Maranta.*) W.

CANNABIS INDICA. *Br.*

Indian Hemp.

The dried flowering tops of the female plants of Cannabis sativa. That which is grown in India, and from which the resin has not been removed, is alone to be employed. *Br.*

See EXTRACTUM CANNABIS.

CANTHARIS. *U. S., Br.*

Cantharides. Spanish Flies.

Cantharis vesicatoria. *U. S., Br.*

Cantharide, *Fr.;* Spanische Fliege, Kantharide, *Germ.;* Cantarelle, *Ital.;* Cantharidas, *Span.*

The term *Cantharis* was employed by the ancient Greek writers to designate many coleopterous insects, or beetles. Linnæus gave the title to a genus not including the officinal blistering insect, and placed this in the genus *Meloë*, which, however, has been since divided into several genera. Geoffroy made the Spanish fly (beetle) the prototype of a new one called *Cantharis*, substituting *Cicindela* as the title of the Linnæan genus. Fabricius altered the arrangement of Geoffroy, and substituted *Lytta* for *Cantharis* as the generic name. The former was adopted by the London College, and at one time was in extensive use; but the latter, having been restored by Latreille, is now recognised in the British and American Pharmacopœias, and is universally employed. By this naturalist the vesicating insects were grouped in a small tribe, corresponding very nearly with the Linnæan genus Meloë, and distinguished by the title *Cantharideæ*. This tribe he divided into eleven genera, among which is Cantharis. Two others of these genera, *Meloë* properly so called, and *Mylabris*, have been employed as vesicatories. *Mylabris cichorii* is thought to be one of the insects described by Pliny and Dioscorides under the name of cantharides, and is to this day employed in Italy, Greece, the Levant, and Egypt; and another species, *M. pustulata*, is used for the same purpose in China. Mr. W. R. Warner has found 500 parts of M. cichorii to yield 2·13 parts of cantharidin, which somewhat exceeded the yield of Spanish flies. (*Am. Journ. of Pharm.*, xxviii. 195.) *Meloë proscarabæus* and *M. majalis* have been occasionally substituted for cantharides in Europe, and *M. trianthemæ* is used in the upper provinces of Hindostan. Several species of Cantharis, closely analogous in medical properties, are found in various parts of the world; but *C. vesicatoria* is the only one recognised as officinal in the United States, Great Britain, and France. A second species, *C. vittata*, was introduced into our national Pharmacopœia, but has been discarded, upon insufficient grounds, we think, in the present edition. Of this, and some other indigenous species, notice will be taken at the end of this article. At present we shall confine our observations to *C. vesicatoria.*

Cantharis. *Class* Insecta. *Order* Coleoptera. *Linn.* — *Family* Trachelides. *Tribe* Cantharideæ. *Latreille.*

Gen. Ch. Tarsi entire; *nails* bifid; *head* not produced into a rostrum; *elytra* flexible, covering the whole abdomen, linear semicylindric; *wings* perfect; *maxillæ* with two membranous *laciniæ*, the external one acute within, subuncinate; *antennæ* longer than the head and thorax, rectilinear; first joint largest, the second transverse, very short; *maxillary palpi* larger at tip. *Say.*

Cantharis vesicatoria. Latreille, *Gen. Crust. et Insect.*, ii. p. 220. This beetle is from six to ten lines in length, by two or three in breadth, and of a beautiful, shining, golden-green colour. The head is large and heart-shaped, bearing two thread-like, black, jointed feelers; the thorax short and quadrilateral; the wing-sheaths long and flexible, covering brownish membranous wings. When alive, the Spanish flies have a strong, penetrating, fetid odour, compared to that of mice, by which swarms of them may be detected at a considerable distance. They attach themselves preferably to certain trees and shrubs, such as the white poplar, privet, ash, elder, and lilac, upon the leaves of which they feed. They abound most in Spain, Italy, and the south of France; but are found also in all the temperate parts of Europe, and in the west of Asia. In the state of larva, they live in the ground and gnaw the roots of plants. They usually make their appearance in swarms upon the trees in May and June, when they are collected. The time preferred for the purpose is in the morning at sunrise, when they are torpid from the cold of the night, and easily let go their hold. Persons with their

faces protected by masks, and their hands with gloves, shake the trees, or beat them with poles; and the insects are received as they fall upon linen cloths spread underneath. They are then plunged into vinegar diluted with water, or exposed in sieves to the vapour of boiling vinegar, and, having been thus deprived of life, are dried either in the sun, or in apartments heated by stoves. This mode of killing the flies by the steam of vinegar is as ancient as the times of Dioscorides and Pliny. In some places they are gathered by smoking the trees with burning brimstone. It has been proposed by M. Lutrand to destroy them by the vapour of chloroform. When perfectly dry, they are introduced into casks or boxes, lined with paper and carefully closed, so as to exclude as much as possible the atmospheric moisture.

Cantharides come chiefly from Spain, Italy, Sicily, and other parts of the Mediterranean. Considerable quantities are also brought from St Petersburg, derived originally, in all probability, from the southern provinces of Russia, where the insect is very abundant. The Russian flies are more esteemed than those from other sources. They may be distinguished by their greater size, and their colour approaching to that of copper.

Properties. Dried Spanish flies preserve the form and colour, and, to a certain extent, the disagreeable odour of the living insect. They have an acrid, burning, and urinous taste. Their powder is of a grayish-brown colour, interspersed with shining green particles, which are the fragments of the feet, head, and wing-cases. If kept perfectly dry, in well-stopped glass bottles, they retain their activity for a great length of time. A portion which had been preserved by Van Swieten for thirty years, in a glass vessel, was found still to possess vesicating properties. But, exposed to a damp air, they quickly undergo putrefaction; and this change takes place more speedily in the powder. Hence, the insects should either be kept whole, and powdered as they are wanted for use, or, if kept in powder, should be well dried immediately after pulverization, and preserved in air-tight vessels. They should never be purchased in powder, as, independently of the consideration just mentioned, they may in this state be more easily adulterated. But, however carefully managed, cantharides are apt to be attacked by mites, which feed on the interior soft parts of the body, reducing them to powder, while the harder exterior parts are not affected. An idea was at one time prevalent, that the vesicating property of the insect was not injured by the worm, which was supposed to devour only the inactive portion. But this has been proved to be a mistake. M. Farines, an apothecary of Perpignan, has satisfactorily shown that, though the hard parts left by these mites possess some vesicating power, and the powder produced by them still more, yet the sound flies are much stronger than either. Camphor, which has been recommended as a preservative, does not prevent the destructive agency of the worm.* It is stated by M. Farines that, when the flies are destroyed by the vapour of pyroligneous acid, instead of common vinegar, they acquire an odour which contributes to their preservation. Cantharides will bear a very considerable heat without losing the brilliant colour of their elytra; nor is this colour extracted by water, alcohol, ether, or the oils; so that the powder might be deprived of all its active principles, and yet retain the exterior characters unaltered. The

* It appears from the experiments of M. Nivet that, though camphor does not preserve the entire fly from the attacks of the larvæ of the *Anthrenus*, it actually destroys the mites of the Cantharis so often found in the powder, and may, therefore, be introduced with advantage, in small lumps, into bottles containing powdered cantharides. (*Journ. de Pharm.*, xix. 604.) Carbonate of ammonia has also been recommended as a preservative. Pereira has found that a few drops of strong acetic acid, added to the flies, are very effectual. Among the best means of preserving them, whether whole or in powder, is the application of the process of Apert, which consists in exposing them, for half an hour, confined in glass bottles, to the heat of boiling water, which destroys the eggs of the insect, without impairing the virtues of the flies. (*Ibid.*, xxii. 246.) Of course the access of water to the flies should be carefully avoided. Lutrand recommends chloroform as the best preservative that he has tried. (*Journ. de Pharm.*, xviii. 214.) We have little doubt that exposure, in a confined vessel, to the vapour of carbolic acid, would be a perfect protection against all forms of insect life.

wing-cases resist putrefaction for a long time, and the shining particles have been detected in the human stomach months after interment.

So early as 1778, Thouvenel attempted to analyze cantharides, and the attempt was repeated by Dr. Beaupoil in 1803; but no very interesting or valuable result was obtained till 1810, when Robiquet discovered in them a crystalline substance, which proved to be the vesicating principle of the insect, and received the name of *cantharidin*. The constituents, according to Robiquet, are, 1. a green oil, insoluble in water, soluble in alcohol, and inert as a vesicatory; 2. a black matter, soluble in water, insoluble in alcohol, and inert; 3. a yellow viscid matter, soluble in water and alcohol, and without vesicating powers; 4. cantharidin; 5. a fatty matter insoluble in alcohol; 6. phosphates of lime and magnesia, acetic acid, and in the fresh insect a small quantity of uric acid. Orfila afterwards discovered a volatile principle, upon which the fetid odour of the fly depends. It is separable by distillation with water. Prof. Dragendorff has found a volatile principle which acts on the system in the same manner as cantharidin. When powdered flies are moistened with water and distilled, the part which passes over, at or below 212°, contains this principle. (*Chem. News*, May 31, 1867.) If, however, the statement of Mr. Guy is correct, that cantharidin sublimes at 212°, there can, we think, be little doubt that the new volatile principle of Dragendorff is cantharidin itself.

Cantharidin is a white substance, in the form of crystalline scales, of a shining micaceous appearance, inodorous, tasteless, insoluble in water, nearly so in cold alcohol, but soluble in ether, chloroform, benzole, the oils, and in hot alcohol and acetic acid, which deposit it upon cooling.* It is fusible and volatilizable† by heat without decomposition, and its vapour condenses in acicular crystals. According to MM. Massing and Dragendorff, cantharidin, with the composition $C_{10}H_6O_4$, is capable of combining with 2 eqs. of water, and thus becomes cantharidic acid $C_{10}H_8O_6$, and in this state forms definite compounds with bases. These may be obtained by heating cantharidin with an alkaline solution. (*Journ. de Pharm. et de Chim.*, Janv. 1868, p. 79.) The most satisfactory test of it is its vesicating property. It may be obtained by macerating powdered flies in ether for several days; introducing the mixture into a percolation apparatus; adding, after the liquid has ceased to pass, fresh portions of ether, till it comes away nearly colourless; displacing the whole of the menstruum still remaining in the mass by pouring water upon it; distilling the filtered liquor so as to recover the ether; then allowing the residue to cool; and, finally, purifying the cantharidin which is deposited by treating it with boiling alcohol and animal charcoal. Alcohol of 34°, or a mixture of alcohol and ether, may be substituted for the ether itself; but the last-mentioned fluid is preferable, as it dissolves less of the green oil, the separation of which from the cantharidin is the most difficult part of the process. By this plan, M. Thierry obtained, from 1000 parts of powdered flies, 4 parts of pure cantharidin. Notwithstanding the insolubility of this principle in water and cold alcohol, the decoction and tincture of cantharides have the medicinal properties of the insect; and Lewis ascertained that both the aqueous and alcoholic extracts acted as effectually in exciting vesication as the flies themselves, while the residue was in each case inert. Cantharidin consequently exists in the insect, so combined with the yellow mat-

* The solubilities of cantharidin have been examined with great care by Professor Procter, with the following results. It is insoluble in water. Cold alcohol dissolves it slightly, hot alcohol freely. It is more soluble in ether, which also dissolves it more freely hot than cold. Chloroform, cold or hot, is its best solvent; and acetone ranks next to it in this respect. Olive oil, at 250° F., dissolves one-twentieth of its weight, and oil of turpentine, boiling hot, one-seventieth; and both deposit the greater portion on cooling. The olive oil solution after deposition vesicates, the terebinthinate does not. Strong acetic, sulphuric, and nitric acids dissolve it, with the aid of heat, and deposit it unchanged on cooling. It is also dissolved by solutions of potassa and soda, and to a small extent by strong solution of ammonia. (*Am. Journ. of Pharm.*, xxiv. 296.)—*Note to the tenth edition.*

† As determined by the experiments of Mr. Wm. A. Guy, the subliming heat of isolated cantharidin is 212° F., or the temperature of boiling water. (*Pharm. J. and Trans.*, Feb. 1868, p. 373.)—*Note to the thirteenth edition.*

ter as to be rendered soluble in water and cold alcohol. It has been found in Cantharis vittata, Mylabris cichorii, and different species of Meloë.* M Ferrer found cantharidin in all parts of the fly, but somewhat more largely in the soft than the hard parts. (*Journ. de Pharm.*, Oct. 1859, p. 279.)

Adulterations. These are not common. Occasionally other insects are added, purposely, or through carelessness. These may be readily distinguished by their different shape or colour. Flies exhausted of their cantharidin by ether are said to have been substituted for the genuine. An account has been published of considerable quantities of variously coloured glass beads having been found in a parcel of the drug; but this would be too coarse a fraud to be extensively practised. Pereira states that powdered flies are sometimes adulterated with euphorbium.

Medical Properties and Uses. Internally administered, cantharides are a powerful stimulant, with a peculiar direction to the urinary and genital organs. In moderate doses, this medicine sometimes acts as a diuretic, and generally excites some irritation in the urinary passages, which, if its use be persevered in, or the dose increased, often amounts to violent strangury, attended with excruciating pain, and the discharge of bloody urine. In still larger quantities, it produces, in addition to these effects, obstinate and painful priapism, vomiting, bloody stools, severe pains in the whole abdominal region, excessive salivation with a fetid cadaverous breath, hurried respiration, a hard and frequent pulse, burning thirst, exceeding difficulty of deglutition, sometimes a dread of liquids, frightful convulsions, tetanus, delirium, and death. Orfila has known twenty-four grains of the powder to prove fatal. Dissection reveals inflammation and ulceration of the mucous coat of the whole intestinal canal. According to M. Poumet, if the intestines be inflated, dried, cut into pieces, and examined in the sun between two pieces of glass, they will exhibit small shining yellow or green points, strongly contrasting with the matter around them. (*Journ. de Pharm.*, 3e sér., iii. 167.) The poisonous effects are to be counteracted by emetics, cathartics, bleeding, and opiates by the stomach and rectum. Dr. Mulock, of Dublin, recommends the officinal solution of potassa as an antidote, having found thirty drops given every hour an effectual remedy in strangury from blisters. (*Dub. Quart. Journ. of Med. Sci.*, N. S., vi. 222.) From the experiments of Schroff it seems that oils somewhat accelerate the poisonous action, probably by dissolving the cantharidin. (See *Am. Journ. of Pharm.*, xxviii. 365.) By experiments upon dogs, M. Thouery, a French apothecary, has satisfied himself that animal charcoal possesses a real antidotal power. (*Journ. de Pharm.*, Janv. 1858, p. 65.) Notwithstanding their exceeding violence, cantharides have been long and beneficially used in medicine. Either these or other vesicating insects appear to have been given by Hippocrates in dropsy and amenorrhœa, in the latter of which complaints, when properly prescribed, they are a highly valuable remedy. In dropsy

* Professor Procter informs us that he has succeeded, by means of chloroform, in isolating cantharidin with great facility. He treats the flies with chloroform by percolation, displacing the last portions by means of alcohol, and allows the resulting solution to evaporate spontaneously. Cantharidin is thus obtained in crystals mixed with the green oil, the greater portion of which may be removed by bibulous paper. The residuary crystals are dissolved in a mixture of ether and alcohol, which, by the spontaneous evaporation of the ether, yields the cantharidin nearly pure. (*Note to the ninth edition.*)

M. Mortreux, having ascertained that cantharidin is insoluble in sulphuret of carbon, proposes to use this fluid for removing the fatty matter associated with the cantharidin crystals obtained by the use of chloroform, as in the foregoing process of Prof. Procter. He employs the same liquid in estimating the proportion of cantharidin, which he has found to be about 20 centigrammes for 40 grammes of the flies, or the half of one per cent. (*Journ. de Pharm. et de Chim.*, 3e sér., xlvi. 33, A.D. 1864.)—*Note to the thirteenth edition.*

Wittstein obtains it by digesting coarsely powdered flies repeatedly with water, straining through linen and expressing, allowing the liquid to settle for a day, separating the supernatant oil, adding a little wood charcoal, evaporating to dryness, treating the residue with sulphuric ether so long as the solution affords a laminated substance on evaporation, evaporating the ethereal solution, treating the residue with cold alcohol of 80 per cent. for one day with frequent shaking, and finally drying the scales. (See *Am. Journ. of Pharm.*, xxviii. 231.) Mr. Williams has obtained it by means of benzole. (*Ibid.*, xxvi. 340.)—*Note to the eleventh edition.*

they sometimes prove useful when the system is in an atonic state, and the vessels of the kidneys feeble. They are also useful in obstinate gleet, leucorrhœa, and seminal weakness; and afford one of the most certain means of relief in incontinence of urine, arising from debility or partial paralysis of the sphincter of the bladder. A case of diabetes is recorded in the *N. Am. Archives* (vol. ii. p. 175), in which recovery took place under the tincture of cantharides. They are used also in certain cutaneous eruptions, especially those of a scaly character, and in chronic eczema. Dr Erven has employed them in scurvy (*Ann. de Thérap.*, 1845); and they have been found useful, internally administered, in obstinate ulcers. Their unpleasant effects upon the urinary passages are best obviated by the free use of diluent drinks; and, when not consequent upon great abuse of the medicine, may almost always be relieved by an anodyne injection, composed of laudanum with a small quantity of mucilaginous fluid. The dose of Spanish flies is one or two grains of the powder, which may be given twice a day, in the form of pill. The tincture, however, is more frequently employed.

Externally applied, cantharides excite inflammation in the skin, which terminates in a copious secretion of serum under the cuticle. Even thus employed, they not unfrequently give rise to strangury or tenesmus; and this is one of the most troublesome attendants upon their operation. It probably results from the absorption of the active principle of the fly. For various methods employed for obviating strangury from blisters, see *Ceratum Cantharidis*.

The blistering fly may be used either as a rubefacient, or to produce a blister. In the former capacity it is seldom employed, except in low states of disease, where external stimulation is required to support the system; but as an epispastic it is preferred to all other substances.

Blisters are calculated to answer numerous indications. Their local effect is attended with a general excitement, which renders them valuable auxiliaries to internal stimulants in low conditions of disease; and they may sometimes be safely resorted to with this view, when the latter remedies are inadmissible. The powerful impression they make on the system is sufficient, in many instances, to subvert morbid associations, and thus to allow the re-establishment of healthy action. Hence their application to the cure of remittent and intermittent fevers, in which they often prove effectual, when so employed as to be in full operation at the period for the recurrence of the paroxysm. On the principle of revulsion, they are useful in a vast variety of complaints. Drawing both the nervous energy and the circulating fluid to the seat of their immediate action, they relieve irritations and inflammations of internal parts; and are employed for this purpose in every disease attended with these derangements. In such cases, however, arterial excitement should be reduced before the remedy is resorted to. Blisters are also capable of substituting their own action for one of a morbid nature, existing in the part to which they are directly applied. Hence their use in tinea capitis, obstinate herpes, and various cutaneous eruptions. Their local stimulation renders them useful in some cases of threatened gangrene, and in partial paralysis. From the serous discharge they occasion, much good results in erysipelas and various other local inflammations, in the immediate vicinity of which their action can be established; and the effects of an issue may be obtained by the continued application of irritants to the blistered surface. Perhaps the pain produced by blisters may be useful in some cases of nervous excitement or derangement, in which it is desirable to withdraw the attention of the patient from subjects of agitating reflection. On some constitutions they produce a poisonous impression, attended with frequent pulse, dryness of the mouth and fauces, heat of skin, subsultus tendinum, and even convulsions. What is the precise condition of system in which these effects result, it is impossible to determine. They probably arise from the absorption of the active principle, and depend on individual peculiarities of constitution. In this respect Spanish flies are analogous to mercury; and any argument drawn from this source against the use of the one would equally apply to the other. The general good resulting from their use far overbalances any partial and un-

certain evil. For some rules relative to the application of blisters, the reader is referred to the article *Ceratum Cantharidis*, where also will be noticed other blistering preparations from cantharides.

In the United States are several species of Cantharis, which have been employed as substitutes for C. vesicatoria, and found equally efficient. Of these, only *C. vittata* has been adopted as officinal; but, as others may be more abundant in particular districts, or in certain seasons, and are not inferior in powers, we shall briefly notice all that have been submitted to experiment.

1. *Cantharis vittata.* Latreille, *Gen. Crust. et Insect.*; Durand, *Journ. of Phil. Col. of Pharm.*, ii. 274, fig. 4. The *potato fly* is rather smaller than *C. vesicatoria*, which it resembles in shape. Its length is about six lines. The head is light-red, with dark spots upon the top; the feelers are black; the elytra or wing-cases are black, with a yellow longitudinal stripe in the centre, and with a yellow margin; the thorax is also black, with three yellow lines; and the abdomen and legs, which have the same colour, are covered with a cinereous down. It inhabits chiefly the potato plant, and appears about the end of July or beginning of August, in some seasons very abundantly. It is found on the plant in the morning and evening, but during the heat of the day descends into the soil. The insects are collected by shaking them from the plant into hot water; and are afterwards carefully dried in the sun. They are natives of the Middle and Southern States. This species of Cantharis was first described by Fabricius in the year 1781; and was introduced to the notice of the profession by Dr. Isaac Chapman, of Bucks county, Pennsylvania, who found it equal if not superior to the Spanish fly as a vesicatory. The testimony of Dr. Chapman has been corroborated by that of many other practitioners, some of whom have even gone so far as to assert that the potato fly is not attended with the inconvenience of producing strangury. But this statement has been ascertained to be incorrect; and, as the vesicating property of all these insects probably depends on the same proximate principle, their operation may be considered as identical in other respects. If the potato fly has been found more speedy in its effects than the Cantharis of Spain, the result is perhaps owing to the greater freshness of the former. It may be applied to the same purposes, treated in the same manner, and given in the same dose as the foreign insect. Professor Procter obtained cantharidin from this species; and Mr. W. R. Warner has shown that the proportion of this ingredient is but slightly less than in Spanish flies, the former yielding 1·99, the latter 2·03 parts in 500. (*Am. Journ. of Pharm.*, xxviii. 195.) Professor Leidy, of the University of Pennsylvania, ascertained, by experiment, that the vesicating property of this insect resides in the blood, the eggs, and a peculiar fatty matter of certain accessory glands of the generative apparatus. (*Am Journ. of Med. Sci.*, Jan. 1860, p. 60.)

2. *Cantharis cinerea* Latreille, *Gen. Crust. et Insect.*; Durand, *Journ. of the Phil. Col. of Pharm.*, ii. 274, fig. 5. The *ash-coloured cantharis* closely resembles the preceding species in figure and size; but differs from it in colour. The elytra and body are black, without the yellow stripes that characterize C vittata, and are entirely covered with a short and dense ash-coloured down, which conceals the proper colour of the insect. The feelers are black, and the first and second joints are very large in the male. This species also inhabits the potato plant, and is occasionally found on other plants, as the English bean and wild indigo. It is a native of the Northern and Middle States. Illiger in 1801 discovered its vesicating properties; but Dr. Gorham was the first to call public attention particularly to the subject, and to the fact of its equality in all respects with the potato fly, in a communication addressed, in the year 1808, to the Medical Society of Massachusetts.

3. *Cantharis marginata.* Latreille, *Gen. Crust. et Insect.*; Durand, *Journ. of the Phil. Col. of Pharm*, ii. 274, fig. 6 This is somewhat larger than *C. vittata*, and of a different shape. The elytra are black with the suture and margin ash-coloured. The head, thorax, and abdomen are black, but nearly covered with an ash-coloured down; and, on the upper part of the abdomen, under the wings,

are two longitudinal lines of a bright clay-colour. The insect is usually found, in the latter part of summer, upon different species of *Clematis*, and frequents especially the lower branches which trail along the ground. Professor Woodhouse, of Philadelphia, first ascertained its vesicating properties; but it had previously been described by Fabricius as a native of the Cape of Good Hope. Dr. Harris, of Massachusetts, found it as efficient as any other species.

4. *Cantharis atrata.* Latreille, *Gen. Crust. et Insect.;* Durand, *Journ. of the Phil. Col. of Pharm.*, ii. 274, fig. 7. The *black cantharis* is smaller than the indigenous species already described; but resembles *C. marginata* in figure. Its length is only four or five lines. It is distinguished by its size, and its uniform black colour. It frequents more especially the different species of *Aster* and *Solidago*, though it is found also on *Prunella vulgaris*, *Ambrosia trifida*, and some other plants. Mr. Durand met with considerable numbers of this insect near Philadelphia, in the month of September; and they continued to appear till the middle of October. They are common in the Northern and Middle States, but are not confined exclusively to this country, being found also in Barbary. Drs. Oswood and Harris, of New England, satisfactorily ascertained their vesicating powers. They are probably identical with the insect noticed as vesicatory by Prof. Woodhouse, under the name of *Meloë niger*.

Several other species have been discovered in the United States, but not yet practically employed. Among these are *C. æneas*, a native of Pennsylvania, discovered by Mr. Say; *C. politus* and *C. aszelianus*, inhabiting the Southern States; *C. Nuttalli*, a large and beautiful insect of Missouri, first noticed by Mr. Nuttall, and said to surpass the Spanish fly in magnitude and splendour; and *C. albida*, another large species, found by Mr. Say near the Rocky Mountains. Of these, *C. Nuttalli* (*Lytta Nuttalli*, Say, *Am. Entomol.*, i. 9) bids fair, at some future period, to be an object of importance in the western section of this country. The head is of a deep-greenish colour, with a red spot in front; the thorax is of a golden green; the elytra, red or golden purple and somewhat rugose on their outer surface, green and polished beneath; the feet black; the thighs, blue or purplish. The exploring party under Colonel Long ascertained the vesicating powers of this insect. It was found in the plains of the Missouri, feeding on a scanty grass. In one spot it was so numerous as to be swept away by bushels, in order that a place might be cleared for encamping. Dr. Geo. H. Horn, in a contribution to the *Medical Zoology* of Dr. Allen, just published (p. 150), mentions two species as inhabiting California, *C. vulnerata* (Lytta vulnerata, *Horn*), and *C. melæna* (Lytta melœna, *Horn*), which have been proved by many trials, internally and externally, to have all the virtues of the officinal Cantharis.

CAPSICUM. *U. S.*

Capsicum. Cayenne Pepper.

The fruit of Capsicum annuum, and of other species of Capsicum. *U. S.*

Off. Syn. CAPSICI FRUCTUS. *Capsicum Fruit.* The dried fruit of Capsicum fastigiatum. Imported from Zanzibar, and distinguished in commerce as Guinea Pepper and Pod Pepper. *Br.*

Poivre de Guinée, Poivre d'Inde, *Fr.;* Spanischer Pfeffer, *Germ.;* Pepperone, *Ital.:* Pimiento, *Span.*

CAPSICUM. *Sex. Syst.* Pentandria Monogynia. — *Nat. Ord.* Solanaceæ.

Gen. Ch. Corolla wheel-shaped. *Berry* without juice. *Willd.*

Numerous species of Capsicum, inhabiting the East Indies and tropical America, are enumerated by botanists, the fruit of which, differing simply in the degree of pungency, may be indiscriminately used. *C. baccatum* or bird pep-

per, and *C. frutescens*, are said to yield most of the Cayenne pepper brought from the West Indies and South America; and Ainslie informs us that the latter is chiefly employed in the East Indies. The Br. Pharmacopœia recognises, as the source of capsicum, *C. fastigiatum*, a species growing in the East Indies, and on the coast of Guinea. The one most extensively cultivated in Europe and this country is that recognised by the U. S. Pharmacopœia, namely, *C. annuum*. The first three are shrubby plants, the last is annual and herbaceous.

Capsicum annuum. Willd. *Sp. Plant.* i. 1052; Woodv. *Med. Bot.* p. 226, t. 80.

The stem of the annual capsicum is thick, roundish, smooth, and branching; rises two or three feet in height; and supports ovate, pointed, smooth, entire leaves, which are placed without regular order on long footstalks. The flowers are solitary, white, and stand on long peduncles at the axils of the leaves. The calyx is persistent, tubular, and five-cleft; the corolla, monopetalous and wheel-shaped, with the limb divided into five spreading, pointed, and plaited segments; the filaments, short, tapering, and furnished with oblong anthers; the germen, ovate, supporting a slender style which is longer than the filaments, and terminates in a blunt stigma. The fruit is a pendulous, pod-like berry, light, smooth and shining, of a bright scarlet, orange, or sometimes yellow colour, with two or three cells, containing a dry, loose pulp, and numerous flat, kidney-shaped, whitish seeds.

The plant is a native of the warmer regions of Asia and America, and is cultivated in almost all parts of the world. It is abundantly produced in this country, both for culinary and medicinal purposes. The flowers appear in July and August, and the fruit ripens in October. Several varieties are cultivated in our gardens, differing in the shape of the fruit. The most abundant is probably that with a large irregularly ovate berry, depressed at the extremity, which is much used in the green state for pickling. The medicinal variety is that with long, conical, generally pointed, recurved fruit, usually not thicker than the finger. Sometimes we meet with small, spherical, slightly compressed berries, not greatly exceeding a large cherry in size. When perfectly ripe and dry, the fruit is ground into powder, and brought into market under the name of *red* or *Cayenne* pepper. Our markets are also partly supplied from the West Indies. A variety of capsicum, consisting of very small, conical, pointed, exceedingly pungent berries, less than an inch in length, is imported from Liberia. It is probably the same that the British Pharmacopœia refers to Capsicum fastigiatum. In England, the fruit of C. annuum is frequently called *chillies*.

Powdered capsicum is usually of a more or less bright-red colour, which fades upon exposure to light, and ultimately disappears. The colour of the Liberia or African pepper, in powder, is a light-brownish yellow. The odour is peculiar and somewhat aromatic, stronger in the recent than in the dried fruit. The taste is bitterish, acrid, and burning, producing a fiery sensation in the mouth, which continues for a long time. The pungency appears to depend on a peculiar principle, which was obtained, though not in a perfectly isolated state, by Braconnot, and named *capsicin*. The fruit, freed from the seeds, was submitted to the action of alcohol, and the resulting tincture evaporated. During the evaporation a red-coloured wax separated, and the residuary liquor by further evaporation afforded an extract, from which ether dissolved the capsicin. This was obtained by evaporating the ether. It resembles an oil or soft resin, is of a yellowish-brown or reddish-brown colour, and, when tasted, though at first balsamic, soon causes an insupportably hot and pungent impression over the whole interior of the mouth. Exposed to heat it melts, and at a higher temperature emits fumes, which, even in very small quantity, excite coughing and sneezing. It is slightly soluble in water and vinegar, and very soluble in alcohol, ether, oil of turpentine, and the caustic alkalies, which it renders reddish-brown. It constitutes, according to Braconnot, 1·9 per cent. of the fruit.* The other in-

* The capsicin of Braconnot, though containing the active principle of capsicum, was shown by Professor Procter to be itself a complex substance. By treating its alcoholic solution with subacetate of lead, he obtained an abundant precipitate, which, when washed with alcohol, proved to be quite tasteless, while the liquid from which it had been precipi-

gredients, as ascertained by the same chemist, are colouring matter, an azotized substance, gum, pectic acid (probably pectin), and saline matters. Red oxide of lead is sometimes added to the powdered capsicum sold in Europe. It may be detected by digesting the suspected powder in diluted nitric acid, filtering, and adding a solution of sulphate of soda, which will throw down a white precipitate if there be any oxide of lead present. Capsicum is said to be sometimes adulterated with coloured sawdust. It is occasionally attacked by insects.

Medical Properties and Uses. Cayenne pepper is a powerful stimulant, producing when swallowed a sense of heat in the stomach, and a general glow over the body, without any narcotic effect. Its influence over the circulation, though considerable, is not in proportion to its local action. It is much employed as a condiment, and proves highly useful in correcting the flatulent tendency of certain vegetables, and aiding their digestion. Hence the advantage derived from it by the natives of tropical climates, who live chiefly on vegetable food. In the East Indies it has been used from time immemorial. From a passage in the works of Pliny, it appears to have been known to the Romans. As a medicine it is useful in cases of enfeebled and languid stomach, and is occasionally prescribed in dyspepsia and atonic gout, particularly when attended with much flatulence, or occurring in persons of intemperate habits. It has also been given as a stimulant in palsy and certain lethargic affections. To the sulphate of quinia it forms an excellent addition in some cases of intermittents, in which there is a great want of gastric susceptibility. Upon the same principle of rousing the susceptibility of the stomach, it may prove useful in low forms of fever, as an adjuvant to tonic or stimulant medicines. Its most important application, however, is to the treatment of malignant sorethroat and scarlet fever, in which it is used both internally and as a gargle. The following formula was employed in malignant scarlatina, with great advantage, in the West Indies, where this application of the remedy originated. Two tablespoonfuls of the powdered pepper, with a teaspoonful of common salt, are infused for an hour in a pint of boiling liquid, composed of equal parts of water and vinegar. This is strained when cool through a fine linen cloth, and given in the dose of a tablespoonful every half hour. The same preparation is also used as a gargle. It is, however, only to the worst cases that the remedy is applied so energetically. In milder cases of scarlatina, with inflamed or ulcerated throat, much relief and positive advantage often follow the employment of the pepper in a more diluted state. Capsicum has been advantageously used in sea-sickness, in the dose of a teaspoonful, given in some convenient vehicle on the first occurrence of nausea. It is thought also to have been beneficial in hemorrhoidal affections. It has long been used as a stomachic stimulant in the enfeebled digestion of drunkards, and has recently been recommended in delirium tremens, in which, when taken early it is said sometimes to produce sleep, and thus to cut short the disease. (Dr. Lyons, *Med. Press and Circ.*, April 18, and June 20, 1866.)

tated yielded, on evaporation, a brownish substance much more pungent than the capsicin itself. Mr. F. V. Heydenreich, by treating the liquid just referred to with hydrosulphuric acid to separate the lead, filtering, and boiling to drive off the acetic and hydrosulphuric acids, obtained an amber-coloured oily substance, which, when purified by solution in alcohol, treatment with animal charcoal, filtration, and exposure to spontaneous evaporation, became of a light lemon-yellow colour, and presented the following properties. It had the aspect of an oil, rather more viscid than olive oil, was lighter than water, with the odour and intensely hot taste of capsicum, became nearly solid at 0° F., and very fluid when heated, without any tendency to crystallize in the former case, and at a high heat gave off very irritating fumes. It was very soluble in ether, chloroform, and alcohol of 0·809, and soluble in 80 parts of officinal alcohol, and appeared to be saponifiable. From his experiments, Mr. Heydenreich concluded that the capsicin, thus purified, consists of two oils, differing in colour and solubility in alcohol, and represents the virtues of capsicum in their most concentrated state. Mr. David Preston has subsequently examined into the subject, and concludes that the pungency of capsicum resides in a fixed oil; but, as nitric acid destroys the pungency of the oil, without otherwise affecting it, is disposed to think that the active principle is not the oil itself, but a distinct substance contained in it, which has not been isolated, and the nature of which remains undetermined. (*Am. Journ. of Pharm.*, May, 1865, p. 165.)—*Note to the twelfth and thirteenth editions.*

Applied externally, Cayenne pepper is a powerful rubefacient, very useful in local rheumatism, and in low forms of disease, where a stimulant impression upon the surface is demanded. It has the advantage of acting speedily without endangering vesication. It may be applied in the form of cataplasm, or more conveniently and efficiently as a lotion, mixed with heated spirit. The powder or tincture, brought into contact with a relaxed uvula, often acts very beneficially. The tincture has also been used advantageously in chilblain. The ethereal extract (*Oleoresina Capsici, U. S.*) is powerfully rubefacient.

The dose of the powder is from five to ten grains, which is most conveniently given in the form of pill. Of an infusion prepared by adding two drachms to half a pint of boiling water, the dose is half a fluidounce. A gargle may be prepared by infusing half a drachm of the powder in a pint of boiling water, or by adding half a fluidounce of the tincture to eight fluidounces of rose-water.

CARBO.

Carbon.

Pure charcoal; Carbone, *Fr., Ital.;* Kohlenstoff, *Germ.;* Carbon, *Span.*

Carbon is an element of great importance, and very extensively diffused in nature. It exists in large quantity in the mineral kingdom, and is the most abundant constituent of animal and vegetable matter. In the crystallized state it constitutes the diamond; and, more or less pure it forms the substances called plumbago, graphite, or black lead, anthracite, bituminous coal, coke, animal charcoal, and vegetable charcoal. Combined with oxygen it forms *carbonic acid*, which is a constituent of the atmosphere, and present in many natural waters, especially those which have an effervescing quality. United with oxygen and a base it forms the carbonates, among others *carbonate of lime*, which is one of the most abundant minerals. There are three allotropic conditions of carbon, represented respectively by the diamond, graphite, and charcoal.

The *diamond* is found principally in India and Brazil. Several diamonds have been found in the gold region of Georgia. This gem is perfectly transparent, and the hardest and most brilliant substance in nature. Its sp. gr. is about 3·5. It is fixed and unalterable in the fire, provided air be excluded; but is combustible in air or oxygen, the product being the same as when charcoal is burned, namely, carbonic acid.

Next to diamond, plumbago and anthracite are the purest natural forms of carbon. *Plumbago* is the substance of which black-lead crucibles and pencils are made. It is found in greatest purity in the mine of Borrowdale, in England; but it also occurs very pure in this country, especially near Bustleton, in Pennsylvania. It was formerly supposed to be a carburet of iron; but, in very pure specimens, it is nearly free from iron, which must, therefore, be deemed an accidental impurity. *Anthracite* occurs in different parts of the world, but particularly in the United States. *Bituminous coal* is a form of the carbonaceous principle, in which the carbon is associated with volatile matter of a bituminous nature. When this is driven off by the process of charring, as in the manufacture of coal gas, a kind of mineral charcoal, called *coke*, is obtained, very useful in the arts as a fuel. When peat is charred, it is converted into *peat charcoal*, which forms a cheap disinfectant and deodorizer, applicable to the purification of hospitals, dissecting rooms, factories, privies, &c.

Carbon may be obtained in a state approaching to purity by several processes. One method is to expose lampblack to a full red heat in a close vessel. It may also be obtained, in a very pure state, by passing the vapour of volatile oils through an ignited porcelain tube; whereby the hydrogen and oxygen of the oil will be dissipated, and the charcoal left in the tube. A pure charcoal is procured by exposing sugar, or other vegetable substances which leave no ashes when burnt, to ignition in close vessels.

Properties. Carbon, in its uncrystallized state, is an insoluble, infusible solid,

generally of a black colour, and without taste or smell. It burns when sufficiently heated, uniting with the oxygen of the air, and generating carbonic acid gas. Its sp. gr. in the solid state, apart from its pores when in mass, is 3·5; but with the pores included, it is only 0·44. It is a very unalterable and indestructible substance, and has great power in resisting and correcting putrefaction in other bodies. When properly prepared, it possesses the property of destroying the colouring and odorous principles of most liquids. (See *Carbo Animalis.*) Its other physical properties differ according to its source, and peculiar state of aggregation. Its equivalent number is 6, and its cymbol C. As a chemical element it enjoys a very extensive range of combination. It forms several compounds with oxygen, the principal of which are carbonic oxide, and carbonic and oxalic acids. With hydrogen it forms a number of compounds, called *carbohydrogens*, of which the most interesting, excluding hypothetical radicals, are light carburetted hydrogen or fire-damp, olefiant gas, the light and concrete oils of wine, and certain non-oxygenous volatile oils. With nitrogen it constitutes cyanogen, the compound radical of hydrocyanic or prussic acid; and united in minute proportion with iron it forms steel.

In the form of anthracite, carbon has recently been used, with great supposed success, by Dr. A. Dyes, in diseases attended with a disordered state of the alimentary canal, as intestinal worms, catarrhal spasm of the stomach and gastric pains from affections of the liver and spleen, in chlorosis, in the splenic enlargement of intermittents, in scurvy, and scrofulous complaints. (*B. and F Med.-chir. Rev.*, Jan. 1866, p 239; from *Schmidt's Jahrbuch.*)

To notice all the forms of the carbonaceous principle would be out of place in this work. We shall, therefore, restrict ourselves to the consideration of those which are officinal, namely, *animal charcoal* and *wood charcoal.* B.

CARBO ANIMALIS. *U.S., Br.*

Animal Charcoal.

Charcoal prepared from bone. *U. S.* The residue of bones, which have been exposed to a red heat without access of the air. *Br.*

Bone black, *Br.;* Charbon animal, *Fr.;* Thierische Kohle, *Germ.;* Carbone Animale, *Ital.;* Carbon animal, *Span.*

The animal charcoal employed in pharmacy and the arts, is usually obtained from bones, by subjecting them to a red heat in close vessels. The residue of the ignition is a black matter, which, when reduced to powder, forms *bone-black*, sometimes incorrectly called *ivory-black.* Ivory by carbonization will furnish a black, which, on account of its fineness and intensely black colour, is more esteemed than the ordinary bone-black; but it is much more expensive.

In manufacturing bone-black, the bones, first boiled in water to separate the fat, are subjected to destructive distillation in iron cylinders, connected with vessels which receive the ammoniacal liquor, called *bone-spirit;* this being a secondary product of the operation. When the bone-spirit ceases to come over, the residue is charred bone, or bone-black. Bone consists of animal matter with phosphate and carbonate of lime. From a new arrangement of the elements of the animal matter, the nitrogen and hydrogen, united as ammonia, and a part of the charcoal, in the form of carbonic acid, distil over; while the remainder of the charcoal is left in the cylinder, intermingled with the calcareous salts. M. Deiss, of Paris, proposes bisulphuret of carbon as a solvent for the fat of bones; as it furnishes a larger and better product of fat, and renders the bones fitter for producing a good bone-black. (*Chem. Gaz.*, April 1, 1856.) This form of animal charcoal necessarily contains phosphate and carbonate of lime.

Properties. Animal charcoal, in the form of bone-black, is a black powder, possessing a slightly alkaline and bitterish taste, and having a general resemblance to powdered vegetable charcoal. It is, however, more dense and less combustible than vegetable charcoal; from which, moreover, it may be distinguished by burning a small portion of it on a red-hot iron, when it will leave

a residuum imperfectly acted on by sulphuric acid; whereas the ashes from vegetable charcoal readily dissolve in this acid, forming a bitterish solution.

Animal charcoal by no means necessarily possesses the decolorizing property; as this depends upon its peculiar state of aggregation. If a piece of pure animal matter is carbonized, it usually enters into fusion, and, from the gaseous matter which is extricated, becomes porous and cellular. The charcoal formed has generally a metallic lustre, and a colour resembling that of black lead. It has, however, little or no decolorizing power, even though finely pulverized.

The decolorizing power of vegetable charcoal was first noticed by Lowitz, of St. Petersburg; and that of animal charcoal, by Figuier, of Montpellier, in 1811. In 1822 the subject was ably investigated by Bussy, Payen, and Desfosses. The power is generally communicated to charcoal by igniting it in close vessels, but not always. The kind of charcoal, for example, obtained from substances which undergo fusion during carbonization scarcely possesses the property, even though it may be afterwards finely pulverized. The property in question is possessed to a certain extent by wood charcoal; but is developed in it in a much greater degree by burning it with some chemical substance, which may have the effect of reducing it to an extreme degree of fineness. The most powerful of all the charcoals for discharging colours are those obtained from certain animal matters, such as dried blood, hair, &c., by first carbonizing them in connection with carbonate of potassa, and then washing the product with water. Charcoal, thus prepared, seems to be reduced to a state of extremely minute division, and is, therefore, very porous. The next most powerful decolorizing charcoal is *bone-black*, in which the separation of the carbonaceous particles is effected by the phosphate of lime present in the bone. Vegetable substances also may be made to yield a good charcoal for destroying colour, provided, before carbonization, they be well comminuted, and mixed with pumice stone, chalk, flint, or other similar substance in a pulverized state.

It results from the foregoing facts that the decolorizing power of charcoal depends upon a peculiar mode of aggregation of its particles, the leading character of which is that they are isolated from one another, and thus enabled to present a greater extent of surface. It is on this principle that certain chemical substances act in developing the property in question, when they are ignited, in a state of intimate mixture, with the substance to be charred. Thus, it is perceived that there is no necessary connection between the animal charcoal and the decolorizing power. Bone-black, for instance, has this property, not because it is an animal charcoal, but because, in consequence of the phosphate of lime present in the bone, the favourable state of aggregation is imparted.*

The following table, abridged from one drawn up by Bussy, denotes the relative decolorizing power of different charcoals.

KINDS OF CHARCOAL.	Decolorizing power on Syrup.	Decolorizing power on Indigo.
Bone-black,	1	1
Bone charcoal treated with an acid,	1·6	1·8
Lampblack, not ignited,	3·3	4
Charcoal from acetate of potassa,	4·4	5·6
Blood ignited with phosphate of lime,	10	12
Lampblack ignited with carbonate of potassa,	10·6	12·2
Blood ignited with chalk,	11	18
White of egg ignited with carbonate of potassa,	15·5	24
Glue ignited with carbonate of potassa,	15·5	36
Bone charcoal, formed from bone deprived of phosphate of lime by an acid, and subsequently ignited with carbonate of potassa,	20	45
Blood ignited with carbonate of potassa,	20	50

* Dr. Stenhouse divides decolorizing charcoals into three classes. First, pure charcoals, which, being in a state of minute division, decolorize by their porosity alone. Second, those which, like aluminized charcoal and artificial bone-black, decolorize solely by the bases they contain, acting as mordants. Third, those which, like bone-black, decolorize, partly by the mineral matter, and partly by the minutely divided charcoal they contain. (*Pharm Journ.*, Jan. 1857, p. 366.)—*Note to the eleventh edition.*

E. Filhol has shown that charcoal is not the only decolorizing agent; but that many substances, such as iron reduced by hydrogen, sulphur, arsenic, deutoxide of manganese, sulphate and artificial sulphuret of lead, possess the same property. The property varies not only in different substances in relation to the same colouring matter, but in the same substance in respect to different colouring matters. (*Chem. Gaz.*, April 15, 1852.)

In order to determine the commercial value of animal charcoal, M. Corenwinder has proposed to ascertain its power of absorbing lime from a solution of saccharate of lime of determinate strength. The value is in proportion to the absorbing power of the charcoal. A given weight of the charcoal to be tested is left in contact, for an hour, with a given volume of the solution of the saccharate, taken in excess. The liquid is then filtered, and a small measure of it saturated with dilute sulphuric acid of known strength. The less the acid necessary for this purpose, the greater the amount of lime absorbed, and the better the animal charcoal. (See *Chem. Gaz.*, Jan. 1, 1854, p. 16.)

Spent animal charcoal, which has been used by the sugar refiners, may have its decolorizing power restored by calcination, which destroys the organic matters that have become fixed in it; and it is stated that it may be submitted to this process twenty times before becoming unfit for use. According to Pelouze, the same object may be accomplished by subjecting it to a weak solution of carbonate of potassa or of soda. In removing the colouring matter, the alkaline solution becomes yellow. After its action the animal charcoal must be carefully washed, first with boiling water, and afterwards with acidulated water. But a process devised by MM. Leplay and Cuisinier is probably more effectual. The charcoal, without being removed from the cylinders, is thoroughly washed, treated by steam to remove viscous substances, and then percolated successively, 1. by a weak alkaline solution, which removes salts and some colouring matters, 2. by weak muriatic acid, which, in removing a certain amount of salts of lime, liberates colouring matter, 3. again with a weak alkaline solution to carry off the remaining colouring matter; and 4. lastly by a solution of biphosphate of lime, by which the decolorizing power of the charcoal is restored. (Dr. F. C. Calvert, *Am. Journ. of Pharm.*, July, 1865, p. 263; from *Chem. News.*)

Animal charcoal is capable of taking the bitter principles from infusions and tinctures, and iodine from liquids which contain it in solution. Its power, however, of acting on solutions and chemical compounds is much more decided in its purified state, as shown by both Warington and Weppen. In this state, it takes a number of salts from their aqueous solutions, and even converts chromate of potassa into the carbonate. (See *Carbo Animalis Purificatus.*)

Bone-black consists of about 90 per cent. of phosphate and carbonate of lime, and 10 per cent. of charcoal.

Pharmaceutical Uses, &c. Animal charcoal is used in pharmacy for decolorizing vegetable principles, such as gallic acid, quinia, morphia, veratria, &c., and in the arts, principally for clarifying syrups in sugar refining, and for depriving spirits distilled from grain of the peculiar volatile oil, called *fusel oil*, which imparts to them an unpleasant smell and taste, as first distilled. (See *page* 85.) The manner in which it is used as a decolorizer is to mix it with the substance to be decolorized, and to allow the mixture to stand for some time. The charcoal unites with the colouring matter, and the solution by filtration is obtained white and transparent. Its use, however, in decolorizing the organic alkalies and other vegetable principles, no doubt causes a loss by absorption; since it has been shown by the experiments of M. Lebourdais, mentioned under the head of purified animal charcoal, that several of these principles may be obtained by the sole action of charcoal. For most pharmaceutical operations, and for use as an antidote, animal charcoal must be purified by muriatic acid from phosphate and carbonate of lime. (See *Carbo Animalis Purificatus.*) In the U. S. formula for sulphate of quinia, however, it is employed without purification. (See *Quiniæ Sulphas.*) According to Guthe, a German chemist, bone charcoal, without purification, is to be preferred as a decolorizer, in all cases in which the calcareous salts exert no injurious effect.

CARBO LIGNI. *U. S., Br.*

Charcoal.

Charcoal prepared from wood. *U. S.* Wood charred by exposure to a red heat without access of air. *Br.*

Vegetable charcoal; Charbon de bois, *Fr.;* Holzkohle, *Germ.;* Carbone di legno, *Ital.;* Carbon de lena, *Span.*

Preparation on the Large Scale. Billets of wood are piled in a conical form, and covered with earth and sod to prevent the free access of air; several holes being left at the bottom, and one at the top of the pile, in order to produce a draught to commence the combustion. The wood is then kindled from the bottom. In a little while the hole at the top is closed, and, after the ignition is found to have pervaded the whole pile, those at the bottom are stopped also. The combustion taking place with a smothered flame, the volatile portions of the wood, consisting of hydrogen and oxygen, are dissipated; while the carbon, in the form of charcoal, is left.

In this process for the carbonization of wood, all the volatile products are dissipated; and a portion of the charcoal itself is lost by combustion. Wood, thus carbonized, yields not more than 17 or 18 per cent. of charcoal. A better method is to char the wood in iron cylinders, when it yields from 22 to 23 parts in 100 of excellent charcoal; and, at the same time, the means are afforded for collecting the volatile products, consisting of pyroligneous acid, empyreumatic oil, and tar. This process for obtaining charcoal has been described under another head. (See *Acidum Aceticum.*) A method of preparing charcoal by subjecting wood to over-heated steam has been invented by M. Violette. When the temperature of the steam is 572°, the wood is converted into a peculiar charcoal, called *red charcoal*, which is intermediate in its qualities between wood and ordinary charcoal. When the temperature is lower, the carbonization is incomplete; when higher, the product is black charcoal. The steam process yields a uniform charcoal for a given temperature, which may be easily regulated, and a product about double that obtained in closed cylinders. Charcoal, prepared in closed cylinders, contains ten times as much ash as that ordinarily made. Charcoal contains *carbon*, in proportion to the temperature at which it is formed; varying from 65 per cent. when made at 482°, to 80 per cent. at 752°. The gaseous matter present is always inversely as the temperature of carbonization. Thus, for charcoal made at 572°, it is one-third of its weight; at 662°, one-fourth. (*Journ. de Pharm.*, Juillet, 1851, p. 35.)

Mr. E. C. C. Stanford has called attention to a variety of vegetable charcoal, obtained by charring a species of sea-weed, *Laminaria digitata*, gathered on the shores of the Hebrides, which, although, on account of the large proportion of carbonate of lime contained in it (20 per cent.), unfit for use in refining sugar, possesses more of the deodorizing and decolorizing power than animal charcoal itself, which, with the exception referred to, it closely resembles in chemical composition. (*Pharm. Journ. and Trans.*, Oct. 1867, p. 186.)

Preparation for Medicinal Use. M. Belloc recommends charcoal for this purpose to be obtained from poplar shoots, cut at the time the sap rises, and deprived of their bark. The carbonization should be performed in cast-iron vessels at a red-white heat. The product is a light and brilliant charcoal, which must be purified by being macerated for three or four days in water, frequently renewed. It is then dried, powdered, and placed in bottles, which should be well stopped. The charcoal most esteemed in Philadelphia, for medicinal purposes, is that prepared by the Messrs. Dupont, near Wilmington, Delaware, for the manufacture of gunpowder. It is made from young willow shoots of two or three years' growth.

Properties. Charcoal is a black, shining, brittle, porous substance, tasteless and inodorous, and insoluble in water. It is a good conductor of electricity, but a bad one of heat. It possesses the remarkable property of absorbing many times its own bulk of certain gases. When exposed to the air after ignition, it increases rapidly in weight, absorbing from 12 to 14 per cent. of moisture. As ordinarily prepared, it contains the incombustible part of the wood amounting to 1 or 2 per cent., which is left as ashes when the charcoal is burned. These may be removed by digesting the charcoal in diluted muriatic acid, and afterwards washing it thoroughly with boiling water.

Medical Properties, &c. Powdered charcoal is disinfectant and absorbent. It is employed with advantage in diarrhœa as an absorbent, and in dyspepsia with fetid breath and eructations. It was given in dysentery by the late Dr. Robert Jackson, who found it to have the effect of soothing the patient, and improving the character and consistence of the stools. It is also useful, in the form of injection, in putrid discharges from the uterus. M. Belloc recommends it strongly in gastralgia, and especially pyrosis, in which, if it fails to remove the disease, it abates the pain, nausea, and vomiting; and his observations have been confirmed by a committee of the French Academy of Medicine. As a remedy in obstinate constipation, Dr. Daniel, of Savannah, speaks of it in high terms. He also found it useful in the nausea and constipation of pregnancy. On the other hand, some practitioners have found charcoal to confine the bowels. Dr. Wilson, of New Zealand, speaks highly of it in the diarrhœa of measles, and in epidemic cholera. Dr. Newman recommends it as a dressing to wounds and ulcers. Mr. Wormald, of St. Bartholomew's Hospital, has made a useful application of the disinfecting power of dry charcoal, in what he calls the *charcoal quilt.* This consists of two sheets of cotton wadding, quilted together in small segments, with a tolerably thick layer of powdered charcoal between them. The quilts, thus prepared, may be of any size, so as to fit a gangrenous sore or stump. Its use as an ingredient of poultices is noticed under *Cataplasma Carbonis.* Several of its varieties are used as tooth-powder. Those generally preferred are the charcoals of the cocoa-nut shell and of bread. It is said that charcoal proves useful in preserving the teeth by absorbing the acid sometimes morbidly present in the mucus of the mouth. The dose of charcoal varies from one to four teaspoonfuls or more. Dr. Daniel gave it in his case of constipation in doses of a tablespoonful, repeated every half hour.

For internal use charcoal is preferred by some in the *granular form.* Mr. W. Lascelles Scott employs the following method of preparing it. He prefers the wood of the box, willow, or linden, which, after being charred, should be allowed to cool out of contact with air, then boiled for some time in dilute muriatic acid, and afterwards, having been thoroughly washed with pure water, in a little weak ammonia. The fragments are again ignited, and then quickly powdered, and passed through a sieve of 80 or 100 apertures to the inch. Nine pounds of this powder are mixed with one pound of pure sugar passed through a 30 sieve, and 4 ounces of gum arabic in impalpable powder. The whole is then moistened with a few ounces of warm distilled water, to which have been added an ounce and a quarter of tincture of benzoin, and a little mucilage. The mass is now granulated on flat steam pans, in the usual manner, at a temperature of 215° or 225°. When perfectly dry it is sifted, and secured in well-stopped bottles. (*Chem. News*, Oct. 18, 1867, p. 204.)

Schönbein has observed the power of charcoal to absorb chlorine, iodine, and bromine, both in the gaseous or vaporous state, and in aqueous solution. He has also noticed its deoxidizing effects, when shaken with certain salts of peroxides, reducing them to salts of protoxides. The power of charcoal to precipitate gold and other metals on its surface has long been known.

Charcoal has been employed with good effect, as a deodorizer, in dissecting rooms, placed in open pans through the room. It has the advantage over the chlorides that it has no smell. When it loses its effect, it requires merely to be recalcined. Water for long voyages is kept sweet by having a little powdered charcoal added to each cask.

Dr. Stenhouse has devised a process for combining alumina with common vegetable charcoal, forming what he calls *aluminized charcoal*, which is an economical substitute for purified animal charcoal, and equally efficacious as a decolorizer. It is prepared by digesting finely powdered charcoal with sufficient of the solution of sulphate of alumina to give an impregnation of 7·5 per cent. of alumina. The whole is evaporated to dryness, and ignited in a covered Hessian crucible, until the water and acid have been dissipated. Aluminized charcoal is perfectly black, though thoroughly impregnated with anhydrous alumina, and only requires to be carefully pulverized to be ready for use. (*Pharm. Journ.*, Jan. 1857, p. 364.) On similar principles, Dr. Stenhouse prepares what he calls *artificial bone-black*, by impregnating powdered wood charcoal with 7·5 per cent. of phosphate of lime, by digesting it in a solution of this salt in muriatic acid, evaporating to dryness, and igniting in covered vessels. This charcoal decolorizes well, but can be used only for neutral solutions.

Charcoal may act either as an oxidizer or deoxidizer; and these contrary powers seem to depend upon its having for oxygen a medium affinity, which enables it to take that element from some bodies, and to yield it to others. Thus, it is known to reduce several oxides; while, on the other hand, it powerfully oxidizes animal matter. The bodies of two dogs having been laid in an open box on a bed of charcoal, a few inches deep, and covered by the same material, were kept by Mr. John Turnbull, of Glasgow, for six months in his laboratory, without emitting any perceptible effluvium; and, when they were examined at the end of this time, scarcely anything remained but the bones. Dr. Stenhouse, who relates this experiment, has confirmed it by observations of his own, and believes that the animal matter thus treated, undergoes putrefaction; though the products, by their rapid oxidation, are prevented from contaminating the air. He, therefore, considers charcoal not to be antiseptic, but the very opposite. (*Chem. Gaz.*, April, 1854, p. 132.)

The study of the absorbent and oxidizing properties of charcoal has led Dr. Stenhouse to apply it to the purpose of preventing the access of noxious effluvia to the lungs in respiration. This object he proposes to effect by covering the nose and mouth with what he calls the *charcoal respirator*. The instrument consists of a layer of coarsely powdered charcoal, a quarter of an inch thick, between two sheets of silvered wire gauze, covered with thin woollen cloth, by means of which the temperature of the inspired air is greatly increased. The frame is made of thin sheet copper; but the edges, of lead padded and lined with velvet so as to fit the lower part of the face. Dr. Stenhouse considers his respirator to act as an air filter, and to be peculiarly adapted to protect the wearer against infectious diseases (*Pharm. Journ.*, Jan. 1855, p. 3-8.) This instrument must not be confounded with Jeffrey's wire ventilator, which is intended solely to warm the air before entering the lungs.

CARDAMOMUM. *U.S., Br.*

Cardamom.

The fruit of Elettaria Cardamomum. *U. S.* CARDAMOMS. The dried capsules of the Malabar Cardamom, Elettaria Cardamomum. The seeds are best kept in their pericarps, from which they should be separated when required for use, the pericarpial coats being rejected. *Br.*

Petit cardamome, *Fr.;* Kleine Cardamomen, *Germ.;* Cardamomo minore, *Ital.;* Cardamomo menor, *Span.;* Ebil, *Arab.;* Kakelah seghar, *Persian;* Capalaga, *Malay;* Gujaratii elachi, *Hindoost.*

The subject of Cardamom has been involved in some confusion and uncertainty, both in its commercial and botanical relations. The name has been applied to the aromatic capsules of various Indian plants belonging to the family

of Scitamineæ. Three varieties have long been designated by the several titles of the *lesser*, *middle*, and *larger*—*cardamomum minus*, *medium*, and *majus*; but these terms have been used differently by different writers, so that their precise signification remains doubtful. To the late Dr. Pereira we are mainly indebted for the clearing up of this confusion. It is well known that the *lesser cardamom* of most writers is the variety recognised by the Pharmacopœias, and generally kept in the shops. The other varieties, though circulating to a greater or less extent in European and Indian commerce, are little known in this country.* The following remarks have reference exclusively to the genuine Malabar or officinal cardamom.

* The following is a sketch of the non-officinal cardamoms, chiefly from Pereira.

1. *Ceylon Cardamom.* This has been denominated variously *cardamomum medium*, *cardamomum majus*, and *cardamomum longum*, and is sometimes termed in English commerce *wild cardamom*. It is the *large cardamom* of Guibourt. In the East it is sometimes called *grains of Paradise*; but it is distinct from the product known with us by that name. It is derived from a plant cultivated in Candy, in the Island of Ceylon, which belongs to the same genus as that producing the officinal cardamom, and is designated by Sir James Edward Smith *Elettaria major*. This plant was described by Pereira in the *Pharmaceutical Journal and Transactions* (ii. 388). The fruit is a lanceolate-oblong, acutely triangular capsule, somewhat curved, about an inch and a half long and four lines broad, with flat and ribbed sides, tough and coriaceous, brownish or yellow ash-coloured, having frequently at one end the long, cylindrical, three-lobed calyx, and at the other the fruit-stalk. It is three-celled, and contains angular, rugged, yellowish-red seeds, of a peculiar fragrant odour, and spicy taste. Its effects are analogous to those of the officinal cardamom.

2. *Round Cardamom.* This is probably the Ἄμωμον of Dioscorides, and the *Amomi uva* of Pliny, and is believed to be the fruit of *Amomum Cardamomum* (Willd.), growing in Sumatra, Java, and other East India islands. The capsules are usually smaller than a cherry, roundish or somewhat ovate, with three convex sides, more or less striated longitudinally, yellowish or brownish-white, and sometimes reddish, with brown, angular, cuneiform, shrivelled seeds, which have a spicy camphorous flavour. They are sometimes, though rarely, met with connected in their native clusters, constituting the *amomum racemosum*, or *amome en grappes* of the French. They are similar in medicinal properties to the officinal, but are seldom used except in the southern parts of Europe.

3. *Java Cardamom.* The plant producing this variety is supposed to be the *Amomum maximum* of Roxburgh, growing in Java and other Malay islands, and said to be cultivated in the mountains of Nepaul. The product of the latter site is called *Nepaul* or *Bengal cardamoms* in the East. The capsules are oval, or oval-oblong, often somewhat ovate, from eight to fifteen lines long, and from four to eight broad, usually flattened on one side and convex on the other, sometimes curved, three-valved, and occasionally imperfectly three-lobed, of a dirty grayish brown colour, and coarse fibrous appearance. They are strongly ribbed, and, when soaked in water, exhibit from nine to thirteen ragged membranous wings, which distinguish them from all other varieties. The seeds have a feebly aromatic taste and smell. This variety of cardamom affords but a very small proportion of volatile oil, is altogether of inferior quality, and, when imported into London, is usually sent to the continent.

4. *Madagascar Cardamom.* This is the *Cardamomum majus* of Geiger and some others, and is thought to be the fruit of *Amomum angustifolium* of Sonnerat, growing in marshy grounds, in Madagascar. The capsule is ovate, pointed, flattened on one side, striated, with a broad circular scar at the bottom surrounded by an elevated, notched, corrugated margin. The seeds have an aromatic flavour analogous to that of officinal cardamom.

5. *Grains of Paradise. Grana Paradisi.* Under this name and that of *Guinea grains*, and *Malegueta* or *Mallaguetta pepper*, are kept in the shops small seeds of a round or ovate form, often angular and somewhat cuneiform, minutely rough, brown externally, white within, of a feebly aromatic odour when rubbed between the fingers, and of a strongly hot and peppery taste. Two kinds of them are known in the English market, one, larger, plumper, and more warty, with a short conical projecting tuft of pale fibres on the umbilicus; the other, smaller and smoother, and without the fibrous tuft. The latter are the most common. It is probable that one of the varieties is produced by *Amomum Grana Paradisi* of Sir J. E. Smith, and the other by Roscoe's *Amomum Melegueta*. (Pereira's *Mat. Med.*, 3d ed., p. 1134.) Dr. W. F. Daniell, who has published (*Pharm. Journ. and Trans.*, xiv. 312 and 356) an elaborate paper on the Amoma of Western Africa, states that the true Mallaguetta pepper is obtained exclusively from varieties of the same species, to which belong the *Amomum Grana Paradisi* of Afzelius, and the *A. Melegueta* of Roscoe; while the *A. Grana Paradisi* of Sir J. E. Smith is a different plant, and yields a different product. These grains are imported from Guinea, and other parts of the western coast of Africa. Similar grains are taken to England from Demarara, where they are obtained from a plant cultivated by the negroes, supposed to have been brought from Africa, and believed by Dr. Pereira to be the *Amomum Melegueta* of Roscoe. (*Ibid.*, vi. 412.) At the international ex

Linnæus confounded, under the name of *Amomum Cardamomum*, two different vegetables—the genuine plant of Malabar, and another growing in Java. These were separated by Willdenow, who conferred on the former Sonnerat's title of *Amomum repens*, while he retained the original name for the latter, though not the true cardamom plant. In the tenth volume of the Linn. Transactions, A. D. 1811, Mr. White, a British Army Surgeon in India, published a very minute description of the Malabar plant, which he had enjoyed frequent opportunities of examining in its native state. From this description, Dr. Maton inferred that the plant, according to Roscoe's arrangement of the Scitamineæ, could not be considered an *Amomum;* and, as he was unable to attach it to any other known genus, he proposed to construct a new one with the name of *Elettaria*, derived from *elettari*, or *elatari*, the Malabar name of this vegetable. Sir James Smith afterwards suggested the propriety of naming the new genus *Matonia*, in honour of Dr. Maton; and the latter title, having been adopted by Roscoe, obtained a place in former editions of the London and U. S. Pharmacopœias. The celebrated Dr. Roxburgh described the Malabar cardamom plant as an *Alpinia*, with the specific name *Cardamomum*. As doubts were entertained of the necessity for the new genus proposed by Maton, Roxburgh was followed in the London and U. S. Pharmacopœias, and the fruit was referred to Alpinia Cardamomum. This decision, however, has been revised in the latest editions of the U S. and British Pharmacopœias, in which the plant is entitled Elettaria Cardamomum. Finally, Roscoe has arranged it with the abandoned genus *Renealmia* of Linnæus, which he has restored.

Elettaria. *Sex. Syst.* Monandria Monogynia.—*Nat. Ord.* Scitamineæ. *Brown.* Zingiberaceæ. *Lindley.*

Gen. Ch. Corolla with the tube filiform and the inner limb one-lipped. *Anther* naked. *Capsule* often berried, three-celled, three-valved. *Seeds* numerous, arillate. *Blume.*

Elettaria Cardamomum. Maton.—*Alpinia Cardamomum.* Roxburgh.—*Amomum Repens.* Sonnerat; Willd. *Sp. Plant.* i. 9.—*Renealmia Cardamomum.* Roscoe, *Monandrous Plants.* Figured in *Linn. Trans.* x. 248, and Carson's *Illust. of Med. Bot.* ii. 55. The Cardamom plant has a tuberous horizontal root or rhizoma, furnished with numerous fibres, and sending up from eight to twenty erect, simple, smooth, green and shining, perennial stems, which rise from six to twelve feet in height, and bear alternate sheathing leaves. These are from nine inches to two feet long, from one to five inches broad, elliptical-lanceolate, pointed, entire, smooth and dark-green on the upper surface, glossy and pale sea-green beneath, with strong midribs, and short footstalks. The flower-stalk proceeds from the base of the stem, and lies upon the ground, with the flowers arranged in a panicle. The calyx is monophyllous, tubular, and toothed at the margin; the corolla monophyllous and funnel-shaped, with the inferior border unilabiate, three-lobed, and spurred at the base. The fruit is a three-celled capsule, containing many seeds.

hibition of 1862, at London, the author noticed a specimen of similar grains, under the name of grains of Paradise, sent from the island of Trinidad. Their effects on the system are analogous to those of pepper; but they are seldom used except in veterinary practice, and to give artificial strength to spirits, wine, beer, and vinegar. In the same journal (ii. 443), Dr. Pereira points out seven distinct scitamineous fruits, to which the name of grains of Paradise has been applied by different authors.

Other products of different Scitamineæ, which have received the name of cardamom, are described by Pereira; but the above are all that are known in commerce, or likely to be brought into our drug markets.

In the *Pharm. Journ. and Trans.* (xiv. 352), and in the same journal for October, 1861 (p. 207), and for September, 1862 (p. 110), are papers by Mr. Daniel Hanbury on some rare kinds of cardamom of Siam, Cochin-China, Tonquin, and China, in which new information is given on varieties already known, and others are noticed which appear hitherto to have escaped the attention of European writers; but as these are of little practical interest to American pharmaceutists, we must content ourselves with referring those who wish to investigate especially the subject of the cardamoms and analogous products to the sources of information alluded to.

This valuable plant is a native of the mountains of Malabar, where it springs up spontaneously in the forests after the removal of the undergrowth. From time immemorial, great numbers of the natives have derived a livelihood from its cultivation. It begins to yield fruit at the end of the fourth year, and continues to bear for several years afterwards. The capsules when ripe are picked from the fruit stems, dried over a gentle fire, and separated by rubbing with the hands from the footstalks and adhering calyx.

Thus prepared, they are ovate-oblong, from three to ten lines long, from two to four thick, three-sided with rounded angles, obtusely pointed at both ends, longitudinally wrinkled, and of a yellowish-white colour. The seeds which they contain are small, angular, irregular, rough as if embossed upon their surface, of a brown colour, easily reduced to powder, and thus separable from the capsular covering, which, though slightly aromatic, is much less so than the seeds, and should be rejected when the medicine is administered. The seeds constitute about 74 parts per cent. by weight. According to Pereira, three varieties are distinguished in commerce:—1. the *shorts*, from three to six lines long, from two to three broad, browner and more coarsely ribbed, and more highly esteemed than the others; 2. the *long-longs*, from seven lines to an inch in length by two or three lines in breadth, elongated, and somewhat acuminate; and 3. the *short-longs*, which are somewhat shorter and less pointed than the second variety. The odour of cardamom is fragrant, the taste warm, slightly pungent, and highly aromatic. These properties are extracted by water and alcohol, but more readily by the latter. They depend on a volatile oil, which rises with water in distillation. The seeds contain, according to Trommsdorf, 4·6 per cent. of volatile oil, 10·4 of fixed oil, 2·5 of a salt of potassa mixed with a colouring principle, 3·0 of starch, 1·8 of azotized mucilage, 0·4 of yellow colouring matter, and 77·3 of ligneous fibre. The volatile oil is colourless, of an agreeable and very penetrating odour, and of a strong, aromatic, burning, camphorous, and bitterish taste. Its sp. gr. is 0·945. It cannot be kept long without undergoing change, and finally, even though excluded from the air, loses its peculiar odour and taste. If ether be made to percolate through the powdered seeds, and the liquor obtained be deprived of the ether, a light greenish-brown fluid remains, consisting almost exclusively of the volatile and fixed oils. It has the odour of cardamom, and keeps better than the oil obtained by distillation. (*Am. Journ. of Pharm.*, xxi. 116.) The seeds should be powdered only when wanted for use; as they retain their aromatic properties best while in the capsules.

Medical Properties and Uses. Cardamom is a warm and grateful aromatic, less heating and stimulating than some others belonging to the class, and very useful as an adjuvant or corrective of cordial, tonic, and purgative medicines. Throughout the East Indies it is largely consumed as a condiment. It was known to the ancients, and derived its name from the Greek language. In this country it is employed chiefly as an ingredient in compound preparations

Daucus. *Sex. Syst.* Pentandria Digynia.—*Nat. Ord.* Umbelliferæ or Apiaceæ.

Gen. Ch. Corolla. somewhat rayed. *Florets* of the disk abortive. Fruit hispid with hairs. *Willd.*

Daucus Carota. Willd. *Sp. Plant.* i. 1389; Woodv. *Med. Bot.* p. 130, t. 50. The *wild carrot* has a biennial spindle-shaped root, and an annual, round, fur-

rowed, hairy stem, which divides into long, erect, flower-bearing branches, and rises two or three feet in height. The leaves are hairy, and stand on footstalks nerved on their under side. The lower are large and tripinnate, the upper, smaller and less compound; in both, the leaflets are divided into narrow pointed segments. The flowers are small, white, and disposed in many-rayed compound umbels, which are at first flat on the top and spreading, but, when the seeds are formed, contract so as to present a concave cup-like surface. A sterile flower, of a deep-purple colour, is often observable in the centre of the umbel. The general involucrum is composed of several leaves, divided into long narrow segments; the partial is more simple. The petals are five, unequal, and cordate. The fruit consists of two plano-convex hispid portions, connected by their flat surfaces.

Daucus Carota is exceedingly common in this country, growing along fences, and in neglected fields, which, in the months of June and July, are sometimes white over their whole surface with its flowers. It grows wild also in Europe, from which it is supposed by some botanists to have been introduced into the United States. The well-known garden carrot is the same plant, somewhat altered by cultivation. The officinal portions are the fruit of the wild, and the root of the cultivated variety.

1. Carrot Seed. Strictly speaking, these should be called the fruit. They are very light, of a brownish colour, of an oval shape, flat on one side, and convex on the other, and on their convex surface present four longitudinal ridges, to which stiff, whitish hairs or bristles are attached They have an aromatic odour, and a warm, pungent, and bitterish taste. By distillation they yield a pale-yellow volatile oil, upon which their virtues chiefly depend. Boiling water extracts their active properties.

Medical Properties and Uses. Carrot seeds are moderately excitant and diuretic, and are employed in chronic nephritic affections, and in dropsy. As they possess the cordial properties of the aromatics, they are especially adapted to cases in which the stomach is enfeebled. They are said to afford relief in the strangury from blisters. From thirty grains to a drachm of the bruised seeds may be given at a dose, or a pint of the infusion, containing the virtues of half an ounce or an ounce of the seeds, may be taken during the day. The whole umbel is often used instead of the seeds alone.

2. Carrot Root. The root of the wild carrot is whitish, hard, coriaceous, branched, of a strong smell, and an acrid, disagreeable taste; that of the cultivated is reddish, fleshy, thick, conical, rarely branched, of a pleasant odour, and a peculiar, sweet, mucilaginous taste. The constituents of the root are crystallizable and uncrystallizable sugar, a little starch, extractive, gluten, albumen, volatile oil, vegetable jelly or *pectin*, malic acid, saline matters, lignin, and a peculiar crystallizable, ruby-red, neuter principle, without odour or taste, called *carotin*. According, however, to MM. Frorde and Sœauer, carotin, as well as a modification which has been named *hydrocarotin*, is in fact *cholesterin* coloured by a red pigment. (*Am. Journ. of Pharm.*, Nov. 1866, p. 505.) The substance called *vegetable jelly* was by some considered a modification of gum or mucilage, combined with a vegetable acid Braconnot found it to be a peculiar principle, and named it *pectin* from the Greek (πηκτις), expressive of its characteristic property of gelatinizing. It exists more or less in all vegetables, and is abundant in certain fruits and roots from which jellies are prepared. It may be separated from the juice of fruits by alcohol, which precipitates it in the form of a jelly. This being washed with weak alcohol and dried, yields a semi-transparent substance bearing some resemblance to ichthyocolla. Immersed in 100 parts of cold water, it swells like bassorin, and ultimately forms a homogeneous jelly. With a larger proportion it exhibits a mucilaginous consistence. It is less acted on by boiling than by cold water. When perfectly pure it is tasteless, and has no effect on vegetable blues. A striking peculiarity is that, by the agency of a fixed alkali or alkaline earthy base, it is instantly converted into pectic acid, which unites with the base to form a pectate. This may be decomposed by the addition of an acid, which unites with the base, and

separates the pectic acid. *Pectic acid* thus obtained is in the form of a colourless jelly, slightly acidulous, with the property of reddening litmus paper, scarcely soluble in cold water, more soluble in boiling water, and forming with the latter a solution, which, though it does not become solid on cooling, is coagulated by alcohol, lime-water, acids, or salts, and even by sugar if allowed to stand for some time. With the alkalies it forms salts, capable of gelatinizing; with the earths and metallic oxides, insoluble salts. Braconnot thinks that pectic acid exists in many plants already formed. M. Frémy found that pectin results, in fruits, from the reaction of acids upon a peculiar insoluble substance they contain when immature, called by him *pectose;* and that pectin is changed into pectic acid not only by alkalies, but also by vegetable albumen.

Medical Properties and Uses. The wild root possesses the same properties as the seeds, and may be used for the same purposes. That of the garden plant has acquired much reputation as an external application to phagedenic, sloughing, and cancerous ulcers, the fetor of which it is supposed to correct, while it sometimes changes the character of the diseased action. It is also useful in the ulcers which follow fevers. The root is brought to the proper consistence by scraping. In this state it retains a portion of the active principles of the plant, which render it somewhat stimulant. Boiled and mashed, as usually recommended, the root is perfectly mild, and fit only to form emollient cataplasms.* W.

CARTHAMUS. *Sex. Syst.* Syngenesia Æqualis. — *Nat. Ord.* Compositæ Cynareæ. *De Cand.* Cynaraceæ. *Lindley.*

Gen. Ch. Receptacle paleaceous, setose. *Calyx* ovate, imbricated, with ovate scales, leafy at the end. *Seed-down* paleaceous, hairy, or none. *Willd.*

Carthamus tinctorius. Willd. *Sp. Plant.* iii. 1706. The *dyers' saffron* or *safflower* is an annual plant, with a smooth, erect stem, somewhat branched at top, and a foot or two in height. The leaves are alternate, sessile, ovate, acute, entire, and furnished with spiny teeth. The flowers are compound, in large terminal, solitary heads. The florets are of an orange-red colour, with a funnel-shaped corolla, of which the tube is long, slender, and cylindrical, and the border divided into five equal, lanceolate, narrow segments.

The plant is a native of India, the Levant, and Egypt, and is cultivated in those countries, as well as in various parts of Europe and America. The florets are the part employed. They are brought to us chiefly from the ports of the Mediterranean. Considerable quantities are produced in this country, and sold as American saffron.

Safflower in mass is of a red colour, diversified by the yellowness of the filaments contained within the floret. It has a peculiar slightly aromatic odour, and a scarcely perceptible bitterness. Among its ingredients are two colouring substances—one red, insoluble in water, slightly soluble in alcohol, very soluble in alkaline liquids, and called *carthamine* or *carthamic acid* by Döbereiner, who found it to possess acid properties; the other yellow, and soluble in water. It is the former which renders safflower useful as a dye-stuff. Cartharmine mixed with finely powdered talc, forms the cosmetic powder called *rouge.* For more detailed information in relation to these principles, the reader is referred to the *Journal de Pharmacie* (3e sér., iii. 203).

These flowers are sometimes fraudulently mixed with saffron, which they re-

* *Carrot Ointment.* The following formula for this ointment has been handed to us by Professor Procter, who has long been in the habit of preparing it. Take of grated carrot root half a pound, lard a pound, wax four ounces. Melt the lard and wax, add the carrot root, evaporate with a moderate heat the moisture of the root, and strain. It may be used in excoriated or ulcerated surfaces, requiring gentle stimulation. (*Note to the tenth edition.*)

semble in colour, but from which they may be distinguished by their tubular form, and the yellowish style and filaments which they enclose.

Medical Properties. In large doses carthamus is said to be laxative; and, administered in the state of warm infusion, it proves somewhat diaphoretic. It is used in domestic practice, as a substitute for saffron, in measles, scarlatina, and other exanthematous diseases, in order to promote the eruption. An infusion, made in the proportion of two drachms to a pint of boiling water, is usually employed, and given without restriction as to quantity. W.

CARUM. *U. S.*

Caraway.

The fruit of Carum Carui. *U. S.*

Off. Syn. CARUI FRUCTUS. *Caraway Fruit.* The dried fruit of Carum Carui. *Br.*

Carvi, *Fr., Ital.;* Gemeiner Kummel, *Germ.;* Alcaravea, *Span.*

CARUM. *Sex. Syst.* Pentandria Digynia.—*Nat. Ord.* Umbelliferæ or Apiaceæ.

Gen. Ch. Fruit ovate-oblong, striated. *Involucre* one-leafed. *Petals* keeled, inflexed-emarginate. *Willd.*

Carum Carui. Willd. *Sp. Plant.* i. 1470; Woodv. *Med. Bot.* p. 102, t. 41. This plant is biennial and umbelliferous, with a spindle-shaped, fleshy, whitish root, and an erect stem, about two feet in height, branching above, and furnished with doubly pinnate, deeply incised leaves, the segments of which are linear and pointed. The flowers are small and white, and in erect terminal umbels, which are accompanied with an involucre, consisting sometimes of three or four leaflets, sometimes of one only, and are destitute of partial involucre.

The caraway plant is a native of Europe, growing wild in meadows and pastures, and cultivated in many places. It has been introduced into this country. The flowers appear in May and June, and the seeds, which are not perfected till the second year, ripen in August. The root, when improved by culture, resembles the parsnep, and is used as food in the north of Europe. The seeds are the part used in medicine. They are collected by cutting down the plant, and threshing it on a cloth. Our markets are supplied partly from Europe, partly from our own gardens. The American seeds are usually rather smaller than the German.

Caraway seeds (half-fruits) are about two lines in length, slightly curved, with five longitudinal ridges, which are of a light-yellowish colour, while the intervening spaces are dark-brown. They have an agreeable aromatic smell, and a sweetish, warm, spicy taste. These properties depend on an essential oil, which they afford largely by distillation. The residue is insipid. They yield their virtues readily to alcohol, and more slowly to water.

Medical Properties and Uses. Caraway is a pleasant stomachic and carminative, occasionally used in flatulent colic, and as an adjuvant or corrective of other medicines. The dose in substance is from a scruple to a drachm. An infusion may be prepared by adding two drachms of the seeds to a pint of boiling water. The volatile oil, however, is most employed. (See *Oleum Cari.*) The seeds are baked in cakes, to which they communicate an agreeable flavour, while they stimulate the digestive organs.

Caryophyllus aromaticus. Linn. *Sp.* 735; De Cand. *Prodrom.* iii. 262; Carson, *Illust. of Med. Bot.* i. 43, pl. 37. — *Eugenia caryophyllata.* Willd. *Sp. Plant.* ii. 965; Woodv. *Med. Bot.* p. 538, t. 193. This small tree is one of the most elegant of those inhabiting the islands of India. It has a pyramidal form, is always green, and is adorned throughout the year with a succession of beautiful rosy flowers. The stem is of hard wood, and covered with a smooth, grayish bark. The leaves are about four inches in length by two in breadth, obovate-oblong, acuminate at both ends, entire, sinuated, with many parallel veins on each side of the midrib, supported on long footstalks, and opposite. They have a firm consistence, and a shining green colour, and when bruised are highly fragrant. The flowers are disposed in terminal corymbose panicles, and exhale a strong, penetrating, and grateful odour.

The natural geographical range of the clove is extremely limited. It was formerly confined to the Molucca Islands, in most of which it grew abundantly before their conquest by the Dutch. By the monopolizing policy of that commercial people, the trees were extirpated in nearly all the islands except Amboyna and Ternate, which were under their immediate inspection. Notwithstanding, however, their jealous vigilance, a French governor of the Isles of France and Bourbon, named Poivre, succeeded, in the year 1770, in obtaining plants from the Moluccas, and introducing them into the colonies under his control. Five years afterwards, the clove-tree was introduced into Cayenne and the West Indies, in 1803 into Sumatra, and in 1818 into Zanzibar. It is now cultivated largely in these and other places; and commerce has ceased to depend on the Moluccas for supplies of this spice.*

The unexpanded flower-buds are the part of the plant employed under the ordinary name of cloves.† They are first gathered when the tree is about six years old. The fruit has similar aromatic properties, but much weaker. The buds are picked by the hand, or separated from the tree by long reeds, and are then quickly dried. In the Moluccas they are said to be sometimes immersed in boiling water, and afterwards exposed to smoke and artificial heat, before being spread out in the sun. In Cayenne and the West Indies they are dried simply by solar heat.

Cloves appear to have been unknown to the ancients. They were introduced into Europe by the Arabians, and were distributed by the Venetians. After the discovery of the southern passage to India, the trade in this spice passed into the hands of the Portuguese; but was subsequently wrested from them by the Dutch, by whom it was long monopolized. Within a few years, however, the extended culture of the plant has thrown open the commerce in cloves to all nations. The United States derive much of their supply from the West Indies and Guiana. The Molucca cloves are said to be thicker, darker, heavier, more oily, and more highly aromatic than those cultivated elsewhere. They are known by the name of *Amboyna cloves.* The *Bencoolen cloves*, from Sumatra, are deemed equal if not superior by the English druggists.

Properties. Cloves resemble a nail in shape, are usually rather more than

* Cloves from Cayenne, and from various West India islands, as Martinique, Guadaloupe, and Trinidad, have been for several years circulating in commerce. The author saw a specimen from Para, in Brazil, at the international exhibition at London (A.D. 1862). They were lighter coloured than those from the E. Indies. (*Note to the twelfth edition.*)

† The peduncles of the flowers have been sometimes employed. They possess the odour and taste of the cloves, though in a less degree, and furnish a considerable quantity of essential oil. The French call them *griffes de girofles.*

half an inch long, and have a round head with four spreading points beneath it. Their colour is externally deep-brown, internally reddish; their odour strong and fragrant; their taste hot, pungent, aromatic, and very permanent. The best cloves are large, heavy, brittle, and exude a small quantity of oil on being pressed or scraped with the nail. When light, soft, wrinkled, pale, and of feeble taste and smell, they are inferior. Those from which the essential oil has been distilled are sometimes fraudulently mixed with the genuine.

Trommsdorff obtained from 1000 parts of cloves 180 of volatile oil, 170 of a peculiar tannin, 130 of gum, 60 of resin, 280 of vegetable fibre, and 180 of water. M. Lodibert afterwards discovered a fixed oil, aromatic and of a green colour, and a white resinous substance which crystallizes in fasciculi, composed of very fine diverging silky needles, without taste or smell, soluble in ether and boiling alcohol, and exhibiting neither alkaline nor acid reaction. This substance, called by M. Bonastre *caryophyllin*, was found in the cloves of the Moluccas, of Bourbon, and of Barbadoes, but not in those of Cayenne, from which, however, it has since been procured. Berzelius considers it a stearoptene, and probably identical with that deposited by the oil of cloves when long kept. To obtain it, the ethereal extract of cloves is treated with water, and the white substance thrown down is separated by filtration, and treated repeatedly with ammonia to deprive it of impurities. Thus procured, Dr. Muspratt found it to consist of carbon, hydrogen, and oxygen, in the proportion represented by the formula $C_{10}H_8O$, or $C_{20}H_{16}O_2$. (*Pharm. Journ.*, x. 343.) Dr. Theod. Martius obtains it cheaply by exposing cloves, previously deprived as far as possible of oil by distillation with water, to distillation at a higher temperature, redistilling the brown liquid obtained until the distillate nearly ceases to have the taste or smell of cloves, and then purifying the residue by washing with water, and treating it with boiling alcohol and animal charcoal repeatedly, until the caryophyllin, which is deposited by the alcohol on cooling, is perfectly white. (See *Am. Journ. of Pharm.*, xxxii. 65.) It is an oxide of the neutral oil of cloves. M. Dumas has discovered another crystalline principle, which forms in the water distilled from cloves, and is gradually deposited. Like caryophyllin, it is soluble in alcohol and ether, but differs from that substance in becoming red when touched with nitric acid. M. Bonastre proposes for it the name of *eugenin*. (*Journ. de Pharm.*, xx. 565.) It is said to be isomeric with eugenic acid, or the acid constituent of oil of cloves. (*Gregory.*) Water extracts the odour of cloves with comparatively little of their taste. All their sensible properties are imparted to alcohol; and the tincture when evaporated leaves an excessively fiery extract, which becomes insipid if deprived of the oil by distillation with water, while the oil which comes over is mild. Hence it has been inferred that the pungency of this aromatic depends on a union of the essential oil with the resin. For an account of the oil, see *Oleum Caryophylli*. The infusion and oil of cloves are reddened by nitric acid, and rendered blue by tincture of chloride of iron; facts of some interest, as morphia yields the same results with these reagents.

Medical Properties and Uses. Cloves are among the most stimulant of the aromatics; but, like others of this class, act less upon the system at large than on the part to which they are immediately applied. They are sometimes administered in substance or infusion to relieve nausea and vomiting, correct flatulence, and excite languid digestion; but their chief use is to assist or modify the action of other medicines. They enter into several officinal preparations. Their dose in substance is from five to ten grains.

The French Codex directs a *tincture of cloves* to be prepared by digesting for six days, and afterwards filtering, a mixture of four ounces of powdered cloves and sixteen of alcohol of 31° Cartier. Three ounces to the pint of alcohol is a sufficiently near approximation.

There has been much confusion in relation to the different species of Croton growing in the West Indies, and as to which of them the Cascarilla of the shops is to be ascribed. At present, however, it is generally admitted that this bark, which is brought exclusively from the Bahama Islands, is the product of Croton Eluteria; and, though it is probable that the proper C. Cascarilla may at one time have yielded a portion of its bark to commerce, at present little or none is derived from that species. The London College committed the error, which it afterwards corrected, of recognising *C. Cascarilla* of Don as the source of it. This botanist mistook the *Copalchi bark* of Mexico, which is produced by *Croton Pseudo-China* of Schiede, and somewhat resembles cascarilla, for the genuine bark, and hence proposed to transfer the specific name of Cascarilla to the Mexican plant. No fact is better ascertained than that the proper cascarilla bark is a West India product, and is never brought from Mexico.*

In relation to the botany of this subject, the former intricacy has been in great measure if not entirely removed by the researches of Mr. John J. Bennett, who, having received specimens of the different species of Croton growing in the Bahamas from Dr. W. F. Daniell, by whom they were collected during a residence in those islands, was enabled, by a comparison of them with former specimens and descriptions, to discriminate accurately the species previously confounded. (*Journ. of Linn. Soc.*, iv. 29.)

Croton Eluteria. Bennett, *Journ. Linn. Soc.*, iv. 29; Daniell, *Pharm. Journ. and Trans.*, 2d ser., iv. 145, figured at p. 150. — *Clutia Eluteria.* Woodv. *Med. Bot.*, 3d ed., iv. 633, t. 223. As described by Dr. Daniell, this, though commonly a shrub of from three to five feet high, sometimes appears in the form of a small

* *Copalchi bark* has been mistaken not only for cascarilla, but also for a variety of cinchona. Portions of it, having been taken to Europe, attracted the attention both of pharmacologists and physicians. Two kinds were noticed; one, in small slender quills, of an ash colour, bearing some resemblance to a variety of pale cinchona, but having the flavour of cascarilla, and burning with a similar odour; the other, in larger quills, with a thick cork-like epidermis, very bitter, and yielding an aromatic odour when burnt. The former is the product of Croton Pseudo-China; the latter is of unknown origin, but conjecturally referred to *C. suberosum.* Mr. J. E. Howard states that the quilled copalchi bark contains a bitter alkaloid, soluble in ether, and precipitable as a white hydrate from its acid solution. (*Pharm. Journ.*, xiv. 319.) Copalchi bark is an aromatic tonic, employed in Mexico in intermittents, and capable of useful application in all cases requiring a mild aromatic bitter. Dr. Stark has employed it advantageously in feeble states of digestion with irritable bowels, and found it, in one or two cases, to exhibit antiperiodic properties. It may be given in infusion, made with half an ounce of the bark to a pint of water, in the dose of one or two fluidounces three times a day. (*Ed. Med. and Surg. Journ.*, April, 1849, p. 410.)—*Note to the ninth and eleventh editions.*

After the publication of the tenth edition of this work, we received from Dr. Pleasants, U. S. Consul at Minatitlan, Isthmus of Tehuantepec, Mexico, a box of bark which it was thought might prove to be Peruvian bark, and had some reputation as an antiperiodic. It is in large quills, or partially rolled pieces, sometimes nearly flat, with a white or whitish epidermis, and a dark-brown colour of the proper bark, the outer surface of which appears irregularly striated on the removal of the epidermis. It has a bitter, aromatic taste, gives out when burnt the musk-like odour of cascarilla similarly treated, and, though much larger than the specimens we have seen of copalchi bark, is probably derived either from the same tree, or from another species of Croton. (*Note to the eleventh edition.*)

tree with a stem from four to eight inches in diameter.* The stem is straight, and marked at intervals with white or grayish stains. The leaves are petiolate, from two to three inches in length by an inch or more in breadth, often somewhat cordate at the base, obtusely acuminate, pale or grayish-green above, and densely covered beneath with shining silvery scales, appearing white at a distance. They are smaller and narrower in the plants of arborescent growth. The flowers, which have a delicious odour, are monœcious, small, white, petiolate, and closely set, in simple terminal or axillary spikes. The shrub is a native of the Bahamas, scarce at present in the island of New Providence, but still abundant in Andros, Long, and Eleutheria islands, from the latter of which it derived its botanical title. Daniell calls the plant sweet-wood. The name of *sea-side balsam* belongs to another species, *C. Balsamiferum* of Linnæus, which grows in the Bahamas and other W. India islands, and owes its name to the circumstance that a balsamic juice exudes from its young branches when wounded.

Croton Cascarilla. Bennett, *Journ. of the Linn. Soc.* iv. 30. — *Clutia Cascarilla.* Linn. *Sp. Plant.* ed. 1, p. 1042. — *Ricinoides elæagnifolio.* Catesby, *Hist Carolin.* ii. t. 46. As described by Daniell, this is a shrub of from four to six feet, much branched, with a pale grayish-green stem, without the white stains of the former species. The leaves are petiolate, long, narrow, lanceolate, tapering towards each end, pointed, with flat or somewhat undular margins, above smooth and green, beneath pale and very hairy. The flowers are monœcious, in simple terminal spikes, with small white petals tinged with yellow. They are very fragrant. The plant is a native of the Bahamas, and is said also to grow in Hayti. In the Bahamas it is much scarcer than formerly, and is said by Dr. Daniell to yield at present none of the Cascarilla of commerce, of which much was formerly derived from it. This species seems to have been confounded by some with *Croton lineare* of Jacquin, which grows in the Bahamas and most of the W. India islands, where it is known by the name of *wild rosemary*, owing probably in part to its fragrant smell, but still more to its narrow linear leaves with reflected margins.

Cascarilla is brought to this market from the West Indies, and chiefly, as we have been informed, from the Bahamas. It comes in bags or casks. We have observed it in the shops in two forms, so distinct as to merit the title of varieties. In one, the bark is in rolled pieces of every size, from three or four inches in length and half an inch in diameter to the smallest fragments, covered externally with a dull-whitish or grayish-white epidermis, which in many portions is partially, sometimes wholly removed, leaving a dark-brown surface, while the inner surface has a chocolate colour, and the fracture is a reddish-brown. The small pieces are sometimes curled, but have a distinct abrupt edge as if broken from the branches. The second variety consists entirely of very small pieces, not more than an inch or two in length, very thin, without the white epidermis, not regularly quilled, but curved more or less in the direction of their length, often having a small portion of woody fibre attached to their inner surface, and presenting an appearance precisely as if shaved by a knife from the stem or branches. Whether these two varieties are derived from distinct species, or differ only from the mode of collection, it is difficult to determine.†

* The plant referred to in former editions of this work, as having been seen by Dr. Wright in Jamaica, and called by him C. Eluteria, is, according to Mr. Bennett, a distinct species, *C. Sloanei*, which was confounded by Linnæus with the genuine cascarilla plant, under the name of *Clutia Eluteria*. The genuine plant was first described by him in his *Hortus Cliffortianus* (pp. 486–7), from a specimen in Clifford's herbarium in the British Museum, and afterwards apparently confused with a Jamaica specimen sent to him by Patrick Brown, from the latter of which the description of his Clutia Eluteria was drawn up, which is quite inapplicable to the original plant. It is the C. Sloanei also that was described by Swartz in his *Flora Indiæ Occidentalis* (p. 1183), under the name of Croton Eluteria, and probably the same that was figured by Dr. Carson in his *Illust. of Med. Bot.* ii. 34, pl. 78. (See *Pharm. Journ.*, Aug. 1859, pp. 132–3.)—*Note to the twelfth edition.*

† We have little doubt that the latter variety, which we have not seen for many years, was the product of C. Cascarilla. The fact that it has ceased to appear in our markets corresponds with the fact, stated by Dr. Daniell, that the bark of this species is not now collected; and the want of a white epidermis, by which the bark of C. Cascarilla is also characterized, tends to confirm this view of its origin. (*Note to the twelfth edition.*)

Properties. Cascarilla has an aromatic odour, rendered much more distinct by friction, and a warm, spicy, bitter taste. It is brittle, breaking with a short fracture. When burnt it emits a pleasant odour, closely resembling that of musk, but weaker and more agreeable. This property serves to distinguish it from other barks. It was analyzed by Trommsdorff, and more recently by M. Duval, of Lisieux, in France. The constituents found by the latter were albumen, a peculiar kind of tannin, a bitter crystallizable principle called *cascarillin*, a red colouring matter, fatty matter of a nauseous odour, wax, gum, volatile oil, resin, starch, pectic acid, chloride of potassium, a salt of lime, and lignin. The oil, according to Trommsdorff, constitutes 1·6 per cent., is of a greenish-yellow colour, a penetrating odour analogous to that of the bark, and of the sp. gr. 0·938. To obtain cascarillin, M. Duval treated the powdered bark with water, added acetate of lead to the solution, separated the lead by sulphuretted hydrogen, filtered, evaporated with the addition of animal charcoal, filtered again, evaporated at a low temperature to a syrupy consistence, and, having allowed the semi liquid substance thus obtained to harden by cooling, purified it by twice successively treating it, first with a little cold alcohol, to separate the colouring and fatty matters, and afterwards with boiling alcohol and animal charcoal. The last alcoholic solution was allowed to evaporate spontaneously. Thus obtained, cascarillin is white, crystalline, inodorous, bitter, very slightly soluble in water, soluble in alcohol and ether, neuter, and destitute of nitrogen. (*Journ. de Pharm.*, 3e sér., viii. 96.) Either alcohol or water will partially extract the active matters of cascarilla; but diluted alcohol is the proper menstruum.

Medical Properties and Uses. This bark is aromatic and tonic. It was known in Germany so early as the year 1690, and was much used as a substitute for Peruvian bark by those who were prejudiced against that febrifuge in the treatment of remittent and intermittent fevers. It has, however, lost much of its reputation, and is now employed only where a pleasant and gently stimulant tonic is desirable; as in dyspepsia, chronic diarrhœa and dysentery, flatulent colic, and other cases of debility of the stomach or bowels. It is said to promote the flow of milk in the lower animals, and has been proposed with a view to the same effect in the human subject. It is sometimes advantageously combined with the more powerful bitters. It may be given in powder or infusion. The dose of the former is from a scruple to half a drachm, which may be repeated several times a day. Prof. Procter has published a formula for a fluid extract, which contains the virtues of a troyounce of the bark in a fluidounce. (*Am. Journ. of Pharm.*, March, 1863, p.113.) In consequence of its pleasant odour when burnt, some smokers mix it in small quantity with their tobacco; but it is said, when thus employed, to occasion vertigo and intoxication.

The tree which yields the purging cassia is ranked by some botanists as a distinct genus, separated from the Cassia, and denominated *Cathartocarpus.* (See *Lindley's Flor. Med.*, 262.)

Cassia Fistula. Willd. *Sp. Plant.* ii. 518; Woodv. *Med. Bot.* p. 445, t. 160; Carson, *Illust. of Med. Bot.* i. 24, pl. 26.—*Cathartocarpus Fistula.* Persoon,

Synops., i. 459. This is a large tree, rising to the height of forty or fifty feet, with a trunk of hard, heavy wood, dividing towards the top into numerous spreading branches, and covered with a smooth ash-coloured bark. The leaves are commonly composed of five or six pairs of opposite leaflets, which are ovate, pointed, undulated, smooth, of a pale-green colour, from three to five inches long, and supported upon short petioles. The flowers are large, of a golden-yellow colour, and arranged in long, pendent, axillary racemes. The fruit consists of long, cylindrical, woody, dark-brown, pendulous pods, which, when agitated by the wind, strike against each other, and produce a sound that may be heard at a considerable distance.

This species of Cassia is a native of Upper Egypt and India, whence it is generally supposed to have been transplanted to other parts of the world. It is at present very extensively diffused through the tropical regions of the old and new continents, being found in Insular and Continental India, Cochin-China, Egypt, Nubia, the West Indies, and the warmer parts of America. The fruit is the officinal portion of the plant. It is imported from the East and West Indies, chiefly the latter, and from South America.

Properties. Cassia pods are a foot or more in length, straight or but slightly curved, cylindrical, less than an inch in diameter, with a woody shell, externally of a dark-brown colour, and marked with three longitudinal shining bands, extending from one end to the other, two of which are in close proximity, appearing to constitute a single band, and the third is on the opposite side of the pod. These bands mark the place of junction of the valves of the legume, and are represented as sometimes excavated in the form of furrows. There are also circular depressions at unequal distances. Internally the pod is divided into numerous cells by thin transverse plates, which are covered with a soft, black pulp. Each cell contains a single, oval, shining seed. The pods brought from the East Indies are smaller, smoother, have a blacker pulp, and are more esteemed than those from the West Indies.

We have seen a quantity of pods in this market sold as cassia pods, which were an inch and a half in diameter, flattened on the sides, exceedingly rough on the outer surface, and marked by three longitudinal very elevated ridges, corresponding to the bands or furrows of the common cassia. The pulp was rather nauseous, but in other respects seemed to have the properties of the officinal purging cassia. They corresponded exactly with a specimen of the fruit of *Cassia Brasilliana* brought from the West Indies, and were probably derived from that plant.

The heaviest pods, and those which do not make a rattling noise when shaken, are to be preferred; as they contain a larger portion of the pulp, which is the part employed. This should be black and shining, and have a sweet taste. It is apt to become sour if long exposed to the air, or mouldy if kept in a damp place. The pulp is extracted from the pods by first bruising them, then boiling them in water, and afterwards evaporating the decoction; or, when the pods are fresh, by opening them at the sutures, and removing the pulp by a spatula.

Cassia pulp has a slight rather sickly odour, and a sweet mucilaginous taste. From the analysis of M. Henry it appears to contain sugar, gum, a substance analogous to tannin, a colouring matter soluble in ether, traces of a principle resembling gluten, and a small quantity of water.

Medical Properties and Uses. Cassia pulp is laxative, and may be advantageously given in small doses in cases of habitual costiveness. In quantities sufficient to purge, it occasions nausea, flatulence, and griping. In this country it is rarely prescribed, except as an ingredient in the confection of senna, which is a pleasant and useful laxative preparation. The dose of the pulp as a laxative is one or two drachms, as a purge one or two ounces.

CASSIA MARILANDICA. *U. S.*

American Senna.

The leaves of Cassia Marilandica. *U. S.*

Cassia. See CASSIA FISTULA.

Cassia Marilandica. Willd. *Sp. Plant.* ii. 524; Bigelow, *Am. Med. Bot.* ii. 116; Barton, *Med. Bot.* i. 137. This is an indigenous perennial plant, of vigorous growth, sending up annually numerous round, erect, nearly smooth stems, which are usually simple, and rise from three to six feet in height. The leaves are alternate, and composed of from eight to ten pairs of oblong-lanceolate, smooth, mucronate leaflets, green on their upper surface, pale beneath, and connected by short petioles with the common footstalk, which is compressed, channeled above, and furnished near its base with an ovate, stipitate gland. The flowers, which are of a beautiful golden-yellow colour, grow in short axillary racemes at the upper part of the stem. The calyx is composed of five oval, obtuse, unequal, yellow leaves; the corolla of the same number of spatulate, concave petals, of which three are ascending, and two descending and larger than the others. The stamens are ten, with yellow filaments and brown anthers, which open by a terminal pore. The three upper stamens bear short abortive anthers; the three lowermost are long, curved, and tapering into a beak. The germ, which descends with the latter, bears an erect style terminating in a hairy stigma. The fruit is a pendulous legume, from two to four inches long, linear, curved, swelling at the seeds, somewhat hairy, and of a blackish colour.

The *American senna*, or *wild senna* as it is sometimes called, is very common in all parts of the United States south of New York, and grows as far northward as the southern boundary of Massachusetts. It prefers a low, moist, rich soil, in the vicinity of water, and, though frequently found in dryer and more elevated places, is most abundant and luxuriant in the flat ground on the borders of rivers and ponds. It is sometimes cultivated in gardens for medical use. In the months of July and August, when in full bloom, it has a rich and beautiful appearance. The leaves should be collected in August or the beginning of September, and carefully dried.

They are sometimes brought into the market, compressed into oblong cakes, like those prepared by the Shakers from most herbaceous medicinal plants. The leaflets are from an inch and a half to two inches long, from one-quarter to half an inch in breadth, thin, pliable, and of a pale-green colour. They have a feeble odour, and a nauseous taste, somewhat analogous to that of senna. Water and alcohol extract their virtues. They were analyzed by Mr. Martin, of Philadelphia, and found to contain a principle analogous to *cathartin*, albumen, mucilage, starch, chlorophyll, yellow colouring matter, volatile oil, fatty matter, resin, and lignin, besides salts of potassa and lime. (*Am. Journ. of Pharm.*, i. 22.)

Medical Properties and Uses. American senna is an efficient and safe cathartic, closely resembling the imported senna in its action, and capable of being substituted for it in all cases in which the latter is employed. It is, however, less active; and, to produce an equal effect, must be administered in a dose at least one-third larger. It is habitually used by many practitioners in the country. Like senna it is most conveniently given in the form of infusion, and should be similarly combined in order to obviate its tendency to produce griping. W.

CASTOREUM. *U. S., Br.*

Castor.

A peculiar concrete substance obtained from Castor fiber. *U. S.* The dried preputial follicles and their secretion, obtained from the Beaver, Castor Fiber, and separated from the somewhat shorter and smaller oil-sacs which are frequently attached to them. *Br.*

Castoreum, *Fr.;* Bibergeil, *Germ.;* Castoro, *Ital.;* Castoreo, *Span.*

In the beaver, *Castor fiber* of naturalists, between the anus and external genitals of both sexes, are two pairs of membranous follicles, of which the lower and larger are pear-shaped, and contain an oily, viscid, highly odorous substance, secreted by glands which lie externally to the sac. This substance is called castor. After the death of the animal, the follicles containing it are removed, and dried either by smoke or in the sun; and in this state are brought into the market.

This drug is derived either from the northern and northwestern parts of America, or from Russia; and is distinguished, according to its source, into the Canadian or American, and Russian castor. It is supposed by some that the American and Russian beavers are distinct species, the former being a building, the latter a burrowing animal; and additional ground for the supposition is afforded by the fact, that the products of the two differ considerably. Of the Russian but a very small portion reaches this country. That which is brought to Philadelphia is derived chiefly from Missouri; but large quantities are collected in the northwestern regions of British America *

Castor comes to us in the form of solid unctuous masses, contained in sacs about two inches in length, larger at one end than at the other, much flattened and wrinkled, of a brown or blackish colour externally, and united in pairs by the excretory ducts which connect them in the living animal. In each pair, one sac is generally larger than the other. They are divided internally into numerous cells containing the castor, which, when the sacs are cut or torn open, is exhibited of a brown or reddish-brown colour, intermingled more or less with the whitish membrane forming the cells. Those brought from Russia are larger, fuller, heavier, and less tenacious than the American; and their contents, which are of a rusty or liver colour, have a stronger taste and smell, and are considered more valuable as a medicine. A variety of Russian castor, described by Pereira under the name of *chalky Russian castor*, is in smaller and rounder sacs than the American, has a peculiar empyreumatic odour very different from that of the other varieties, breaks like starch under the teeth, and is characterized by effervescing with dilute muriatic acid. In a specimen examined by Müller, 40·646 per cent. of carbonate of lime was found. In the castor from Missouri, the contents of the sac are sometimes almost white, and evidently inferior. According to Jannarch, castor varies with the time of year at which it is collected, being lighter coloured, more fluid, and less copious in the follicles from February to July than in the remainder of the year. (*Pharm. Cent. Blatt*, Mai, 1847, p. 318.) It is said by M. Kohli that the Canadian castor, treated with distilled water and ammonia, affords an orange precipitate, while the matter thrown down from the Russian under similar treatment is white.

Properties. Good castor has a strong, fetid, peculiar odour; a bitter, acrid, and nauseous taste; and a colour more or less tinged with red. It is of a softer or harder consistence, according as it is more or less thoroughly dried. When perfectly desiccated, though still somewhat unctuous, it is hard, brittle, and of a resinous fracture. Its chemical constituents, according to Brandes, are volatile oil; a resinous matter; albumen; a substance resembling osmazome; mucus; urate, carbonate, benzoate, phosphate, and sulphate of lime; acetate and

* The statement in the text, that the lower of the two pairs of sacs is the one containing the castor, was made on the authority of Cuvier. In an appendix by Dr. W. W. Ely, in a treatise recently published on the "American Beaver and his Works," by Lewis H. Morgan, it is stated by Dr. Ely, who appears to have thoroughly studied the anatomy of the animal, at least in reference to this particular subject, that the upper pair are the real castor sacs, the lower containing an oily secretion, with very little dark-coloured castor. (*Pages* 300 and 303.)

In the same communication by Dr. Ely, the question is discussed as to the identity of the Russian and American beavers; and the conclusion arrived at, that, though there are striking differences between the skulls of the two, as also in some respects in the contents of the castor sacs, yet these are nothing more than can be accounted for by the different circumstances in which they are placed, and by their long separation on the two continents; and consequently the Russian and American beavers should be considered merely as varieties of the same species. (*Note to the thirteenth edition.*)

muriate of soda; muriate, sulphate, and benzoate of potassa; carbonate of ammonia; membranous matter; and a peculiar proximate principle discovered by M. Bizio, an Italian chemist, and called by him *castorin*. This principle crystallizes in long, diaphanous, fasciculated prisms, has the smell of castor, and a copperish taste. It is insoluble in cold water and cold alcohol; but is dissolved by 100 parts of the latter liquid at the boiling temperature, and by the essential oils. It possesses neither alkaline nor acid properties. It may be obtained by treating castor, minutely divided, with six times its weight of boiling alcohol, filtering the liquor while hot, and allowing it to cool. The *castorin* is slowly deposited, and may be purified by means of cold alcohol. M. Valenciennes, who could not obtain the crystals white and pure by simple treatment with alcohol, succeeded by first boiling a mixture of equal parts of castor and hydrated lime with water, and acting upon the residue, separated and dried, with boiling alcohol of the sp. gr. 0·823. The product exceeded 1 per cent. (*Pharm. Journ.*, Dec. 1861, p. 329.) It has been thought to be the active principle; but its claims are doubtful. The *volatile oil* may be obtained by repeated distillation with the same portion of water. It is pale-yellow, and has the smell and taste of castor.

F. Wöhler has ascertained the existence of salicin in castor; also that it contains a small quantity of *carbolic acid*, one of the products of the distillation of coal-tar, to which he ascribes its odour. (See *Chem. Gaz.*, Jan. 1, 1849.) Dr. Pereira found that a portion of water distilled from American castor gradually lost its peculiar odour, and acquired that of the flowers of *Spiræa ulmaria*, and afterwards presented no trace of the presence of oil of castor. Upon testing it, he ascertained the existence in it of *hydruret of salicyl* (*oil of Spiræa ulmaria*), and concluded that the oil of castor had been converted into that principle. He further inferred that the oil is probably a volatile product of the salicin of the castor, and ascribes the carbolic acid to the same source. (*Pharm. Journ.*, xi. 200.) The salicin of the castor probably proceeds from the willow and poplar on which the beaver feeds.

Alcohol and ether extract the virtues of castor. An infusion made with boiling water has its sensible properties in a slight degree; but the odorous principle of the drug is dissipated by decoction.

The virtues of castor are impaired by age; and the change is more rapid in proportion to the elevation of temperature. Moisture promotes its speedy decomposition. It should not, therefore, be kept in damp cellars. In a dry cool place it may be kept for a long time without material deterioration. When quite black, with little taste or smell, it is unfit for use. The castor follicles are sometimes partly deprived of the castor, and its place supplied with sawdust. A factitious preparation has been sold, consisting of a mixture of various drugs, scented with genuine castor, intermingled with membrane, and stuffed into the scrotum of a goat. The fraud may be detected by the comparatively feeble odour, the absence of other characteristic sensible properties, and the want of the smaller follicles containing fatty matter, often attached to the bags of castor.

Medical Properties and Uses. Castor is moderately stimulant and antispasmodic. The experiments of Thouvenel prove that, in large doses, it quickens the pulse, increases the heat of the skin, and produces other symptoms of general excitement; but its force is directed chiefly to the nervous system, and in small doses it scarcely disturbs the circulation. It has also enjoyed a high reputation as an emmenagogue. It was employed by the ancients. Pliny and Dioscorides speak of it as useful in hysteria and amenorrhœa. In Europe, especially on the continent, it is still frequently prescribed in low forms of fever attended with nervous symptoms, in spasmodic diseases, such as hysteria and epilepsy, in many anomalous nervous affections, and in diseases dependent on or connected with suppression or retention of the menses. It is less used in this country. The dose in substance is from ten to thirty grains, which may be given in bolus or emulsion. The tincture is sometimes employed.

CATARIA. *U.S.*

Catnep.

The leaves of Nepeta Cataria. *U. S.*

Cataire, *Fr.;* Katzenmünze, *Germ.;* Cattara, *Ital.;* Gatera, *Span.*

Nepeta. *Sex. Syst.* Didynamia Gymnospermia.—*Nat. Ord.* Lamiaceæ or Labiatæ.

Gen. Ch. Calyx dry, striate, five-toothed. *Corolla* with the upper lip undivided, the under lip three-parted, the middle division crenate. *Stamens* approximate.

Nepeta Cataria. Catnep or *catmint* is a perennial herbaceous plant, with a quadrangular, branching, somewhat hoary stem, from one to three feet high, and furnished with opposite, petiolate, cordate, dentate, pubescent leaves, which are green above and whitish on their under surface. The flowers are whitish or slightly purple, are arranged in whorled spikes, and appear in July and August. The plant is abundant in the United States, but is supposed to have been introduced from Europe.

The whole herb is used; but the leaves only are recognised in the U. S. Pharmacopœia. They have a strong, peculiar, rather disagreeable odour, and a pungent, aromatic, bitterish, camphorous taste. They yield their virtues to water. The active constituents are volatile oil, and tannin of the kind which produces a greenish colour with the salts of iron.

In its operation upon the system, catnep is tonic and excitant, bearing considerable resemblance to the mints. It has had the reputation also of being antispasmodic and emmenagogue. Cats are said to be very fond of it, and it has been asserted to act as an aphrodisiac in these animals. It is employed as a domestic remedy, in the form of infusion, in amenorrhœa, chlorosis, hysteria, the flatulent colic of infants, &c.; but is little known in regular practice. Some of the older writers speak favourably of its powers. The leaves are said to relieve toothache if chewed, or held for a few minutes in contact with the diseased tooth. Two drachms of the dried leaves or herb may be given as a dose in infusion.

W.

CATECHU. *U.S.*

Catechu.

An extract prepared principally from the wood of Acacia Catechu. *U.S.*

Off. Syn. CATECHU PALLIDUM. *Pale Catechu.* An extract of the leaves and young shoots of Uncaria Gambir (Nauclea Gambir). *Br.*

Cachou, *Fr.;* Catechu, *Germ.;* Catecu, Catciu, Catto, *Ital.;* Catecu, *Span.;* Cutt, *Hindoostanee.*

The British Pharmacopœia has entirely rejected the proper catechu, which, in the former edition, was recognised under the inappropriate name of Catechu Nigrum, retaining, by the name of Catechu Pallidum, a product which, though analogous to catechu, is entirely distinct, being derived from a different plant, and known commonly by a different name, that, namely, of gambir. We treat in the text of the proper catechu, and, in a note, of gambir among the catechus not recognised by the U. S. Pharmacopœia.

Acacia. See ACACIA.

Acacia Catechu. Willd. *Sp. Plant.* iv. 1079; Woodv. *Med. Bot.* p. 433, t. 157; Carson, *Illust. of Med. Bot.* i. 32, pl. 24. According to Mr. Kerr, whose description has been followed by most subsequent writers, Acacia Catechu is a small tree, seldom more than twelve feet in height, with a trunk one foot in diameter, dividing towards the top into many close branches, and covered with a thick, rough, brown bark. The leaves, which stand alternately upon the younger branches, are composed of from fifteen to thirty pairs of pinnæ nearly two inches long, each of which is furnished with about forty pairs of linear leaflets, beset with short hairs. At the base of each pair of pinnæ is a small gland upon the

common footstalk. Two short recurved spines are attached to the stem at the base of each leaf. The flowers are in close spikes, which arise from the axils of the leaves, and are about four or five inches long. The fruit is a lanceolate, compressed, smooth, brown pod, with an undulated thin margin, and contains six or eight roundish flattened seeds, which when chewed emit a nauseous odour.

This species of Acacia is a native of the East Indies, growing abundantly in various provinces of Hindostan, and in the Burmese Empire. Pereira says that it is now common in Jamaica. Like most others of the same genus, it abounds in astringent matter, which may be extracted by decoction. Catechu is an extract from the wood of the tree.

This drug had been long known before its source was discovered. It was at first called *terra Japonica*, under the erroneous impression that it was an earthy substance derived from Japan. When ascertained by analysis to be of vegetable origin, it was generally considered by writers on the Materia Medica to be an extract of the *betel nut*, which is the fruit of a species of palm, denominated *Areca Catechu*. Its true origin was made known by Mr. Kerr, assistant surgeon of the civil hospital in Bengal, who had an opportunity of examining the tree from which it was obtained, and observing the process of extraction. According to Mr. Kerr, the manufacturer, having cut off the exterior white part of the wood, reduces the interior brown or reddish-coloured portion into chips, which he then boils in water in unglazed earthen vessels, till all the soluble matter is dissolved. The decoction thus obtained is evaporated first by artificial heat, and afterwards in the sun, till it has assumed a thick consistence, when it is spread out to dry upon a mat or cloth, being, while yet soft, divided by means of a string into square or quadrangular pieces. The account subsequently given by Dr. Royle, of the preparation of the extract in Northern India, is essentially the same The process, as he observed it, was completed by the pouring of the extract into quadrangular earthen moulds. Our countryman, the Rev. Howard Malcolm, states, in his "Travels in South Eastern Asia," that catechu is largely prepared from the wood of Acacia Catechu near Prome, in Burmah. Two kinds, he observes, are prepared from the same tree; one *black*, which is preferred in China, and the other *red*, which is most esteemed in Bengal. It is said that the unripe fruit and leaves are also sometimes submitted to decoction.

The name *catechu* in the native language signifies the *juice of a tree*, and appears to have been applied to astringent extracts obtained from various plants. According to the U. S. Pharmacopœia, however, the term is properly restricted to the extract of Acacia Catechu; as it was not intended to recognise all the astringent products which are floating in Asiatic commerce; and those from other sources than the Acacia, though they may occasionally find their way into our shops, do so as an exception to the general rule. A minute account of the diversified forms and exterior characters which officinal catechu presents as produced in different localities, would rather tend to perplex the reader than to serve any good practical purpose. These characters are, moreover, frequently changing, as the drug is procured from new sources, or as slight variations may occur in the mode of its preparation. Commerce is chiefly supplied with catechu from Bahar, Northern India, and Nepaul through Calcutta, from Canara through Bombay, and from the Burmese dominions. We derive it directly from Calcutta, or by orders from London, and it is sold in our markets without reference to its origin. It is frequently called *cutch* by the English traders, a name derived, no doubt, from the Hindoostanee word *cutt*.*

* In order not to embarrass the text unnecessarily, we have thrown together, in the form of a note, the following observations upon the varieties of catechu; those being first considered which are probably derived from *Acacia Catechu*, and, therefore, recognised as officinal in the U. S. Pharmacopœia.

1. *Officinal Catechu. U. S.*

The following, so far as we have been able to distinguish them, are the varieties of officinal catechu to be found in the markets of Philadelphia.

1. *Plano-convex Catechu. Cake Catechu.* This is in the form of circular cakes, flat on one

Properties. Catechu, as it comes to us, is in masses of different shapes, some in balls more or less flattened, some in circular cakes, some saucer-shaped, others

side, convex on the other, and usually somewhat rounded at the edge, as if the soft extract had been placed in saucers, or vessels of a similar shape, to harden. As found in the retail shops, it is generally in fragments, most of which, however, exhibit some evidences of the original form. The cakes are of various size, from two or three to six inches or more in diameter, and weighing from a few ounces to nearly two pounds. Their exterior is usually smooth and dark-brown; but we have seen a specimen in which the flat surface exhibited impressions as if produced by coarse matting. The colour internally is always brown, sometimes of a light yellowish-brown or chocolate colour, but more frequently dark reddish-brown, and sometimes almost black. The cakes are almost always more or less cellular in their interior; but in this respect great diversity exists. Sometimes they are very porous, so as almost to present a spongy appearance, sometimes compact and nearly uniform; and this difference may be observed even in the same piece. The fracture is sometimes rough and dull, but in the more compact parts is usually smooth and somewhat shining; and occasionally a piece split in one direction will exhibit a spongy fracture, while in another it will be shining and resinous, indicating the consolidation of the extract in layers. This variety of catechu is often of good quality. It is common at present in our market, but we have been unable to trace its origin accurately. There can be little doubt, from its internal character, that it comes from the East Indies, and is the product of *A. Catechu:* but no accounts that we have seen of the preparation of the drug, in particular geographical sites, indicate this particular shape; and it is not impossible that portions of it may be formed out of other varieties of catechu by a new solution and evaporation.

2. *Pegu Catechu.* This is the product derived from the Burmese dominions, and named from that section of the country whence it is exported. It enters commerce, probably in general through Calcutta, in large masses, sometimes of one cwt., consisting of layers of flat cakes, each wrapped in leaves, said to be those of the *Nauclea Brunonis.* In this form, however, we do not see it in the shops; but almost always in angular, irregular fragments, in which portions of two layers sometimes cohere with leaves between them, indicating their origin. It is characterized by its compactness, shining fracture, and blackish-brown or dark Portwine colour, so that when finely broken it bears considerable resemblance to kino. This is an excellent variety of catechu, and is not unfrequent in the shops.

3. *Catechu in Quadrangular Cakes.* This is scarcely ever found in the shops in its complete form, and the fragments are often such that it would be impossible to infer from them the original shape of the cake. This is usually between two and three inches in length and breadth, and somewhat less in thickness, of a rusty-brown colour externally, and dark-brown or brownish-gray within, with a somewhat rough and dull fracture, but, when broken across the layers in which it is sometimes disposed, exhibiting a smoother and more shining surface. Guibourt speaks of the layers as being blackish externally and grayish within, and bearing some resemblance to the bark of a tree, a resemblance, however, which has not struck us in the specimens which have fallen under our notice. There is little doubt that this variety comes from the provinces of Bahar and Northern India, where the preparation of the drug was witnessed by Mr. Kerr and Dr. Royle, who both speak of it as being brought, when drying, into the quadrangular form. It has been called *Bengal Catechu,* because exported from that province.

Pale catechu, so far as the term is not applied to *gambir,* may be considered as belonging to this variety. A specimen with this name, which was sent from India to the great London exhibition, and which we had an opportunity of examining, was in oblong rectangular pieces, or fragments of such pieces, about three and a half inches long by an inch and a half in breadth, of a dirty yellowish colour within, and an earthy fracture, quite free from gloss, and bearing a much stronger resemblance to gambir than to ordinary catechu.

4. *Catechu in Balls.* We have seen this in two forms—one consisting of globular balls about as large as an orange, very hard, and heavy, of a ferruginous aspect externally, very rough when broken, and so full of sand as to be gritty under the teeth; the other in cakes, originally, in all probability, globular, and of about the same dimensions, but flattened and otherwise pressed out of shape before being perfectly dried, sometimes adhering two together, as happens with the lumps of Smyrna opium, and closely resembling in external and internal colour, and in the character of their fracture, the quadrangular variety last described. The former kind is rare, and the specimens we have seen had been twenty years in the shop, and had very much the appearance of a factitious product. The latter is in all probability the kind known formerly as the *Bombay catechu;* as Dr. Hamilton, and, more recently, Major Mackintosh, in describing the mode of preparing catechu on the Malabar coast, of which Bombay is the entrepot, say that, while the extract is soft, it is shaped into balls about the size of an orange.

2. *Catechus not recognised as officinal in the U. S. Pharmacopœia.*

1. *Gambir. Terra Japonica. Catechu Pallidum, Pale Catechu.* Br. An astringent extract is abundantly prepared in certain parts of the East Indies, under the name of *gambir* or *gambeer,* and imported into Europe and America under that of terra Japonica. The plant from

cubical or oblong, or quite irregular, and of every grade in size, from small angular pieces, which are evidently fragments of the original cakes, to lumps

which it is obtained, called by Mr. Hunter, who first minutely described it, *Nauclea Gambir*, but by Roxburgh, De Candolle, and others, *Uncaria Gambir*, is a climbing shrub, of the class and order *Pentandria Monogynia*, and natural order *Rubiaceæ* of Jussieu, *Cinchonacea* of Lindley. It is a native of Malacca, Sumatra, Cochin-China, and other parts of Eastern Asia, and is largely cultivated in the Islands of Bintang, Singapore, and Prince of Wales. The gambir is prepared by boiling the leaves and young shoots in water, and evaporating the decoction either by artificial or solar heat. When of a proper consistence, it is spread out into flat cakes in moulds or otherwise, and then cut into small cubes, which are dried in the sun. Sometimes these cohere into a mass when packed before being quite dry.

Gambir is in cubes, with sides about an inch square, is light and porous, so that it floats when thrown in water, is deep-yellowish or reddish-brown externally, but pale-yellowish within, presents a dull earthy surface when broken, is inodorous, and has a strongly astringent, bitter, and subsequently sweetish taste. It softens and swells up when heated, and leaves a minute proportion of ashes when burnt. It is partially soluble in cold water, and almost wholly so in boiling water, which deposits a portion upon cooling. Duhamel, Ecky, and Procter dissolved 87·5 per cent. of it in cold water by means of percolation. (*Am. Journ. of Pharm.*, xvi. 166.) Nees von Esenbeck found it to consist of from 36 to 40 per cent. of tannic acid, a peculiar principle called *catechuin* or catechuic acid, gum or gummy extractive, a deposit like the cinchonic red, and 2·5 per cent. of lignin. *Catechuic acid*, when perfectly pure, is snow-white, of a silky appearance, crystallizable in fine needles, unalterable if dry in the air, fusible by heat, very slightly soluble in cold water with which it softens and swells up, soluble in boiling water which deposits it on cooling, and soluble also in alcohol and ether. It very slightly reddens litmus paper, and, though colouring the solution of chloride of iron green, and producing with it a grayish green precipitate, differs from tannic acid in not affecting a solution of gelatin. It bears considerable analogy to gallic acid in its relations to the metallic salts, but does not, according to Neubauer, bear the same relation to the tannic acid of catechu that gallic acid does to that of galls. On the contrary, instead of resulting from the oxidation of tannic acid, it is by heat converted into a substance analogous to tannin. (*Am. Journ. of Pharm.*, xxviii. 329 and 331; from *Liebig's Annalen*, xcvi. 337.) M. Barthe has stated facts tending to show that the acid is tribasic, and that it is capable of being converted into gallic acid. (*Journ. de Pharm. et de Chim.*, Oct. 1867, p. 309.) Neubauer gives the composition as $C_{17}H_{12}O_{10}$, with the loss of one eq. of water at 212° F. According to MM. Kraut and Van Delden, who are said to confirm the results of Neubauer, the composition is $C_{24}H_{12}O_{10}$ (*Chem. News*, March 17, 1865, p. 125); but the difference in the proportion of carbon would seem to be altogether incompatible with this statement; and the probability is that there has been some mistake in giving the number of eqs. of this ingredient. To prepare it, the precipitate which falls upon the cooling of the decoction of gambir is well washed upon a filter with cold water, and again dissolved in boiling water with a little purified animal charcoal. The solution being filtered and allowed to stand, gradually deposits the acid, of a snow-white colour. To obtain it perfectly white in the dry state, it must be dried under an exhausted receiver with sulphuric acid. (*Wackenroder, Annal. der Pharm.*, xxxi. 72.) The sweet taste of gambir is thought to depend on this constituent.

Several varieties of gambir are described. Sometimes it is in oblong instead of cubical pieces, without differing in other respects from the ordinary kind; sometimes in small circular cakes, or short cylindrical pieces, heavier than water, of a pale reddish-yellow colour, moderately astringent, gritty under the teeth, and quite impure; sometimes in very small cubes, distinguishable by the black colour they afford with tincture of iodine, indicating the admixture of sago, or other amylaceous matter; and, finally, in circular cakes of the size of a small lozenge flat on one side, and somewhat convex on the other, of a pale pinkish yellowish-white colour, and a chalky feel. This is most highly esteemed by the natives in India. (*Pereira.*) None of these varieties occur to any extent in our commerce.

Gambir was probably the substance first brought from the East under the name of *terra Japonica*. It is largely consumed in the East by the betel-chewers. Great quantities are imported into Europe, where it is used for tanning, calico-printing, dyeing, &c. In this country it is also largely consumed by the calico-printer. It is a strong astringent, and applicable to the same purposes as the officinal catechu.

2. *Areca Catechu.* This is obtained from the *areca nut*, or *betel nut*, which is the seed of *Areca Catechu*, a palm cultivated in all parts of India. (See *Part Third.*) It is prepared by boiling the nuts in water, and evaporating the decoction. There are two varieties; one of a black colour, very astringent, mixed with paddy husks and other impurities, and obtained by evaporating the first decoction; the other, yellowish-brown, of an earthy fracture, and pure, resulting from the evaporation of a decoction of the nuts which had been submitted to the previous boiling. The first is called *kassu*, the other *coury*. (Heyne, *Tracts, &c. on India.*) They are prepared in Mysore, and Ainslie states that both varieties are sold in the bazaars of Lower India, and used for the same purpose as the officinal catechu by the native and European practitioners. They are also much used for chewing

which weigh one or two pounds. The colour is externally of a rusty brown more or less dark, internally varying from a pale-reddish or yellowish-brown to a dark liver colour. In some specimens it is almost black, in others somewhat like the colour of Port wine, and in others again, though rarely, dull-red like annotta. The extract has been distinguished into the *pale* and *dark* varieties; but there does not appear to be sufficient ground for retaining this distinction, at least in relation to the proper catechu obtained from the wood of A. Catechu. Under the name, however, of *pale catechu*, an astringent product has been recognised in the British Pharmacopœia, the proper name of which is *gambir*, and which has a wholly different origin. This is described in a note, among the catechus not recognised by our officinal standard. (See *page* 242.) Catechu is inodorous, with an astringent and bitter taste, followed by a sense of sweetness. It is brittle, and breaks with a fracture which is rough in some specimens, in others uniform, resinous, and shining. That which is preferred in our market is of a dark colour, easily broken into small angular fragments, with a smooth glossy surface, bearing some resemblance to kino. Catechu is often mixed with sand, sticks, and other impurities. From 200 parts of Bombay catechu, Sir H. Davy obtained 109 parts of tannic acid, 68 of extractive, 13 of mucilage, and 10 of insoluble residue. The same quantity of Bengal catechu yielded 97 of tannic acid, 73 of extractive, 16 of mucilage, and 14 of insoluble residue. Other experimenters have obtained results somewhat different. The proportion of tannic acid, which may be considered the efficient principle, varies from about 30 to 55 per cent. in the different varieties of the drug. The portion designated by Davy as extractive is said to contain, if it do not chiefly consist of a principle discovered by Buchner, and now called *catechuin* or *catechuic acid*. For a particular account of this principle, the reader is referred to the note (*page* 243), on the subject of gambir (*pale catechu*, Br.), of which it is a characteristic ingredient. The *tannic acid* is of the variety which precipitates iron of a greenish-black colour, and differs from most of the other varieties in not yielding grape-sugar when digested with dilute sulphuric acid. It is not, therefore, a glucoside. It precipitates gelatin, but not tartar emetic (*Kane*), and is not, like the tannic acid of galls, converted into gallic acid by exposure to the air. It may be distinguished by the name of *catechu-tannic acid*, or, as proposed by Berzelius, *mimotannic acid*, from its source in one of the *Mimoseæ*. Catechu is almost wholly soluble in a large quantity of water, to which it imparts a brown colour. The extractive or catechuic acid is much less soluble than the astringent principle, which may be almost entirely separated from it by the frequent application of small quantities of cold water. Boiling water dissolves it much more readily than cold, and deposits it of a reddish-brown colour upon cooling. Both principles are readily dissolved by alcohol or proof spirit, and are soluble also in ether. For the important reactions of catechu, see *Acidum Tannicum*.

Medical Properties and Uses. Catechu is gently tonic, and powerfully as-

by the natives. But they are seldom exported, and it is uncertain whether they find their way into European or American commerce. Pereira thought he had identified the *kassu* with a variety of catechu derived from Ceylon, where he had been informed that an extract of the areca nut is prepared. It was in circular flat cakes, from two to three inches in diameter, scarcely an inch thick, covered on one side with paddy husks, and internally blackish-brown and shining, like Pegu catechu.

Guibourt and Pereira describe other varieties, which we have not met with, and which are probably rare. One of these is the *Siam catechu*, in conical masses shaped like a betel nut, and weighing about a pound and a half. Its fracture is shining and liver-coloured, like that of hepatic aloes; in other respects it resembles Pegu catechu. Another is the *black mucilaginous catechu* of Guibourt, in parallelopipeds, an inch and a half in length by an inch in breadth. Internally it is black and shining, and its taste is mucilaginous and feebly astringent. A third is the *dull-reddish catechu* of Guibourt, in somewhat flattened balls, weighing three or four ounces, of a dull-reddish, wavy, and often marbled fracture. We saw something like this many years since, which had been brought upon speculation by a merchant from Calcutta, but it is not now in the market. Lastly, there is a *pale* or *whitish* catechu, in small roundish or oval lumps, with an irregular surface, dark or blackish-brown externally, very pale and dull internally, and of a bitter, astringent, and sweetish taste, with a smoky flavour. It is unknown in commerce.

tringent. The dark-coloured has the latter property in a somewhat greater degree than the light, and is therefore usually preferred. The latter, being rather sweeter, is preferred by the Malays, Hindoos, and other Indians, who consume vast quantities of this extract by chewing it, mixed with aromatics and a small proportion of lime, and wrapped in the leaf of the *Piper Betel*. Catechu may be advantageously used in most cases where astringents are indicated, and, though less employed in this country than kino, is not inferior to it in virtues. The complaints to which it is best adapted are diarrhœa dependent on debility or relaxation of the intestinal exhalants, and passive hemorrhages, particularly that from the uterus. A small piece, held in the mouth and allowed slowly to dissolve, is an excellent remedy in relaxation of the uvula, and the irritation of the fauces and troublesome cough which depend upon it. Applied to spongy gums, in the state of powder, it sometimes proves useful; and it has been recommended as a dentifrice in combination with powdered charcoal, Peruvian bark, myrrh, &c. Sprinkled upon the surface of indolent ulcers, it is occasionally beneficial, and is much used in India for the same purpose, in the form of an ointment. An infusion of catechu may be used as an injection in obstinate gonorrhœa, gleet, and leucorrhœa, and we have found it highly beneficial, when thrown up the nostrils, in arresting epistaxis. The dose is from ten grains to half a drachm, which should be frequently repeated, and is best given with sugar, gum arabic, and water.*

CERA FLAVA. *U. S., Br.*

Yellow Wax.

A peculiar concrete substance prepared by Apis mellifica. *U. S.* The prepared honeycomb of the Hive Bee, Apis mellifica. *Br.*

Cire Jaune, *Fr.;* Gelbes Wachs, *Germ.;* Cera gialla, *Ital.;* Cera amarilla, *Span.*

Wax is a product of the common bee, *Apis mellifica* of naturalists, which constructs with it the cells of the comb in which the honey and larvæ are deposited. It was at one time doubted whether the insect elaborated the wax by its own organs, or merely gathered it from vegetables. The question was set at rest by Huber, who fed a swarm of bees exclusively on honey and water, and found that they formed a comb consisting of wax. This, therefore, is a proper secretion of the insect. It is produced in the form of scales under the rings of the belly. But wax also exists in plants, bearing in this, as in other respects, a close analogy to the fixed oils. It is, however, the product of the bee only that is recognised by the Pharmacopœias. This is directed in two forms: 1. that of *yellow wax* procured immediately from the comb; and 2. that of *white wax* prepared by bleaching the former. We shall consider these separately, and afterwards give an account of *vegetable wax.*

1. Cera Flava or *Yellow wax.* This is obtained by slicing the comb taken

* *Fluid Extract of Catechu.* Prof. Procter has suggested the following formula for a *fluid extract of catechu* based on the solvent power of glycerin over this extract. Eight *troyounces* of pure catechu, in moderately coarse powder, are mixed in a mortar with *four fluidounces* of glycerin so as to form a paste, to which enough diluted alcohol is added to make a pint. The liquid is poured into a bottle, shaken occasionally for twenty-four hours, and then strained through muslin. Each fluidrachm of the fluid extract represents thirty grains of catechu. (*Proceed. of Am. Pharm. Assoc.*, A.D.1863, p. 241.)—*Note to the twelfth edition.*

from the hive, draining and afterwards expressing the honey, and melting the residue in boiling water, which is kept hot for some time in order to allow the impurities to separate, and either subside or be dissolved by the water. When the liquid cools the wax concretes, and, having been removed and again melted in boiling water, is strained and poured into pans or other suitable vessels. It is usually brought to market in round flat cakes of considerable thickness The druggists of Philadelphia are supplied chiefly from the Western States and North Carolina, especially the latter, and from Cuba. Some of inferior quality is imported from Africa.

In this state, wax has a yellowish colour, an agreeable somewhat aromatic odour, and a slight peculiar taste. To the touch it is rather soft and unctuous, though of a firm solid consistence and brittle. It has a granular fracture; but when cut with a knife presents a smooth glossy surface, the lustre of which is so peculiar as, when met with in other bodies, to be called waxy. It does not adhere to the fingers, nor to the teeth when chewed, but is softened and rendered tenacious by a moderate heat. Its point of fusion is 142° F.; its specific gravity from 0·960 to 0·965. The colour, odour, and taste of yellow wax depend upon some associated principle or principles.

Various adulterations have been practised, most of which may be readily detected. Meal, earth, and other insoluble substances are at the same time discovered and separated by melting and straining the wax. When the fracture is smooth and shining instead of being granular, the presence of resin may be suspected. This is dissolved by cold alcohol, while the wax is left untouched. For other adulterating substances used, and the modes of detecting them, see the remarks which follow on white wax.

Yellow wax is used in medicine chiefly as an ingredient of plasters and cerates.

2. Cera Alba or *White Wax.* The colour of yellow wax is discharged by exposing it, with an extended surface, to the combined influence of air, light, and moisture. The process of bleaching is carried on to a considerable extent in Philadelphia. The wax, previously melted, is made to fall in streams upon a revolving cylinder, kept constantly wet, upon which it concretes, forming thin riband-like layers. These, having been removed, are spread upon linen cloths stretched on frames, and exposed to the air and light; care being taken to water and occasionally turn them. In a few days they are partially bleached; but, to deprive the wax completely of colour, it is necessary to repeat the whole process once, if not oftener. When sufficiently white, it is melted and cast into small circular cakes. The colour may also be discharged by chlorine; but the wax is said to be somewhat altered.* White wax sometimes contains one or more free fatty acids, consequent probably upon the employment of alkalies in bleaching it, which render it an unfit ingredient in the unctuous preparations of certain salts. Of these acids it may be deprived by means of alcohol.

Perfectly pure wax is white, shining, diaphanous in thin layers, inodorous, insipid, harder and less unctuous to the touch than the yellow, soft and ductile at 95° F., and fusible at about 155°, retaining its fluidity at a lower temperature. According to Saussure, its sp. gr. in the solid state is 0·966, at 178° F. 0·834, and at 201° 0·8247. By a great heat it is partly volatilized, partly decomposed; and, when flame is applied to its vapour, it takes fire and burns with a clear bright light. It is insoluble in water, and in cold alcohol or ether, but is

* The following process for purifying wax by steam has been patented by M. Cassgrand, in France, and is said to have been employed advantageously. Wax melted by steam is passed along with the steam through a coiled tube or worm, is received into a double bottom heated by steam, where it is washed with water, and is then raised by a pump into another pan, also heated by steam, where it is again washed with water; and the whole operation is repeated three or four times; the wax being allowed to rest for about four or five minutes in the upper pan after each operation, and, after the last one, an hour or two for the subsidence of impurities. The wax is then granulated by means of cold water, allowed to dry for two or three days, and then exposed to light and air. The whole process is completed in a few days. (See *Am. Journ. of Pharm.*, xxvi. 525; from *Dub. Journ. of Industrial Progress.*)—*Note to the eleventh edition.*

slightly soluble in boiling alcohol and ether, which deposit it in a great measure upon cooling. The volatile and fixed oils dissolve it with facility, resin readily unites with it by fusion, and soaps are formed by the action of soda and potassa in solution. It is not affected by the acids at ordinary temperatures, but is converted into a black mass when boiled with concentrated sulphuric acid. Its ultimate constituents are carbon, hydrogen, and oxygen. Dr. John found it to consist of two distinct principles, one of which he called *cerin*, the other *myricin*. According to MM. Boudet and Boissenot, the former constitutes at least 70 per cent. of wax, melts at about 143°, dissolves in 16 parts of boiling alcohol, and is saponifiable with potassa, yielding margaric acid, a little oleic acid, and a fatty matter insusceptible of saponification called *cerain;* the latter melts at 149°, is dissolved by 200 parts of boiling alcohol, and is not saponifiable by potassa. M. Lewy inferred from his experiments that cerin and myricin are isomeric with each other and with wax; that by a boiling solution of potassa wax is wholly saponified, without the formation of glycerin; that both wax and cerin are converted into stearic acid by saponification; and that this, by a further oxidation, is changed into margaric acid. (*Journ. de Pharm.*, 3e sér., iii. 315.) Messrs. Warington and Francis, however, have found that the substance supposed to be stearic acid, though similar to that body in appearance, is wholly different from it in properties and composition, and is isomeric, if not identical, with the cerain above referred to. (*Philos. Mag.*, Jan. 1844, p. 20.)*

White wax has been variously adulterated. *White lead* sinks to the bottom of the vessel when the wax is melted. *Starch, meal,* and other *insoluble substances* remain behind when the wax is dissolved in oil of turpentine or benzine; and the starch is known by producing a blue colour with iodine added to water in which the wax has been boiled. *Water,* which is said to be sometimes

* New views have been put forth as to the constitution of wax, in communications from B. Collins Brodie to the Royal Society of London. *Cerin*, when quite pure, he considers as a peculiar acid, having the constitution $C_{54}H_{54}O_4$, which he names *cerotic acid.* This he procures by precipitating a boiling alcoholic solution of cerin by means of an alcoholic solution of acetate of lead, treating the precipitated cerotate of lead by hot alcohol and ether until everything soluble is removed, then decomposing it with concentrated acetic acid, washing the separated cerotic acid with boiling water, and still further purifying it by solution in boiling absolute alcohol and refrigeration. The acid is deposited pure. It melts at 172° F., and on cooling concretes into a crystalline mass. When distilled alone, the greater portion of it passes unchanged; whereas, if mixed with the other constituents of wax, it is wholly decomposed; and it is, consequently, not found in the results of the distillation of wax itself. It is a singular fact that cerotic acid was not found in some beeswax brought from Ceylon, showing that wax varies much according to the circumstances under which it is produced. *Myricin*, when entirely separated from the cerotic acid, is saponifiable, but with difficulty; and from the results of saponification palmitic acid ($C_{32}H_{32}O_4$) was isolated, and a peculiar body, called by Mr. Brodie *melissine*, having the composition ($C_{60}H_{62}O_2$), and considered by him as a wax-alcohol, convertible by the loss of two eqs. of hydrogen and the gain of two of oxygen, into melissic acid, as alcohol is converted into acetic acid. (See *Acetum.*)

In the examination of a variety of wax from China, Mr. Brodie found a substance called by him *cerotine* ($C_{54}H_{56}O_2$), which he regards as the alcohol of cerotic acid, into which it was convertible by loss of hydrogen and gain of oxygen as above; that is, by oxidation, two eqs. of the hydrogen being converted into water.

According to these views, the varieties of wax are composed of substances having to each other similar relations to those which characterize alcohol and acetic acid resulting from fermentation. (*Chem. Gaz.*, vi. 225, and vii. 46.)

The *China wax*, above referred to, called *pe-la* by the Chinese, resembles spermaceti in whiteness and crystalline appearance, but is distinguished by greater hardness and friability, and a somewhat fibrous fracture. It melts at about 181° F., is very slightly soluble in alcohol or ether, is insoluble in cold oil of turpentine and rectified petroleum, but is dissolved by these fluids with the aid of heat. These solubilities distinguish it from spermaceti. (*Pharm. Journ.*, xiv. 9.) It was formerly supposed to be of vegetable origin; but has been ascertained to be the product of an insect belonging to the genus Coccus, which fixes itself to the branches of a certain tree, and, investing them closely, becomes embedded in a waxy material, which is scraped off with the insects, and constitutes the crude wax. It is purified by melting and straining. (Hanbury, *Pharm. Journ.*, xii. 476.) The tree from which the wax is obtained has been ascertained to be the Fraxinus Chinensis of Roxburgh. (*Ibid.*, Sept. 1, 1859, p. 176.)

fraudulently incorporated with it, by agitation when partially melted, is driven off by heat. *Fatty substances* render lime-water turbid, when agitated with it and allowed to stand. For the detection of stearin and stearic acid, M. Lebel dissolves the suspected wax in two parts of oil, beats the cerate thus formed with its weight of pure water, and then adds a few drops of solution of subacetate of lead. If stearin is present, there is an immediate decomposition, and the mixture acquires an extraordinary solidity from the formation of stearate of lead. (*Journ. de Pharm.*, 3e sér., xv. 302.) Vogel proposes chloroform as a means of detecting the adulteration with fatty matters. That liquid dissolves only 25 per cent. of wax, but stearin and stearic acid completely. If, therefore, wax, treated with 6 or 8 parts of chloroform, loses more than one-quarter of its weight, it may be considered as impure. (*Ibid.*, xvii. 374.) Overbeck detects stearic acid by the abundant effervescence produced from the escape of carbonic acid, when a small portion of the suspected wax is boiled in a solution, composed of one part of carbonate of soda and fifty of distilled water. (*Pharm. Journ.*, xi 128.) Fehling detects *stearic acid* and *resin* by boiling one part of the wax in twenty of alcohol, filtering the solution when cool, and then adding water. If either of these substances be present, there will be a flocculent precipitate, whereas if the wax be pure there will scarcely be an observable turbidness. The natural fats, as *tallow*, *suet*, *lard*, &c., are not amenable to this test; but it may be applied by first saponifying them, and thus converting them into the fatty acids, as the stearic. But, as wax itself is somewhat liable to be affected, it is necessary to avoid too strong an alkaline solution, and too long boiling in the process. To obviate such a result, 30 grains of the wax are to be boiled with two or three fluidounces of water containing 6 grains of pure hydrate of soda, and the mass saturated with a very dilute acid, and heated. The wax is then to be separated, dried between folds of blotting paper, and treated as above for stearic acid. (*Neues Repert. für Pharm.*, viii. 78.) To detect *paraffin*, which is another adulteration said to be frequent, Prof. Landolt, of Bonn, heats the wax with fuming sulphuric acid (*Nordhausen*), which destroys the wax, converting it into a black jelly-like mass, while the paraffin is left as a transparent layer on the surface. (See *Am. Journ. of Pharm.*, xxxiv. 35.) M. Lies Bodart detects the same impurity by a somewhat complex process, based on the etherification of the wax; the paraffin being left sufficiently pure to enable its proportion to be estimated. For the particulars of the process, the reader is referred to the *Journ. de Pharm. et de Chim.* (4e sér., iii. 287, A.D. 1866). A simpler method is that of M. Dullo, who treats the adulterated wax with ether. If this dissolves more than 50 per cent., the presence of paraffin is indicated. M. Payen resorts to the point of fusion as a means of detecting paraffin. This substance melts at a lower temperature than wax, and lowers the melting point of wax with which it is mixed. (*Ibid.*, 4e sér. ii. 233.) White wax should not melt below 150°; yellow not below 140°. (*Br.*) *Japan wax* is said also to be largely employed for adulterating beeswax; so that sometimes but little of the product of the bee is to be found in the mixture. To detect Japan wax, M. Dullo boils together for a minute 10 grammes (150 grains) of wax, 120 grammes of water, and 1 of soda. If there be Japan wax present, a soap will immediately form, which will slowly solidify on cooling. Beeswax does not saponify under these circumstances. (*Ibid.*, 4e sér., i. 448.) There are other less precise methods of detecting adulterations. Thus, spermaceti and lard render wax softer and less cohesive, of a smoother and less granular fracture, and of a different odour when heated. The melting point and specific gravity are lowered by tallow, suet, and lard. Legrip's cereometer is based upon the altered specific gravity of wax when adulterated. Any one may apply this principle by making a mixture of alcohol and water such that pure wax will neither sink nor rise in it, but remain wherever placed. Adulterated wax would either swim or sink in this liquid. Pereira says that pure wax is yellowish-white; and that the white wax in circular cakes always contains spermaceti, added to improve its colour.

Medical Properties and Uses. Wax has little effect upon the system. Under the impression that it sheathes the inflamed mucous membrane of the bowels, it has been occasionally prescribed in diarrhœa and dysentery; and it is mentioned by Dioscorides as a remedy in the latter complaint. By Pœrner it is highly recommended in excoriations of the bowels, attended with pain and obstinate diarrhœa. His mode of using it is to melt the wax with oil of almonds or olive oil, and, while the mixture is still hot, to incorporate it by means of the yolk of an egg with some mucilaginous fluid. The dose is half a drachm three or four times a day. Another method is to form an emulsion by means of soap; but it is evident that the soap would be the most energetic ingredient. Wax is also used to fill cavities in carious teeth. Its chief employment, however, is in the formation of ointments, cerates, plasters, and suppositories. It is an ingredient in almost all the officinal cerates, which owe to it their general title.

3 VEGETABLE WAX. Many vegetable products contain wax. It exists in the pollen of numerous plants, and forms the bloom or glaucous powder which covers certain fruits, and the coating of varnish with which leaves are sometimes supplied. In some plants it is so abundant as to be profitably extracted for use. Such is the *Ceroxylon Andicola*, a lofty palm growing in the South American Andes. Upon the trunk of this tree, in the rings left by the fall of the leaves, is a coating of wax-like matter, about one sixth of an inch thick, which is removed by the natives, and employed in the manufacture of tapers. It contains, according to Vauquelin, two-thirds of a resinous substance, and one-third of pure wax. Two kinds of wax are collected in Brazil, one called *carnauba*,* from the leaves of a palm growing in the province of Ceara, the other *ocuba*, from the fruit of a shrub of the province of Para. (*Journ. de Pharm.*, 3e sér , v. 154.)† But the form of vegetable wax best known in this country is that derived from *Myrica cerifera*, and commonly called *myrtle wax*. The *wax myrtle* is an aromatic shrub, from one to twelve feet high, growing in the United States from New England to Louisiana, and flourishing especially on the sea-coast. The fruit, which grows in clusters closely attached to the stems and branches, is small, globular, and covered with a whitish coat of wax, which may be separated for use. Other parts of the plant are said to possess medical virtues. The bark of the root is acrid and astringent, and in large doses emetic, and has been popularly employed in jaundice. The process for collecting the wax is simple. The berries are boiled in water, and the wax, melting and floating on the surface, is either skimmed off and strained, or allowed to concrete as the liquor cools, and then removed. To render it pure, it is again melted and strained, and cast into large cakes. It is collected in New Jersey, North Carolina, and New England, and particularly in Rhode Island.

Myrtle wax is of a pale grayish-green colour, somewhat diaphanous, more brittle and unctuous to the touch than beeswax, of a feeble odour, and a slightly

* This is obtained from *Ceroxylon carnauba* and other palms of Brazil, being found on the under surface of the leaves. It is hard, brittle, and buff-coloured, resembling the resins more than wax, and melts at 192° F., which is much higher than the fusing point of other kinds of vegetable wax. "It takes a fine polish when rubbed with any soft material," does not receive impressions from the finger at the natural temperature of the hand, and is adapted for polishing furniture, either alone or mixed with wax. (B. S. Proctor. See *Am. J. of Pharm.*, xxxv. 527.)—*Note to the twelfth edition.*

† *Japan Wax.* A substance under this name has been imported into Europe in considerable quantities, either directly from Japan, or through the Chinese ports. It is obtained from the berries of the *Rhus succedaneum* of Linnæus. It has come in two forms, the one, as originally distinguished by Mr. Hanbury, of circular cakes, about four inches in diameter, and an inch thick, flat on one side and somewhat convex on the other; the second, as brought directly from Japan, of large rectangular blocks, which are packed in chests. It bears a considerable resemblance to purified beeswax, but is not quite so white, having a slightly yellowish tint, is softer, more friable, and has a somewhat rancid smell and taste. Its melting point is below that of wax, varying from 120°, as stated by Prof. Procter, to 125°, 126°, and even 131°, as observed in different specimens by Mr. Hanbury. It is much more soluble in alcohol than beeswax, is saponifiable with the alkalies, and is said to consist of palmitic acid and glycerin. It has been employed in the preparation of candles, which yield as brilliant light as those made of common wax. It is possible that it may be found useful in the preparation of cerates, &c. (*Note to the twelfth edition.*)

bitterish taste. It is about as heavy as water, and melts, according to Mr. G. E. Moore, at from 116° to 120°. It is insoluble in water, scarcely soluble in cold alcohol, soluble, excepting about 13 per cent., in twenty parts of boiling alcohol, which deposits the greater portion on cooling, soluble also in boiling ether, and slightly so in oil of turpentine. It is readily saponifiable with the alkalies. By Dr. John it was found to consist, like beeswax, of cerin and myricin, containing 87 per cent. of the former and 13 of the latter; but a more accurate analysis by Mr. Moore gives as its constituents one part of palmitin and four of palmitic acid, with a little laurin or lauric acid. (*Am. Journ. of Sci. and Arts*, May, 1852, p. 319.) The green colour and bitterness depend upon distinct principles, which may be separated by boiling with ether. On cooling, the wax is deposited colourless, while the ether remains green. The colour is ascribed by Mr. Moore to chlorophyll.

Medical Properties and Uses. This variety of wax has been popularly employed in the United States as a remedy for dysentery; and we are told by Dr. Fahnestock that he found great advantage from its use in numerous cases, during an epidemic prevalence of that complaint. He gave the powdered wax in doses of a teaspoonful frequently repeated, mixed with mucilage or syrup. (*Am. Journ. of Med. Sci.*, ii. 313.) It is occasionally substituted by apothecaries for beeswax in the formation of plasters, and is used in the preparation of tapers and candles. It is somewhat fragrant when burning, but emits a less brilliant light than common lamp oil. W.

CERII OXALAS. *Br.*

Oxalate of Cerium.

Formula "$2CeO,C_4O_6+6HO$. A salt which may be obtained as a precipitate by adding solution of oxalate of ammonia to a soluble salt of cerium." *Br.*

Cerium is a metal, which was discovered in 1803 by Berzelius and Hisinger, and about the same time by Klaproth, who, however, described it as an earth. By the two former chemists it was recognised as a metal, and named cerium in honour of the goddess Ceres. It was obtained from a Swedish mineral, formerly from its great weight called *heavy stone of Bastnas* (Bastnas Schwerstein), but now named *cerite*, after the metal extracted from it. Besides cerite, it has been found in several other minerals, as gadalonite, orthite, &c. in the North of Europe, a number of different minerals from Greenland, and allanite near Bethlehem, in Pennsylvania. It is not easy to obtain it pure in the metallic state, as its oxides and salts are difficult of reduction. Berzelius describes it as in the form of pulverulent masses, of a deep chocolate-brown, which exhibit, however, under the burnisher a metallic appearance, and a dark gray colour. It is a bad conductor of electricity. Heated in the air it takes fire before the point of ignition, and burns vividly, passing to the state of peroxide. At ordinary temperatures it is oxidized in a moist atmosphere, giving out a strong and disagreeable smell of hydrogen. In water, especially when moderately heated, it rapidly oxidizes with the evolution of hydrogen, and the water does not become alkaline. There are two oxides of cerium, the protoxide and sesquioxide, which form salts with the acids. Sulphur and phosphorus combine with it. Of its compounds two only have been introduced into medicine, the nitrate and oxalate, of which the latter is recognised for the first time officinally in the present edition of the British Pharmacopœia.

Oxalate of cerium may be obtained from cerite, and Prof. F. F. Mayer, of New York, gives a process for the purpose of which the following is an outline.

The mineral consists of silicates of cerium, lanthanium, and didymium, with numerous substances in smaller proportion, the oxide of cerium constituting about 39 per cent. of the whole. The powdered mineral is made into a paste with sulphuric acid, and then heated over a lamp until the mass ceases to swell up, and no longer absorbs sulphuric acid very cautiously added. Upon the cooling of the mass, it is powdered, and exposed in a crucible to the heat of an anthracite fire until it assumes a pale brownish-red colour. It is now lixiviated

first with hot water and then with nitric acid, and the solution treated with sulphuretted hydrogen in order to get rid of various metals by precipitation. To the clear liquid some muriatic acid is first added, and then a solution of oxalic acid, the former of which holds in solution the oxalate of lime produced, the latter throws down oxalates of cerium and other metals. The precipitate having been washed with warm water, is formed into a paste with a quantity of carbonate of magnesia equal to half that of the mineral employed; and the paste is dried on porous fire brick, finely powdered, and calcined till it becomes of a cinnamon colour. It now contains all of the cerium in the form of peroxide. To separate this the mass is treated with an excess of nitric acid, the solution evaporated to get rid of the excess of acid, then diluted with warm water, and lastly poured into a vessel containing boiling water acidulated with a little more than half of one per cent. of sulphuric acid. A yellow precipitate of basic sulphate of peroxide of cerium is formed, while a little of the neutral sulphate, and all the lanthanium and didymium, remain dissolved. The precipitate is now dissolved in stronger sulphuric acid, the solution digested with a few crystals of hyposulphite of soda in order to reduce the peroxide of cerium to protoxide, and the liquid, having been filtered, is treated with solution of oxalic acid, which causes a precipitate of oxalate of protoxide of cerium. This is washed with warm water, and dried. (*Am. Journ. of Pharm.*, Jan. 1860, p. 4.)

Thus obtained, oxalate of cerium is a snow-white granular powder, without smell or taste, the composition of which is represented by the formula $2CeO,C_4O_6+6HO$, as stated in the British Pharmacopœia. It is insoluble in water, alcohol, or ether, but is dissolved by sulphuric acid. According to Prof. Mayer, its solution yields a precipitate with caustic alkalies, even in the presence of chloride of ammonium, which is not soluble in an excess of the precipitant. The British Pharmacopœia states that "if the salt be boiled with solution of potash and filtered, the filtrate is not affected by solution of chloride of ammonium, but, when supersaturated with acetic acid, it gives with chloride of calcium a white precipitate soluble in hydrochloric acid" When heated to dull redness it yields a reddish-brown powder, which is wholly soluble without effervescence in boiling muriatic acid, and the resulting solution gives with solution of sulphate of potassa a white crystalline precipitate. *Br.*

Medical Properties. The salts of cerium are supposed to act as a tonic, with a special influence over the nervous centres, as those of nitrate of silver, subnitrate of bismuth, sulphate of zinc, &c. But it is chiefly as a remedy in the sick stomach of pregnant women that the oxalate has been employed. Sir J. Y. Simpson, of Edinburgh, through whose authority the remedy has been brought into use, considers it the most successful remedy in that complaint that he has employed. (*Med. Times and Gaz.*, Sept. 1859, p. 280.) It is recommended also by Dr. Charles Lee, of New York, who has used it advantageously not only in the vomiting of pregnancy, but in that also of various other affections, as phthisis, hysteria, pyrosis, and atonic dyspepsia. (*Am. Journ. of Med. Sci.*, Oct. 1860, p. 393.) When in Edinburgh, in the autumn of 1860, we were informed by Prof. Simpson, that he considered oxalate of cerium as a good nervine tonic, and almost a specific in chorea. Dr. Thos. J. McKee, of Woodlawn, S C., has employed oxalate of cerium with the happiest effects in a case of obstinate vomiting connected with uterine disease, and has, besides, found it a safe, pleasant, and highly useful remedy in the derangement of stomach and bowels to which children of a certain age are so liable. He has also seen it used, with the happiest effects, in the case of a young woman affected with incessant nausea and vomiting in an attack of fever. (*N. O. Med. and Surg. Journ.*, May, 1867, p. 746.) The dose is a grain, doubled if necessary, and repeated three times a day, or more frequently if a return of the vomiting should seem to require it. It may be given in pill or suspended in water.

Nitrate of cerium has also been employed, though not officinal. Dr. Simpson believes it to act as a nervine tonic, and has seen it useful in chronic intestinal eruption, irritable dyspepsia with gastrodynia and pyrosis, and chronic vomit-

ing generally, as well as in that of pregnancy. The dose is the same as that of the oxalate, though it would be prudent to begin with a smaller quantity, as, being a soluble salt, it might be more disposed to irritate in overdoses. W.

CETACEUM. *U. S., Br.*

Spermaceti.

A peculiar concrete substance obtained from Physeter macrocephalus. *U. S.* Nearly pure cetine, obtained, mixed with oil, from the head of the Sperm Whale, Physeter macrocephalus; separated from the oil by filtration and pressure, and afterwards purified. *Br.*

Blanc de baleine, Spermaceti, Cetine, *Fr.;* Wallrath, *Germ.;* Spermaceti, *Ital.;* Esperma de bellena, *Span.*

The spermaceti whale is from sixty to eighty feet long, with an enormous head, not less in its largest part than thirty feet in circumference, and constituting one-third of the whole length of the body. The upper part of the head is occupied by large cavities, separated by cartilaginous partitions, and containing an oily liquid, which, after the death of the animal, concretes into a white spongy mass consisting of spermaceti mixed with oil. This mass is removed, and the oil allowed to separate by draining. The crude spermaceti, obtained from a whale of the ordinary size, is more than sufficient to fill twelve large barrels. It still contains much oil and other impurities, from which it is freed by expression, washing with hot water, melting, straining, and repeated washing with a weak boiling ley of potash. Common whale oil and the oil of other cetaceous animals contain small quantities of spermaceti, which they slowly deposit on standing.

Spermaceti is in white, pearly, semitransparent masses, of a crystalline foliaceous texture; friable, soft, and somewhat unctuous to the touch; slightly odorous; insipid; of the sp. gr. 0·943; fusible at 112° F. (*Bostock*), not under 100° (*Br.*); volatilizable at a high temperature without change, in *vacuo*, but partially decomposed if the air is admitted; inflammable; insoluble in water; soluble in small proportion in boiling alcohol, ether, and oil of turpentine, but deposited as the liquids cool; readily soluble in chloroform* and in the fixed oils; not affected by the mineral acids, except the sulphuric, which decomposes and dissolves it; rendered yellowish and rancid by long exposure to hot air, but capable of being again purified by washing with a warm ley of potash. As found in the shops it is not chemically pure, containing a fixed oil, and often a peculiar colouring principle. From these it is separated by boiling in alcohol, which on cooling deposits it in crystalline scales. Thus purified, it does not melt under 120° F., is soluble in 40 parts of boiling alcohol of the sp. gr. 0·821 (*Thenard*), and is harder, more shining, and less unctuous than ordinary spermaceti. The name of *cetin* was proposed for pure spermaceti by Chevreul. Its ultimate constituents are carbon, hydrogen, and oxygen. By the agency of the alkalies, it is with difficulty saponified, yielding an acid, called by MM. Dumas and Stass *ethalic acid*, and a peculiar principle named *ethal* by Chevreul. From a more recent analysis, however, by Dr. Heintz, it would appear that the ethalic acid is complex, consisting of not less than five distinct acids, viz. the margaric, palmitic, *cetic*, myristic, and cocinic, and that consequently pure spermaceti is a mixture of the salts of these acids with ethal. (*Chem. Gaz.*, x. 321.) *Ethal* is considered as bearing to a hypothetical carbohydrogen *cetyl* ($C_{32}H_{33}$) the same relation that alcohol bears to ethyl; that is, to be a hydrated oxide of cetyl, and is accordingly denominated *cetylic alcohol* ($C_{32}H_{33}O,HO$).

Medical Properties and Uses. Like the fixed oils, spermaceti has been given as a demulcent in irritations of the pulmonary and intestinal mucous membranes; but it possesses no peculiar virtues, and its internal use has been generally abandoned. It may be reduced to powder by the addition of a little alcohol or almond

* In consequence of its solubility in chloroform, stains made by dropping it on cloth may be quickly removed by this liquid. (*Note to the twelfth edition.*)

oil, or suspended in water by means of mucilage, or the yolk of eggs and sugar. A convenient mode of forming an emulsion with spermaceti, is to mix it first with half its weight of olive oil, then with powdered gum arabic, and lastly with water gradually added. Externally it is much employed as an ingredient of ointments and cerates.

CETRARIA. *U. S., Br.*

Iceland Moss.

Cetraria Islandica. *U. S.* The entire Lichen. *Br.*

Lichen d'Islande, *Fr.;* Isländisches Moos, *Germ.;* Lichene Islandico, *Ital.;* Liquen Islandico, *Span.*

CETRARIA. *Sex. Syst.* Cryptogamia Lichenes. — *Nat. Ord.* Lichenaceæ.

Gen. Ch. Plant cartilagino-membranous, ascending or spreading, lobed, smooth, and naked on both sides. *Apothecia* shield-like, obliquely adnate with the margin, the disk coloured, plano-concave; border inflexed, derived from the frond. *Loudon's Encyc.*

The genus *Lichen* of Linnæus has been divided by subsequent botanists into numerous genera, which have been raised to the dignity of a distinct order, both in the natural and artificial systems of arrangement. The name *Cetraria* has been conferred on the genus to which the Iceland moss belongs.

Cetraria Islandica. Acharius, *Lichenog. Univ.* 512. — *Lichen Islandicus.* Woodv. *Med. Bot.* p. 803, t. 271. Iceland moss is foliaceous, erect, from two to four inches high, with a dry, coriaceous, smooth, shining, laciniated frond or leaf, the lobes of which are irregularly subdivided, channeled, and fringed at their edges with rigid hairs. Those divisions upon which the fruit is borne are dilated. The colour is olive-brown or greenish-gray above, reddish at the base, and lighter on the under than the upper surface. The fructification is in flat, shield-like, reddish-brown receptacles, with elevated entire edges, placed upon the surface of the frond near its border. The plant is found in the northern latitudes of the old and new continents, and on the elevated mountains further south. It received its name from the abundance in which it prevails in Iceland. It is also abundant on the mountains and in the sandy plains of New England.

The dried moss is of diversified colour, grayish-white, brown, and red, in different parts, with less of the green tint than in the recent state. It is inodorous, and has a mucilaginous, bitter taste. Macerated in water, it absorbs rather more than its own weight of the fluid, and, if the water be warm, renders it bitter. Boiling water extracts all its soluble principles. The decoction thickens upon cooling, and acquires a gelatinous consistence, resembling that of starch in appearance, but without its viscidity. After some time the dissolved matter separates, and when dried forms semitransparent masses, insoluble in cold water, alcohol, or ether, but soluble in boiling water, and in solution forming a blue compound with iodine. This principle resembles starch in its general characters, but differs from it in some respects, and has received the distinctive name of *lichenin.* Berzelius found in 100 parts of Iceland moss 1·6 of chlorophyll, 3·0 of a peculiar bitter principle, 3·6 of uncrystallizable sugar, 3·7 of gum, 7·0 of the apotheme of extractive, 44·6 of the peculiar starch-like principle, 1·9 of the bilichenates of potassa and lime mixed with phosphate of lime, and 36·2 of amylaceous fibrin—the excess being 1·6 parts.

The name of *cetrarin* has been conferred on the bitter principle. The following process for obtaining it is that of Dr. Herberger. The moss, coarsely powdered, is boiled for half an hour in four times its weight of alcohol of 0·883. The liquid when cool is expressed and filtered, and treated with dilute muriatic acid, in the proportion of three drachms to every pound of moss employed. Water is then added in the quantity of about four times the bulk of the liquid, and the mixture left for a night in a closed matrass. The deposit which forms is

collected on a filter, allowed to drain as much as possible, and submitted to the press. To purify it, the mass, while still moist, is broken into small pieces, washed with alcohol or ether, and treated with two hundred times its weight of boiling alcohol, which dissolves the cetrarin, leaving the other organic principles by which it has hitherto been accompanied. The greater part is deposited as the liquor cools, and the remainder may be obtained by evaporation. By this process one pound of moss yielded to Dr. Herberger 133 grains of cetrarin. This principle is white, not crystalline, light, unalterable in the air, inodorous, and exceedingly bitter, especially in alcoholic solution. Its best solvent is absolute alcohol, of which 100 parts dissolve 1·7 of cetrarin at the boiling temperature. Ether also dissolves it, and it is slightly soluble in water. Its solutions are quite neutral to test paper. It is precipitated by the acids, and rendered much more soluble by the alkalies. Concentrated muriatic acid changes its colour to a bright blue. It precipitates the salts of iron, copper, lead, and silver. In the dose of two grains, every two hours, it has been used successfully in intermittent fever. (*Journ. de Pharm.*, xxiii. 505.) Drs. Schnedermann and Knopp have ascertained that the cetrarin above referred to consists of three distinct substances; 1. *cetraric acid*, which is the true bitter principle, crystallizable, and intensely bitter; 2. a substance resembling the fatty acids, called *lichstearic acid;* and 3. a green colouring substance, which they name *thallochlor*. These principles are obtained perfectly pure with great difficulty. (*Ann. der Pharm.*, lv. 144.)

The gum and starch contained in the moss render it sufficiently nutritive to serve as food for the inhabitants of Iceland and Lapland, who employ it powdered and made into bread, or boiled with milk, having first partially freed it from the bitter principle by repeated maceration in water. The bitterness may be entirely extracted by macerating the powdered moss, for 24 hours, in twenty-four times its weight of a solution formed with 1 part of an alkaline carbonate and 375 parts of water, then decanting the liquid, and repeating the process with an equal quantity of the solution. The powder, being now dried, is perfectly sweet and highly nutritious. This process was suggested by Berzelius.

Medical Properties and Uses. Iceland moss is demulcent, nutritious, and tonic, and well calculated for affections of the mucous membrane of the lungs and bowels, with debility of the digestive organs, or of the system generally. Hence it has been found useful in chronic catarrhs, and other chronic pulmonary affections attended with copious puruloid expectoration, in dyspepsia, in chronic dysentery and diarrhœa, and in the debility succeeding acute disease, or dependent on copious purulent discharge from external ulcers. At one time it possessed much reputation as a remedy in pulmonary consumption. It had long been employed in this disease, and in hæmoptysis, by the Danish physicians, before it became generally known. In the latter half of the last century it came into extensive use, and numerous cures supposed to have been effected by it are on record. But now that the pathology of phthisis is better understood, physicians have ceased to expect material advantage from it in that disease; and there is reason to believe that the cases which have recovered under its use, were simply chronic bronchitis. It acts only as a mild, nutritious, demulcent tonic; and can exercise no specific influence over the tuberculous affection.

It is usually employed in the form of decoction. (See *Decoctum Cetrariæ.*) By some writers it is recommended to deprive it of the bitter principle by maceration in water or a weak alkaline solution, before preparing the decoction; but we thus reduce it to the state of a simple demulcent, or mild article of diet, in which respect it is not superior to the ordinary farinaceous or gummy substances used in medicine. The powder is sometimes given in the dose of thirty grains or a drachm; and a preparation at one time obtained some repute, in which the ground moss was incorporated with chocolate, and used at the morning and evening meal as an ordinary beverage.

Off. Prep. Decoctum Cetrariæ. W.

CHENOPODIUM. *U. S.*

Wormseed.

The fruit of Chenopodium anthelminticum. *U. S.*

Chenopodium. *Sex. Syst.* Pentandria Digynia. — *Nat. Ord.* Chenopodiaceæ. *Gen. Ch. Calyx* five-leaved, four-cornered. *Corolla* none. *Seed* one, lenticular, superior. *Willd.*

Chenopodium anthelminticum. Willd. *Sp. Plant.* i. 1304; Barton, *Med. Bot.* ii. 183. This is an indigenous perennial plant, with an herbaceous, erect, branching, furrowed stem, which rises from two to five feet in height. The leaves are alternate or scattered, sessile, oblong-lanceolate, attenuated at both ends, sinuated and toothed on the margin, conspicuously veined, of a yellowish-green colour, and dotted on their under surface. The flowers are very numerous, small, of the same colour with the leaves, and arranged in long, leafless, terminal panicles, composed of slender, dense, glomerate, alternating spikes.

This species of Chenopodium, known commonly by the names of *wormseed* and *Jerusalem oak*, grows in almost all parts of the United States, but most vigorously and abundantly in the southern section. It is usually found in the vicinity of rubbish, along fences, in the streets of villages, and in open grounds about the larger towns. It flowers from July to September, and ripens its seeds successively through the autumn. The whole herb has a strong, peculiar, offensive, yet somewhat aromatic odour, which it retains when dried. All parts of the plant are occasionally employed; but the fruit only is strictly officinal. This should be collected in October.*

Wormseed, as found in the shops, is in small grains, not larger than the head of a pin, irregularly spherical, very light, of a dull, greenish-yellow, or brownish colour, a bitterish, somewhat aromatic, pungent taste, and possessed in a high degree of the peculiar smell of the plant. These grains, when deprived, by rubbing them in the hand, of a capsular covering which invests the proper seed, exhibit a shining surface of a very dark colour. They abound in a volatile oil, upon which their sensible properties and medical virtues depend, and which is obtained by distillation. (See *Oleum Chenopodii.*) The same oil impregnates to a greater or less extent the whole plant.

Medical Properties and Uses. Wormseed is one of our most efficient indigenous anthelmintics, and is thought to be particularly adapted to the expulsion of the round worms in children. A dose of it is usually given before breakfast in the morning, and at bedtime in the evening, for three or four days successively, and then followed by calomel or some other brisk cathartic. If the worms are not expelled, the same plan is repeated. The medicine is most conveniently administered in powder, mixed with syrup, in the form of an electuary. The dose for a child two or three years old is from one to two scruples. The volatile oil is more frequently given than the fruit in substance; though its offensive odour and taste sometimes render it of difficult administration. The dose for a child is from five to ten drops, mixed with sugar, or in the form of emulsion. A tablespoonful of the expressed juice of the leaves, or a wineglassful of the decoction prepared by boiling an ounce of the fresh plant in a pint of milk, with the addition of orange-peel or other aromatic, is sometimes substituted in domestic practice for the ordinary dose of the fruit and oil.

The fruit of *Chenopodium ambrosioides*, which is also an indigenous plant,

* C. anthelminticum is cultivated to a considerable extent in Maryland, twenty or thirty miles north of Baltimore. The seeds are sown in small beds of rich mould early in spring, and during the month of June the young plants are pulled up, and set out in ridges three feet apart, with intervals of from six to ten inches. The plants do not require to be renewed oftener than once in four or five years. The crop of the second year is more productive than the first. The plant is fit for distillation during the first half of September. The distillation is carried on in the same neighbourhood. The whole herbaceous part of the plant is used. It is said to yield from 1·5 to 2 per cent. of the oil, and the produce of an acre will yield 20 pounds. (See *Am. Journ. of Pharm.* xxii. 304.)

and very prevalent in the Middle States, is said to be used indiscriminately with that of *C. anthelminticum*. It may be distinguished by its odour, which is weaker and less offensive, and to some persons agreeable. The plant itself is often confounded with the true wormseed, from which it differs in having its flowers in leafy racemes. This species of Chenopodium has been employed in Europe as a remedy in nervous affections, particularly chorea. Five or six cases of this disease, reported by Plenk, after having resisted the ordinary means, yielded to the daily use of an infusion of two drachms of the plant in ten ounces of water, taken in the dose of a cupful morning and evening, and associated with the employment of peppermint.

C. Botrys, known by the vulgar name of *Jerusalem oak*, is another indigenous species, possessing anthelmintic virtues. It is said to have been used in France with advantage in catarrh and humoral asthma.

Off. Prep. Oleum Chenopodii, *U. S.* W.

CHIMAPHILA. *U. S.*

Pipsissewa.

The leaves of Chimaphila umbellata. *U. S.*

Chimaphila. *Sex. Syst.* Decandria Monogynia. — *Nat. Ord.* Pyrolaceæ.

Gen. Ch. Calyx five-toothed. *Petals* five. *Style* very short, immersed in the germ. *Stigma* annular, orbicular, with a five-lobed disk. *Filaments* stipitate; stipe discoid, ciliate. *Capsules* five-celled, opening from the summits, margins unconnected. *Nuttall.*

This genus was separated from *Pyrola* by Pursh. It embraces two species, *C. umbellata* and *C. maculata*, which are both indigenous, and known by the common title of *winter-green*. The generic title is formed of two Greek words, χειμα winter, and φιλος a friend. *C. umbellata* only is officinal.

Chimaphila umbellata. Barton, *Med. Bot.* i. 17; Carson, *Illust. of Med. Bot.* i. 62, pl. 53. — *Pyrola umbellata.* Willd. *Sp. Plant.* ii. 622; Bigelow, *Am. Med. Bot.* ii. 15. The pipsissewa is a small evergreen plant, with a perennial, creeping, yellowish root (rhizoma), which gives rise to several simple, erect or semi-procumbent stems, from four to eight inches in height, and ligneous at their base. The leaves are wedge-shaped, somewhat lanceolate, serrate, coriaceous, smooth, of a shining, sap-green colour on the upper surface, paler beneath, and supported upon short footstalks, in irregular whorls, of which there are usually two on the same stem. The flowers are disposed in a small terminal corymb, and stand upon nodding peduncles. The calyx is small and divided at its border into five teeth or segments. The corolla is composed of five roundish, concave, spreading petals, which are of a white colour tinged with red, and exhale an agreeable odour. The stamens are ten, with filaments shorter than the petals, and with large, nodding, bifurcated, purple anthers. The germ is globular and depressed, supporting a thick and apparently sessile stigma, the style being short and immersed in the germ. The seeds are numerous, linear, chaffy, and enclosed in a roundish, depressed, five-celled, five-valved capsule, having the persistent calyx at the base.

This humble but beautiful evergreen is a native of the northern latitudes of America, Europe, and Asia. It is found in all parts of the United States, extending even to the Pacific Ocean. It grows under the shade of woods, and prefers a loose sandy soil, enriched by decaying leaves. The flowers appear in June and July. All parts of the plant are endowed with active properties. The leaves and stems are kept in the shops.

C. maculata, or *spotted winter-green*, probably possesses similar virtues. The character of the leaves of the two plants will serve to distinguish them. Those of C. maculata are lanceolate, rounded at the base, where they are broader than near the summit, and of a deep olive-green, veined with greenish-white; those of the officinal species are broadest near the summit, gradually narrowing to the base, and of a uniform shining green.

Properties. Pipsissewa, when fresh and bruised, exhales a peculiar odour. The taste of the leaves is pleasantly bitter, astringent, and sweetish; that of the stems and root unites with these qualities a considerable degree of pungency. Boiling water extracts the active properties of the plant, which are also imparted to alcohol. The leaves have been examined by Mr. Samuel Fairbank, who found in them gum, starch, sugar, extractive, pectic acid, tannic acid, resin, fatty matter, chlorophyll, yellow colouring matter, lignin, a peculiar whitish substance which he calls chimaphilin, and various inorganic substances, as potassa, lime, magnesia, chloride of sodium, and sulphuric, phosphoric, and silicic acids. The *chimaphilin* was obtained by agitating a tincture with chloroform, allowing the mixture to stand, removing the lighter liquid, and allowing the chloroformic solution to evaporate. A yellow crystalline substance was left, which, purified by solution in alcohol, filtration, and spontaneous evaporation, constituted the substance in question. It was also obtained by simply distilling the stems with water. It is in beautiful, golden-yellow, acicular crystals, inodorous, tasteless, fusible, volatilizable unchanged, insoluble or nearly so in water, soluble in alcohol, ether, chloroform, and the fixed and volatile oils, and possessed of neither acid nor alkaline properties. (*Journ. and Trans. of the Md. Col. of Pharm.*, March, 1860.) The active principle of the leaves does not appear to have been isolated, though probably contained in the substance called bitter extractive. The so-named chimaphilin has no claims to this character, nor, we think, to the name given to it, which should be reserved for the active principle when discovered. The pungency of the stems is said by Mr. Fairbank to reside in the resin.

Medical Properties and Uses. This plant is diuretic, tonic, and astringent. It was employed by the aborigines in various complaints, especially scrofula, rheumatism, and nephritic affections. From their hands it passed into those of the European settlers, and was long a popular remedy in certain parts of the country, before it was adopted by the profession. The first regular treatise in relation to it that has come to our knowledge, was the thesis of Dr. Mitchell, published in the year 1803; but it was little thought of till the appearance of the paper of Dr. Sommerville, in the 5th volume of the London Medico-chirurgical Transactions. By this writer it was highly recommended as a remedy in dropsy; and his favourable report has been sustained by the subsequent statements of many practitioners. It is particularly useful in cases attended with disordered digestion and general debility, in which its tonic properties and usual acceptability to the stomach prove highly useful auxiliaries to its diuretic powers. Nevertheless, it cannot be relied on exclusively in the treatment of the complaint; for, though it generally produces an increased flow of urine, it has seldom effected cures. Other disorders, in which it is said to have proved useful, are calculous and nephritic affections, and in general all those complaints of the urinary passages for which uva ursi is prescribed. It is much esteemed by some practitioners as a remedy in scrofula, both before and after the occurrence of ulceration; and it has certainly proved highly advantageous in obstinate ill-conditioned ulcers and cutaneous eruptions, supposed to be connected with the strumous diathesis. In these cases it is used both internally, and locally as a wash.

The decoction is the preparation usually preferred, and may be taken to the amount of a pint in twenty-four hours. The watery extract may be given in the dose of twenty or thirty grains four times a day. Prof. Procter prepares a syrup by macerating four ounces of the leaves, finely bruised, in eight fluidounces of water for thirty-six hours, and then subjecting the mass to percolation till a pint of fluid is obtained, which is reduced one-half by evaporation, and incorporated with twelve ounces of sugar. One or two tablespoonfuls may be given for a dose. Prof. Procter has suggested also a fluid extract, prepared in the same manner as the saccharine fluid extracts of the U. S. Pharmacopœia, especially that of uva ursi. A fluidrachm of it would represent a drachm of pipsissewa.

Off. Prep. Decoctum Chimaphilæ, *U. S.* W.

CHIRETTA. *U. S.*

Chiretta.

The herb and root of Agathotes Chirayta. *U. S.*

Off. Syn. CHIRATA. *Chiretta.* The entire plant, Ophelia Chirata. *Br.* AGATHOTES. *Sex. Syst.* Pentandria Monogynia.—*Nat. Ord.* Gentianaceæ.

Gen. Ch. Corolla withering, rotate, in æstivation twisted to the right; with glandular hollows protected by a fringed scale upon the segments. *Anthers* not changing. *Stigmas* sessile. *Capsules* conical; one-celled, with spongy placentæ upon the sutures. *Seeds* indefinite, minute. (*Lindley.*)

Agathotes Chirayta. Don, *Lond. Philos. Mag.* 1836, p. 76.—*Gentiana Chirayta.* Fleming, *Asiat. Research.* xi. 167.—*Ophelia Chirata.* Grisbach. The *chirayta* or *chiretta* is an annual plant, about three feet high, with a branching root, and an erect, smooth, round stem, branching into an elegant leafy panicle, and furnished with opposite, embracing, lanceolate, very acute, entire, smooth, three or five-nerved leaves. The flowers are numerous, peduncled, yellow, with a four-cleft calyx having linear acute divisions, the limb of the corolla spreading and four-parted, four stamens, a single style, and a two-lobed stigma. The capsules are shorter than the permanent calyx and corolla. The plant is a native of Nepaul, and other parts of northern India. The whole of it is officinal. It is gathered when the flowers begin to decay.

The dried plant is imported into Europe in bundles, consisting mainly of the stems, with portions of the root attached. The stems, which have been already described, contain a yellowish pith. All parts of the plant have a very bitter taste, which is strongest in the root. It is without odour. It imparts its virtues to water and alcohol; and they are retained in the extract. According to Lassaigne and Boissel, the stems contain resin, a yellow bitter substance, brown colouring matter, gum, and various salts.

Medical Properties and Uses. Chiretta has long been used in India. It has been introduced into Europe, and appears to be highly esteemed; but has not been employed to any considerable extent in this country. Its properties are those of the pure bitters, and probably do not differ from those of the other members of the family of Gentianaceæ. (See *Gentiana.*) Like these, in overdoses it nauseates and oppresses the stomach. Some have supposed that, in addition to its tonic properties, it exerts a peculiar influence over the liver, promoting the secretion of bile and correcting it when deranged, and restoring healthy evacuations in cases of habitual costiveness. But it may well be doubted whether it produces any other effects of this kind than such as are incident to its tonic power. It has been used in dyspepsia, and in the debility of convalescence, and generally in cases in which corroborant measures are indicated. In India it has been successfully employed in intermittents and remittents, combined with the seeds of *Guilandina Bonduc.* It may be given in powder, infusion, tincture, or extract. The dose in substance is twenty grains. A fluid extract may be made in the same manner as that of gentian.

CHLOROFORMUM VENALE. *U. S.*

Commercial Chloroform.

In the U. S. Pharmacopœia of 1850 a process was given for the preparation of chloroform; in the present edition, the drug, in its impure commercial form, has been placed in the Materia Medica Catalogue, while a process is given in the second part of the work for its purification. Thinking it expedient that what is to be said on the subject should all be included under the same head, we refer the reader to the article Chloroformum Purificatum in Part II.

Off. Prep. Chloroformum Purificatum, *U. S.* B.

CHONDRUS. *U. S.*

Irish Moss.

Chondrus crispus. *U. S.*

CHONDRUS. *Sex. Syst.* Cryptogamia Algæ. — *Nat. Ord.* Algaceæ.

Gen. Ch. Frond cartilaginous, dilating upwards into a flat, nerveless dichotomously divided expansion, of a purplish or livid-red colour. *Fructification*, subspherical capsules in the substance of the frond, rarely supported on little stalks, and containing a mass of minute free seeds. *Greville.*

Chondrus crispus. Greville, *Alg. Brit.* 129, t. 15. — *Sphærococcus crispus.* Agardh. — *Fucus crispus.* Linn. The *Irish moss*, or *carrageen* as it is frequently called, consists of a flat, slender, cartilaginous frond, from two to twelve inches in length, dilated as it ascends until it becomes two or three lines in width, then repeatedly and dichotomously divided, with linear, wedge-shaped segments, and more or less curled up so as to diminish the apparent length. The capsules are somewhat hemispherical, and are embedded in the disk of the frond. The plant grows upon rocks and stones on the coast of Europe, and is especially abundant on the southern and western coasts of Ireland, where it is collected. It is also a native of the United States, and is said to be gathered largely on the southern sea-coast of Massachusetts, where it is partly torn from the rocks, and partly collected upon the beach, on which it is thrown up during storms. It is prepared for market by spreading it out high on the beach, to dry and bleach in the sun. (Aug. P. Melzar, *Proceed. of Am. Pharm. Assoc.*, A.D. 1860.)

When collected, it is washed and dried. In the fresh state it is of a purplish colour, but, as found in the shops, is yellowish or yellowish-white, with occasionally purplish portions. It is translucent, of a feeble odour, and nearly tasteless. It swells in cold water but does not dissolve. Boiling water dissolves a large proportion of it, and the solution, if sufficiently concentrated, gelatinizes on cooling. According to Feuchtwanger, it contains starch and pectin, with compounds of sulphur, chlorine, and bromine, and some oxalate of lime. Herberger found 79·1 per cent. of pectin, and 9·5 of mucus, with fatty matter, free acids, chlorides, &c., but neither iodine nor bromine. M. Dupasquier discovered in it both of these elements, which had generally escaped attention in consequence of their reaction, as soon as liberated, upon the sulphuret of sodium resulting from the decomposition of the sulphate of soda of the moss when charred. (*Journ. de Pharm.*, 3e sér., iii. 113.) The pectin Pereira thinks peculiar, and proposes to call *carrageenin*. It is distinguished from gum by affording, when dissolved in water, no precipitate with alcohol; from starch, by not becoming blue with tincture of iodine; from pectin, by yielding no precipitate with acetate of lead, and no mucic acid by the action of nitric acid. M. Ch. Blondeau gives the name of *goëmine* to a substance obtained by boiling carrageen (goëmon, *Fr.*) for several hours in distilled water, and precipitating the mucilaginous liquid by alcohol. The precipitate, being redissolved in water, yields on evaporation thin, transparent, elastic plates, resembling ichthyocolla, which soften and swell up on contact with cold water. This substance, which is probably complex, is without smell or taste, neutral to test-paper, and dissolves completely in alkaline liquids. Upon analysis, it gave 21·80 per cent. of carbon, 4·87 of hydrogen, 21·36 of nitrogen, 2·51 of sulphur, and 49·46 of oxygen. The most noteworthy point is the large proportion of nitrogen, exceeding that of most albuminoid substances, and probably giving highly nutritious properties to the Irish moss (*Journ. de Pharm. et de Chim.*, 4e sér., ii. 159, A.D. 1865.)

Carrageen is nutritive and demulcent, and, being easy of digestion and not unpleasant to the taste, forms a useful article of diet in cases in which the farinaceous preparations, such as tapioca, sago, barley, &c., are usually employed. It has been particularly recommended in chronic pectoral affections, scrofulous complaints, dysentery, diarrhœa, and disorders of the kidneys and bladder. It

may be used in the form of decoction, made by boiling a pint and a half of water with half an ounce of the moss down to a pint. Sugar and lemon-juice may usually be added to improve the flavour. Milk may be substituted for water, when a more nutritious preparation is required. It is recommended to macerate the moss for about ten minutes in cold water before submitting it to decoction. Any unpleasant flavour that it may have acquired from the contact of foreign substances is thus removed. W.

CIMICIFUGA. *U. S.*

Cimicifuga. Black Snakeroot.

The root of Cimicifuga racemosa. *U. S.*

CIMICIFUGA. *Sex. Syst.* Polyandria Di-Pentagynia.—*Nat. Ord.* Ranunculaceæ.

Gen. Ch. Calyx four or five-leaved. *Petals* four to eight, deformed, thickish, sometimes wanting. *Capsules* one to five, oblong, many-seeded. *Seeds* squamose. *Nuttall.*

Cimicifuga racemosa. Torrey, *Flor.* 219; Carson, *Illust. of Med. Bot.* i. 9, pl. 3.—*C. Serpentaria.* Pursh, *Flor. Am. Sept.* p. 372.—*Actæa racemosa.* Willd. *Sp. Plant.* ii. 1139.—*Macrotys racemosa.* Eaton's *Manual*, p. 288. This is a tall stately plant, having a perennial root, and a simple herbaceous stem, which rises from four to eight feet in height. The leaves are large, and ternately decomposed, having oblong-ovate leaflets, incised and toothed at their edges. The flowers are small, white, and disposed in a long, terminal, wand-like raceme, with occasionally one or two shorter racemes near its base. The calyx is white, four-leaved, and deciduous; the petals are minute, and shorter than the stamens; the pistil consists of an oval germ and sessile stigma. The fruit is an ovate capsule containing numerous flat seeds.

The *black snakeroot*, or *cohosh* as this plant is sometimes called, is a native of the United States, growing in shady or rocky woods from Canada to Florida, and flowering in June and July. The root is the part employed.

Properties. The dried root consists of a thick, irregularly bent or contorted body or caudex, from one-third of an inch to an inch in thickness, often several inches in length, furnished with many slender radicles, and rendered exceedingly rough and jagged in appearance by the remains of the stems of successive years, which to the length of an inch or more are frequently attached to the root. The colour is externally dark-brown, almost black, internally whitish; the odour, though not strong, is peculiar and rather disagreeable, and is gradually lost by keeping; the taste is bitter, herbaceous, and somewhat astringent, leaving a slight sense of acrimony. The root yields its virtues to boiling water. It was found by Mr. Tilghman, of Philadelphia, to contain gum, starch, sugar, resin, wax, fatty matter, tannic and gallic acids, a black colouring matter, a green colouring matter, lignin, and salts of potassa, lime, magnesia, and iron. (*Journ. of Phil. Col. of Pharm.*, vi. 20.) It no doubt also contains, when fresh, a volatile principle, with which its virtues may be in some degree associated; as we are confident that it is more efficacious in the recent state, than when long kept. In fact, Mr. Geo. H. Davis, in a more recent analysis, has separated by distillation a small proportion of volatile oil, having decidedly the peculiar odour of the root. Mr. Davis also found, in addition to the principles above mentioned, albumen and extractive among the organic, and silica among the inorganic constituents. The sugar, moreover, noticed by him was of the uncrystallizable variety, and the resin of two kinds, one soluble in alcohol but not in ether, the other soluble in both these menstrua. (*Am. Journ. of Pharm.*, xxxiii. 396.)

Medical Properties and Uses. The effects of cimicifuga in health have not been fully investigated. It was at one time considered a mild tonic, with the property of stimulating the secretions, particularly those of the skin, kidneys, and bronchial mucous membrane; and has been thought by some to have an especial affinity for the uterus. It undoubtedly exercises considerable influence over the nervous system, probably of a sedative character; but this influence, so

far as our observation has gone, is shown more in morbid states of that system than in health. Dr. Hildreth, of Ohio, found it, in large doses, to produce vertigo, impaired vision, nausea and vomiting, and a reduction of the circulation; but from very large quantities he observed no alarming narcotic effects. Dr. N. S. Davis uniformly found it to lessen the force and frequency of the pulse, to soothe pain, and allay irritability. (*Trans. of Am. Med. Assoc.*, i. 352.) Its common name was probably derived from its supposed power as an antidote to the bite of the rattlesnake. It was originally employed in domestic practice in rheumatism, dropsy, hysteria, and various affections of the lungs, particularly those resembling consumption. The first published notice of its use in phthisis was by Dr. Thomas J. Garden, of Charlotte, Virginia. (*Am. Med. Recorder*, October, 1823.) Several cases of chorea were recorded by Dr. Jesse Young, in which it effected cures; and the editor of the *Am. Journ. of the Med. Sciences* stated that he had been informed by Dr. Physick that he had known it, in the dose of ten grains every two hours, to prove successful in the cure of that complaint in several instances. Dr. Young gave a teaspoonful of the powdered root three times a day. (*Am. Journ. of Med. Sci.*, ix. 310.) We have administered the medicine in chorea with complete success, and have derived the happiest effects from it in a case of periodical convulsions connected with uterine disorder. Dr. Hildreth has found it, in combination with iodine, very advantageous in the early stages of phthisis. (*Ibid.*, N. S., iv. 281.) Dr. F. N. Johnson has employed it with extraordinary success in acute rheumatism; the disease generally yielding completely within eight or ten days. (*Trans. of Am. Med. Assoc.*, i. 352.)

It may be given in substance, decoction, tincture, or extract. The dose of the powder is from a scruple to a drachm. The *decoction* has been much used, but is thought by some not to contain all the virtues of the root. An ounce of the bruised root may be boiled for a short time in a pint of water, and one or two fluidounces given for a dose. From half a pint to a pint of the decoction may be taken without inconvenience during the day. The *tincture* may be made in the proportion of four ounces to the pint of diluted alcohol, and given in the dose of one or two fluidrachms. In acute rheumatism, the remedy is recommended by Dr. Davis, in the dose of from thirty to sixty drops of the tincture, or twenty grains of the powder, repeated every two hours till its effects are observed. (*Ibid.*, p. 356.) Dr. Brundige speaks, in the strongest terms, of the efficacy of a saturated tincture of the dried root, as an application about the eye, and to the outer surface of the eyelids in ophthalmia. (*Med. Exam.*, N. S., vii. 809; from the *N. Y. Med. Gaz.*) Dr. Kœhler, of Schuylkill Haven, Pa., after failing with the decoction and simple tincture in the treatment of chorea, succeeded satisfactorily with an *acetous tincture*, made by digesting, for fourteen days, five ounces of the root with a menstruum consisting of one fluidounce of diluted acetic acid, eight of alcohol, and eleven of water. The dose is the same as that of the simple tincture. (*N. Am. Med.-chir. Rev.*, iii. 189.) A *fluid extract* is now officinal; and a *dry extract* has been prepared by Professor Procter. The dose of the former is from 30 to 60 minims, of the latter from 4 to 8 grains.* The practitioners calling themselves eclectics use, under the name of *cimicifugin*, an impure resin obtained by precipitating a saturated tincture of the root with water. It is given in the dose of a grain or two. The name, however, is inappropriate, as it should be reserved for the pure active principle when discovered. (See *N. J. Med. Reporter*, viii. 247.)

Off. Prep. Extractum Cimicifugæ Fluidum, *U. S.* W.

* The dry extract is prepared in the following manner. Sixteen ounces of the recently dried root, in powder, are put into a percolator for volatile liquids, and a mixture of a pint of alcohol and half a pint of ether is gradually added. After the liquid has ceased to pass, diluted alcohol is poured in until the filtered liquid equals a pint and a half, which is set aside in a warm place, and allowed to evaporate spontaneously until reduced to half a pint. The percolation is continued with diluted alcohol until two pints of tincture are obtained. The two tinctures are evaporated separately to the consistence of syrup, then mixed, and carefully evaporated to dryness by means of a water-bath. (*Am. Journ. of Pharm.*, xxvi. 107.)—*Note to the eleventh edition.*

Botanical History.

Though the Peruvian bark was introduced into Europe so early as 1640, it was not till the year 1737 that the plant producing it was known to naturalists. In that year La Condamine, on a journey to Lima, through the province of Loxa, had an opportunity of examining the tree, of which, upon his return, he published a description in the Memoirs of the French Academy. Soon afterwards Linnæus gave it the name of *Cinchona officinalis*, in honour of the Countess of Cinchon, who is said to have first taken the bark to Europe; but, in his description of the plant, he united the species discovered by La Condamine with *C. pubescens*, a specimen of which had been sent to him from Santa Fé de Bogota. For a long time it was not known that more than one species existed; and C. officinalis continued, till a comparatively recent period, to be recognised by the Pharmacopœias as the only source of the Peruvian bark of commerce. But a vast number of plants belonging to the Linnæan genus Cinchona were in the course of time discovered; and the list became at length so unwieldy and heterogeneous, that botanists were compelled to distribute the species into seve-

* The British Pharmacopœia gives the following methods of testing these varieties.

1. "*Test of Yellow Cinchona.* Boil 100 grains of the bark, reduced to very fine powder, for a quarter of an hour, in a fluidounce of distilled water acidulated with ten minims of hydrochloric acid; and allow it to macerate for twenty-four hours. Transfer the whole to a small percolator, and, after the fluid has ceased to percolate, add at intervals about an ounce and a half of similarly acidulated water, or until the fluid which passes through is free from colour. Add to the percolated fluid solution of subacetate of lead until the whole of the colouring matter has been removed, taking care that the fluid remains acid in reaction. Filter, and wash with a little distilled water. To the filtrate add about thirty-five grains of caustic potash, or so much as will cause the precipitate which is at first formed to be nearly redissolved, and afterwards six fluidrachms of pure ether. Then shake briskly, and, having removed the ether, repeat the process twice with three fluidrachms of ether, or until a drop of the ether employed leaves on evaporation scarcely any perceptible residue. Lastly, evaporate the mixed ethereal solutions in a capsule. The residue, which consists of nearly pure quinia, when dry, should weigh not less than two grains, and should be readily soluble in diluted sulphuric acid.

2. "*Test for Pale Cinchona.* Two hundred grains of the bark, treated in the manner directed in the test for yellow cinchona bark, with the substitution of chloroform for ether, should yield not less than one grain of alkaloids.

3. "*Test for Red Cinchona.* One hundred grains of the bark, treated in the manner directed in the test for yellow cinchona, with the substitution of chloroform for ether, should yield not less than 1·5 grain of alkaloids." *Br.* (*Note to the thirteenth edition.*)

ral groups, each constituting a distinct genus, and all associated in the natural family of Cinchonaceæ. Among these genera, the *Cinchona* is that which embraces the true Peruvian bark trees, characterized by the production of the alkaloids, quinia, cinchonia, &c., as well as by certain botanical peculiarities, among which the most distinctive is probably the dehiscence of the capsule from the base towards the apex, or from below upward. The new genera *Exostemma* and *Buena* embrace species which have been, perhaps, most frequently referred to as Cinchonas; but they are sufficiently characterized, the former by the projection of the stamens beyond the corolla, a peculiarity which has given name to the genus, the latter by the different shape of the corolla, the separation of the calyx from the fruit at maturity, and the opening of the capsule from above downward. More recently Weddell has separated several generally admitted species from Cinchona, and instituted a new genus, which he proposes to name *Cascarilla*. This includes the former *Cinchona magnifolia* of Ruiz and Pavon (*C. oblongifolia* of Mutis), the *C. stenocarpa* of Lambert, the *C. acutifolia* of Ruiz and Pavon, the *C. oblongifolia* of Lambert, the *C. macrocarpa* of Vahl, and the *C. cava* of Pavon, which differ from the true Cinchona in having the dehiscence of the capsules from the apex towards the base, or from above downward, and the barks of which contain neither of the alkaloids above referred to. (Weddell, *Hist. Nat. des Quinquinas*, p. 77.) With this brief preliminary notice, we shall proceed to consider the true Cinchonas. It may be proper, however, first to say, that the botanists who have personally observed these plants, besides *La Condamine*, of whom we have before spoken, are chiefly *Joseph de Jussieu*, who in the year 1739 explored the country about Loxa, and gathered specimens still existing in the cabinets of Europe; *Mutis*, who in 1772 discovered Cinchona trees in New Granada, and afterwards, aided by his pupil *Zea*, made further investigations and discoveries in the same region; *Ruiz* and *Pavon*, who in 1777 began a course of botanical inquiries in the central portions of Lower Peru, and discovered several new species; *Humboldt* and *Bonpland*, who visited several of the Peruvian bark districts, and published the results of their observations after 1792; *Pöppig*, who travelled in Peru so late as 1832, and published an account of his journey about the year 1835; and finally *Weddell*, whose researches in Bolivia are so well known, and have been so productive of valuable information in relation to the Calisaya bark.

Cinchona. *Sex. Syst.* Pentandria Monogynia. — *Nat. Ord.* Cinchonaceæ.

Gen. Ch. Calyx with a turbinate tube, and a persistent five-toothed limb. *Corolla* with a round tube, a five-parted limb, and oblong lobes valvate in æstivation. *Stamens* with short filaments inserted into the middle of the tube, and linear anthers entirely closed. *Stigma* bifid, subclavate. *Capsule* ovate or oblong, somewhat furrowed on each side, bilocular, crowned with the calyx, septicidal-dehiscent, with the mericarps loosened from the base towards the apex, the introflexed part disjoined. *Placentæ* elongated. *Seeds* numerous, erect, imbricated upward, compressed, winged, with a membranous margin, and a fleshy albumen.—The plants composing this genus are trees or shrubs. The leaves are opposite, upon short petioles with flat margins, and are attended with ovate or oblong, foliaceous, free, deciduous stipules. The flowers are terminal, in corymbose panicles, and of a white or purplish rose colour. (*De Candolle.*)

The genuine Cinchona trees are natives exclusively of South America.* In that continent, however, they are widely diffused, extending from the 19th degree of south latitude, considerably south of La Paz, in Bolivia, to the mountains of Santa Martha, or, according to Weddell, to the vicinity of Caracas, on the northern coast, in about the 10th degree of north latitude. They follow, in this distance, the circuitous course of the great mountain ranges, and for the most part

* *Transplantation of the Cinchona trees.* For a long time after the discovery of the virtues of Peruvian bark, no attempt appears to have been made to transplant to other countries the trees which produced it. In 1737, La Condamine collected a large number of young plants, with a view of conveying them to Europe; but, after having descended the Amazon in safety for more than a thousand leagues, they were washed overboard, near the

occupy the eastern slope of the second range of the Cordilleras. Those which yield the bark of commerce grow at various elevations upon the Andes, seldom less than 4000 feet above the sea; and require a temperature considerably lower than that which usually prevails in tropical countries.

mouth of that river, from the boat containing them, and were all lost. After this failure, though the idea of transplanting the Cinchonas was occasionally suggested, nothing was done until 1846-7, when Dr. Weddell, now celebrated for his successful exploration of the region of the Calisaya bark, sent some seeds to France, which were planted with success in the *Jardin des Plantes*, and thus supplied some of the conservatories of Europe with specimens of the plant. But the first successful effort, with a view to great practical results, was made in 1853, by the Dutch Government, by whom Mr. Hasskarl, formerly superintendent of the botanical garden in Java, was sent to South America on this important mission. A number of young Cinchona plants were sent by him directly across the Pacific to Batavia, which they reached before the close of 1854. From these, and from seeds obtained from other sources, which were planted in the mountains of Java, in sites selected for their supposed conformity in climate with the native locality of the Cinchona, have sprung plantations, which in 1860 contained nearly a million of trees, of which 15,000 or 16,000 were of the C. Calisaya. Dr. De Vry obtained from the bark of one of the Cinchona plants of Java, not five years old, 3·12 per cent. of quinia, which is equal to the product of the Bolivian trees. Many of the trees, at the end of 1861, were thirty feet high. Unfortunately, however, most of the plants in Java are comparatively valueless species; and the success of the Dutch has thus been retarded.

The English East India Government has been more successful. Stimulated by the suggestions of Dr. Royle, and by the partial success of the Dutch, they engaged, in 1859, the services of Mr. Clements R. Markham, who proceeded to Bolivia, in South America, and, after almost incredible hardships, arising partly from the nature of the country and partly from the jealousy of the native authorities, succeeded in collecting and transmitting to England upwards of 400 Calisaya plants. Most of these, however, were so much injured, on their way from England to India, by the excessive heat of the Red Sea, that very few, on their arrival in Hindostan, had sufficient life remaining to grow when planted. Happily, the deficiency was supplied by seeds of C. Calisaya sent from Java, where they were produced, to Calcutta, at the request of the English Governor General. (De Vry, *Pharm. Journ.*, April, 1863, p. 440.) Whilst Mr. Markham was in Bolivia, other agents were collecting other species in Peru and Ecuador, whence seeds of the pale and red bark Cinchonas reached India, and, being planted in the selected sites, proved to be very productive.

The sites selected for the Cinchona plantations were in the Neilgherry Hills, in Southern India, in the Presidency of Madras, at the junction of the East and West Ghauts, near the Sanitary Station of Ootacamund, at heights varying from 5000 to 7450 feet above the sea. These positions unite the peculiar characters of the native region of the Cinchonas in the Andes, not only as regards elevation and latitude, but also as to atmospheric moisture, an excess of which, for the greater portion of the year, seems essential to the perfection of these trees. But, though a certain excess of atmospheric moisture is necessary, yet the trees do not grow well in a wet soil, as Mr. Cross, who personally inspected the region in the Andes where the best barks are obtained, found the Cinchona plants only on the dry slopes, and never on wet ground. He remarked, moreover, that constant dampness of the atmosphere is unfavourable, as a certain amount of dry weather is necessary for the ripening of the capsules. In regard to the temperature, which is about the same throughout the year, he observed that during the hottest days the thermometer rose to 59° or 60°, falling to 46° or 48° at night; but at the upper limit it ranged, during the day, from 46° to 48°, and at night fell to 35° or 36°. (*Am. Journ. of Pharm.*, March, 1867, p. 161.)

Besides the Neilgherry Hills, other sites were selected for experimental plantations; and, since the first introduction of the Cinchona trees, their culture has been extended to various points from Hakgalla, in the Island of Ceylon, to the Himalaya Mountains; as in the Wynaad, the Coorg, the hills of Travancore, and especially at Peermede in the Presidency of Madras; in Sikhim and Darjeeling in the Presidency of Bengal; at Lingmulla in the Presidency of Bombay; and in the valley of Kangra in the Punjab; from the southern to the northern extremity of British India. As stated in the twelfth edition of the Dispensatory, the success of the enterprise was at that time secure. In April, 1863, there were in the Neilgherry plantations alone 120,000 Cinchona trees, of which 45,000 were of the C. succirubra, which yields the genuine red bark, 1500 of the *C. Calisaya*, and others of less valuable, but still productive species. It had also at that time been determined, that the bark of the young cultivated trees was quite as productive in alkaloids as that of the same species in their native country of the Andes. Under the fostering care of the British Government, and the wise and energetic management of Mr. W. G. MacIvor, to whom the superintendence of the government plantations has been entrusted, the undertaking has been prosecuted with great, indeed with astonishing success: so that a new source of Cinchona bark has been opened to meet the demands of the world, which is capable of indefinite extension, and which will ere long rival in productiveness, if it

There has been much difficulty in properly arranging the species of Cinchona. One source of the difficulty is the varying shape of the leaves of the same species, according to the degree of elevation upon the mountainous declivities, to the severity or mildness of the climate, the greater or less humidity of the soil, and to various circumstances in the growth of individual plants. Even the same tree often produces foliage of a diversified character; and a person, not aware of this fact, might be led to imagine that he had discovered different species from an examination of the leaves from one and the same branch. The

do not exceed, the South American Andes. In the various localities above indicated, the government has favoured the extension of the enterprise among the native chiefs and private individuals, thus securing the cultivation of the Cinchonas as one of the permanent industries of that great region. Already, in April, 1866, the number of these trees cultivated in British India much exceeded two millions; and the bark is now obtained in such quantities as to be actually delivered for consumption in the London market. (*Journ. de Pharm. et de Chim.*, Dec. 1867, p. 433.)

Besides the general fact of the success of the culture, other results, as unexpected as they are important, have been obtained within the last few years. It was ascertained at an early period, that the productiveness of these plants in alkaloids had not been diminished by the transplantation; it is now known that this productiveness has in fact been very considerably increased. Another highly important result is the discovery by Mr. MacIvor, that the yield in alkaloids is greatly augmented by a certain treatment of the trees. It had been noticed that the cinchona alkaloids, especially in any other form than that of sulphate, were apt, on exposure to the direct light of the sun, to become reddened by the generation of colouring matter, at the expense of the alkaloid. It was a very natural inference that a similar change might take place in the living plant, as a consequence of which the proportion of alkaloids they were capable of producing might be greatly diminished. To obviate this presumed effect, Mr. MacIvor was induced to make the experiment of covering the stems of the growing trees with a layer of moss, so as completely to protect the bark against the influence of sunlight. The result was favourable beyond all expectation; and the yield of the bark thus protected in alkaloids is said to be doubled, tripled, or increased even in larger proportion. Another highly important fact has been ascertained, that the South American plan of cutting down the trees, and then decorticating them is not only unnecessary, but is greatly wasteful. For, though shoots are often put forth from the stump, which in time will become fruitful trees, yet a much more economical plan is to make the old tree continuously productive. For this purpose, nothing more is necessary than to treat them as the cork-bearing oak of the south of Europe is treated by the cork gatherers. If a slip is removed longitudinally from the trunk, from top to bottom, by covering the decorticated portion with moss, the bark is renewed, at least as rich as previously in the alkaloids, while from time to time other strips may be taken, till the whole of the old bark is removed, and the new ready for removal by a repetition of the same process; and the tree is thus preserved indefinitely, probably for the whole normal length of its life.

It will be remembered that the first successful effort towards the transplantation of the Cinchona trees, on a large scale, was made by the Dutch in the Island of Java. Unfortunately, as before stated, the plants first introduced were mostly of inferior species; and moreover, the system of cultivation first adopted, of planting the Cinchonas in the thick shade of the original forest, was not the one most favourable to their growth. From these causes the progress of the culture towards useful practical results was less rapid than in British India; but a supply of seeds from the valuable species has been obtained from Hindostan; and a better method of cultivation has been adopted, so that the enterprise is advancing more favourably; and there is no doubt that Java, like British India, will in future times be an important source of supply, to meet the increasing demand.

Attempts have also been made to introduce the new culture into the West India island of Jamaica; and the Cinchonas which were planted in the mountains, at an elevation of 4000 feet, are said to be growing luxuriantly; so that there is every reason to believe that the great work may ultimately succeed in this locality also.

The French have been less successful than the Dutch and English. The first plants taken by Weddell from Peru to Paris have all perished. Subsequently trials have been made in the Isle of Bourbon, and at Guadaloupe, but these are yet only at the commencement. In Algiers, where situations believed to be suitable were selected for plantations among the mountains, no satisfactory results have yet been attained. The Brazilians have had somewhat better success near Rio Janeiro, though the plantations are yet recent; and it is said that plants have been introduced into the Azores, which are growing well. (Soubeiran, *Journ. de Pharm. et de Chim.*, Feb. 1868, p. 139.)

It is somewhat doubtful whether, within the limits of the United States, there are conditions of climate essential to the profitable cultivation of these trees; but the question is one of great interest, and well worth the attention of our government. (***Note to the twelfth and thirteenth editions.***)

fructification partakes, to a certain extent, of the same varying character. Lambert, in his "*Illustration of the genus Cinchona*," published in 1821, after admitting with Humboldt the identity of several varieties which had received specific names from other botanists, described nineteen species. De Candolle enumerated only sixteen. Lindley admits twenty-one known species, and five doubtful. Weddell describes twenty-one species, including eight new ones of his own, and two doubtful, and excluding several before admitted by other writers, which he joins to his new genus Cascarilla.

Until very recently, it was impossible to decide from which species of Cinchona the several varieties of bark were respectively derived. The former references of the yellow bark to *C. cordifolia*, of the pale to *C. lancifolia*, and of the red to *C. oblongifolia*, have been very properly abandoned in all the Pharmacopœias. It is now universally admitted that the officinal barks, known in the market by these titles, are not the product of the species mentioned. It is stated by Humboldt, that the property of curing agues belongs to the barks of all the Cinchonas with hairy and woolly blossoms, and to these alone. All those with smooth corollas belong to the genus Cascarilla of Weddell. Within a few years much light has been thrown upon the botanical history of the different varieties of bark, and at present most if not all of the valuable varieties can be traced to their sources. The following species are acknowledged by the Pharmacopœia of the U. States.

1. *Cinchona Calisaya.* Weddell, *Hist. Nat. des Quinquinas*, p. 30, t. 3. This is a lofty tree, with a trunk often two feet or more in diameter, and a summit usually rising above the other trees of the forest. The leaves are petiolate, oblong or lanceolate-obovate, from three to six inches long and one or two in breadth, obtuse, acute or slightly attenuated at the base, softish, above smooth, of a velvety aspect, and obscurely green, beneath smooth and of a pale emerald hue, with scrobiculi at the axils of the veins, but scarcely visible on the upper surface. The stipules are about as long as the petioles, oblong, very obtuse, and very smooth. The flowers are in ovate or subcorymbose panicles. The calyx is pubescent, with a cup-shaped limb, and short triangular teeth; the corolla is rose-coloured, with a cylindrical tube about four lines long, and a laciniate limb fringed at the edges; the stamina are concealed in the tube, with anthers more than twice as long as the filaments. The fruit is an ovate capsule scarcely as long as the flower, enclosing elliptical lanceolate seeds, the margin of which is irregularly toothed, with a fimbriated appearance. The tree grows in the forests, upon the declivities of the Andes, at the height of 6000 or 7000 feet above the ocean, in Bolivia and the southernmost part of Peru.*

A variety of this species, described by Weddell under the name of *Josephiana*, is a mere shrub, not more than twelve feet high, with a slender stem, erect branches, and a strongly adherent bark. This variety is found in some places covering extensive surfaces destitute of forest trees. Weddell supposes that these tracts had once been covered with forests, which, having been destroyed by fires, have

* The cultivation of the C. Calisaya, which in its native mountains is said to be the most beautiful, as well as the richest in quinia of all the species, has been less successful than that of the C. succirubra, micrantha, &c., in the E. Indies. Though great pains had been taken to secure proper seeds and young plants for transplantation, from some unknown cause, probably from ignorance of the precise circumstances of climate and soil best adapted to this species, the attempts made for its introduction have not met with satisfactory success. The plants are of stunted growth, with the appearance of shrubs rather than of trees, and a sombre aspect of the leaves, the furthest possible from the magnificent *Calisaya* trees in their native forest of Bolivia. Nor has the chemical examination of the bark of the young trees been more satisfactory. According to Mr. Markham, the Calisaya avoids the banks of a river, never being found within several hundred feet of it, and prefers the steepest declivities of the mountain sides, and a great deal of shade, though not too much of it; and he considers the best locality for the young trees, one in which they may receive shade from taller trees, while they receive sunshine through the spreading branches. Nor is it certain that the best variety of the Calisaya is that which has been introduced into India. It is hoped, therefore, that better success may reward further efforts for the naturalization of this species, by due attention to the circumstances referred to. (*Journ. de Pharm. et de Chim.*, Juillet, 1867, p. 22; also *Am. Journ. of Pharm.*, Sept. 1866, p. 421.)—*Note to the thirteenth edition.*

been succeeded by this stunted growth springing from the roots, and prevented from receiving its full development by the want of protection from other trees.

Mr. Markham states that the natives recognise three varieties of the Calisaya; 1. *Calisaya amarilla or fina* (*a. vera* of Weddell); 2. *C. morada* (*C. Boliviana*, Wedd.), and 3. *C. verde* or *alta*, a very large tree, growing lower in the valley than the other varieties, and distinguished by having the veins of the leaves never purple, but always green (*Am. J. of Pharm.*, 1866, p. 422.)

By the discovery of this species, the long unsettled point of the botanical source of Calisaya bark has been determined. The immense consumption of that bark, and the wasteful methods pursued by the bark gatherers have caused the rapid destruction of the tree; and already it has disappeared from the neighbourhood of inhabited places, except in the form of a shrub. Weddell was compelled to make long journeys on foot through the forests, by paths scarcely opened, before he could get a sight of the tree in its full vigour.

2. *Cinchona Condaminea.* Humb. and Bonpl. *Plant. Equin.* i. p. 33, t. 10; Lindley, *Flor. Med.* 414; Carson, *Illust. of Med. Bot.* i. 53, pl. 45.—*Cinchona officinalis.* Linn.; Hooker, *Bot. Mag.* t. 5364. This tree, when full grown, has a stem about eighteen feet high and a foot in thickness, with opposite branches, of which the lower are horizontal, and the higher rise at their extremities. The bark of the trunk yields when wounded a bitter astringent juice. The leaves are of variable shape, but generally ovate-lanceolate, about four inches in length by less than two in breadth, smooth, and scrobiculate at the axils of the veins beneath. The flowers are in axillary, downy, corymbose panicles. The tree grows on the declivities of the mountains, at an elevation of from about a mile to a mile and a half, and in a mean temperature of 67° F. It was seen by Humboldt and Bonpland in the neighbourhood of Loxa, and is said also to grow near Guancabamba and Ayavaca in Peru. It is now admitted to be the source of the *crown bark of Loxa.* Weddell considers as varieties of this species, though with some hesitation, as he has never seen them alive, the following: 1. *Candolli* (*C. macrocalyx* of Pavon and De Candolle); 2. *lucumæfolia* (*C. lucumæfolia* of Pavon and Lindley); 3. *lancifolia* (*C. lancifolia* of Mutis), hereafter referred to as a distinct species; and 4. *Pitayensis*, growing in New Granada.* The last mentioned variety has subsequently been raised by Weddell to the rank of a distinct species.

3. *C. micrantha.* Ruiz and Pavon, *Fl. Peruv.* ii. 52, t. 194; Lindley, *Flor. Med.* 412; Carson, *Illust. of Med. Bot.* i. 52, pl. 44. This is a large tree, forty

* Botanists seem disposed to return to the old Linnæan designation of this species *Cinchona officinalis*, of which three varieties are recognised, under the names of *Bonplandiana*, *Uritusinga*, and *Crespilla*, all yielding the crown barks. Of these the *Bonplandiana* seems to have been most successfully transplanted, as upwards of 750,000 are now growing in the plantations of British India. (*Broughton.*) The varieties of this species seem to flourish best at a greater elevation than the C. succirubra, growing at heights from 5500 or 6000 feet even to 8350 feet above the level of the sea. The effect of the moss in increasing the productiveness of this species in alkaloids has been highly satisfactory. (*Markham.*) Instead, however, of cinchonia being the prominent alkaloid of this species, as in the pale barks of Loxa, the quinia has been found most abundant in the Indian bark, and, though the former alkaloid is generally present, yet it is usually in small proportion. Indeed, Mr. Broughton states that the trees of the variety Bonplandiana yield a bark nearly equal to the fine Calisaya bark of Bolivia, and superior in some respects for manufacturing purposes to the richer red barks, as it yields its alkaloids more readily in a free state, in consequence of the smaller amount of resin and colouring matter contained in it.

The following results were obtained by Mr. Broughton in the chemical examination of the bark of this species. The dried bark of the trunk yielded altogether in alkaloids (hydrated) 3·6 per cent., of which 2·8 per cent. was quinia (or of alkaloid soluble in ether), and only 0·8 per cent. was of cinchonia and cinchonidia jointly; and 2·8 per cent. of crystallized sulphate of quinia was obtained. Another specimen was even more productive, yielding 3·0 per cent. of quinia. The bark of the same species, which had been renewed in six months under the mossing process, gave a total of alkaloids (hydrated) 6·8 per cent., of which 4·8 was of quinia, and 2·0 of cinchonia and cinchonidia jointly; and 4·1 per cent. of crystallized sulphate of quinia was obtained. (*Pharm. Journ. and Trans.*, Nov. 1867, p. 241.)—*Note to the thirteenth edition.*

feet high, with oblong leaves, from four to twelve inches in length and from two to six in breadth, scarcely acute, smooth, shining on the upper surface, and scrobiculate at the axils of the veins beneath. The flowers are in terminal, loose, leafless panicles, and are smaller than those of any other species except C. lancifolia. (*Lindley.*) The tree grows, according to Ruiz and Pavon, in the mountains near Chicoplaya, Monzon, and Puebla de San Antonio, according to Pöppig, at Cuchero, and, according to Weddell, in the Peruvian province of Carabaya, and in Bolivia. Ruiz states that its bark is always mixed with that sent into the market from the provinces of Panatahuas, Huamilies, and Huanuco. The Edinburgh and Dublin Colleges ascribed to it the *cinchona cinerea*, the *gray* or *silver bark* of British commerce; and the U.S. Pharmacopœia recognises it as one of the sources of pale bark, as it undoubtedly is.*

Though not recognised in our officinal code, there is another species, recently determined, which, as the source of the genuine red bark, is scarcely less important than either of the preceding, and has, within a few years, acquired additional value from the great success with which it has been transplanted, and propagated in the Highlands of Hindostan. We refer to the species denominated, after Pavon, Cinchona succirubra.

4. *C. succirubra.* Pavon, *MS.;* Howard, *Pharm. Journ. and Trans.*, Octob. 1856, p. 209, with a figure. — *C. ovata*, var. *erythroderma.* Weddell, *Hist. Nat. des Quinquin.* p. 60. This species has been satisfactorily ascertained to produce the proper officinal red bark, the origin of which remained so long unknown, or at least undetermined. The name of C. succirubra originated with Pavon, having been applied by him, in an unpublished manuscript, to an undescribed species yielding the bark called *cinchona colorada de Huaranda*, which has been shown to be identical with officinal red bark; while a specimen of the plant itself, in the collection of Ruiz and Pavon at Kew, upon examination by Mr. J. E. Howard, of London, proved to correspond exactly with a specimen of the red-bark tree which that gentleman had received from South America. The same plant was described by Weddell, in his *Natural History of the Cinchonas*, as a variety of C. ovata, under the designation of *Cinchona ovata*, var. *erythroderma*, and was conjectured by him to be the source of red bark, though he did not at the time feel justified in giving a decided opinion. This point, however, having been subsequently determined, and the plant elevated to the dignity of a new species, Mr. Howard proposed at first to name it *Cinchona erythroderma*, not only from courtesy to Dr. Weddell, but also from the appropriateness of the name itself, implying the redness of the bark; but Pavon's name of *succirubra* was afterwards preferred on the ground of priority, being itself also (red-juiced) expressive of a quality of the tree. This species is, when full grown, of great magnitude; but almost all the older trees have been destroyed, and few now remain with a

* The C. micrantha, which is the source of the Lima or Huanuco pale bark, is among the species which have been most successfully cultivated in India. The successful introduction of this species into Hindostan is ascribed to the sagacious and prompt measures of Mrs. Markham, who, having accompanied her husband Mr. Markham to Arequipa, during his absence in the forests, engaged an agent, furnishing him with necessary instructions, to collect and send to the coast the young plants of this species. The C. micrantha is cultivated along with C. succirubra, at an elevation less than 6000 feet, and attains a similar magnitude. It is a most singular fact that, though in its native country of Huanuco and Huamilies, the C. micrantha yields barks which contain cinchonia, almost to the exclusion of all other alkaloids, yet, when transplanted to India, it undergoes a great change in this respect, and, as there cultivated, has been found by Mr. Howard to yield a large proportion of quinidia. The effect of mossing the stem in this species is equal to that produced on the succirubra. Thus, the bark of a tree two and a half years old, with its stem unprotected, furnished only 1·86 of alkaloids altogether; while a bark of the same age which had been covered with moss for a year, gave 7·52 per cent. of alkaloids, of which 5·82 were of the more valuable kinds. (Markham, *Journ. de Pharm. et de Chim.*, Juillet, 1867, p. 21.) But it appears that this change in the micrantha bark does not always take place; for Mr. Broughton gives, as the result of an analysis of this bark, taken from a tree four and a half years old, 7·1 per cent. as the total yield of alkaloids, of which cinchonia constituted 6·8 per cent., and quinia only 0·3. (*Pharm. J. and Trans.*, Nov. 1867, p. 242.)—*Note to the thirteenth edition.*

stem so much as a foot in diameter. The branches have a silvery epidermis, corresponding with that of the red bark in quills as often seen in the market. The leaves are ovate, varying greatly in size, often as much as nine inches by six, narrowing towards the base, somewhat membranaceous, pubescent beneath, and green on both sides. The tree inhabits a region, in the present republic of Ecuador, on the western slope of Chimborazo, the sea-port of which is the town of Guayaquil.*

Besides the foregoing species, several others deserve a brief notice, either as contributing to furnish the bark of commerce, or on account of the attention they have received from pharmacologists.

5. *C. scrobiculata.* Humb. and Bonpl. *Plant. Equin.* i. p. 165, t. 47; Weddell, *Hist. Nat. des Quinquinas*, p. 42, t. 7. This species was united by Lindley with C. micrantha; but Weddell, who has had ample opportunities of forming a just

* This species is that which has, up to the present time, been most successfully cultivated in British India. The following account of it, as cultivated in the East, is taken from a letter from Mr. Markham, who has done so much for the introduction of the Cinchonas, dated at Ootacamund, January 16, 1866. The finest trees, under favourable circumstances, attain in two years an average height of 6 feet, and diameter of stem of 6 inches, and in the third year a height of 15 feet and a diameter of 15 inches. This species grows most perfectly at a height of from 4000 to 5000 feet above the sea. At a lower elevation the bark is much thinner, and less rich in alkaloids. This species is peculiarly disposed to send up shoots from its stump when cut down; and, if these are treated with moss to the stem, they will, if cut at the end of three years, yield a considerable product of alkaloids, so that a periodical harvest may be obtained from them; and though this is less successful than the method of removing strips of the bark, as practised in the government gardens, yet, as it requires less care, it may probably be advantageously practised among native cultivators, should these engage largely in the work Mr. Markham has noticed two varieties of the C. succirubra growing in India, one with rose-coloured flowers and beautifully green leaves, the other with flowers nearly white, and pale leaves; and the difference in this and other analogous cases may be connected with the proportion or variety of the alkaloid.

As to the yield of the C. succirubra in alkaloids, Mr. Markham states that, while the bark of a tree two years and a half old gives 2·43 per cent. when not treated with moss, it will yield 5·20 per cent. if kept covered with moss for one year; and that the alkaloid product, under the treatment with moss, has gradually increased from 2·80 per cent. after continuance of the treatment for only 6 months, to 11·34 per cent. when it had extended to 18 months. The yield of the reserved bark, after partial decortication, obeys a similar rule, being 2·72 per cent. after one year, and 5·85 at the end of 18 months. Much the largest proportion of alkaloid product of this species consists of quinia; but it also yields a considerable proportion of cinchonia, and is less easily treated for extraction of the quinia than Calisaya bark, in consequence of the large proportion of red colouring matter contained in it. (*Journ. de Pharm. et de Chim.*, Juillet, 1867, p. 17.)

In the month of April, 1867, it was estimated that the number of this species growing in British India was about 800,000; the whole number of all the species being nearly 2,500,000. (*Ibid.*, Mars, 1868, p. 208.)

From an official report by Mr. J. Broughton, Quinologist to the Indian Government, made April 1, 1867, the following table is extracted, containing the product in alkaloids of 4 different specimens of C. succirubra bark, obtained from the government plantations.

VARIETIES.	I.	II.	III.	IV.
Total alkaloids (hydrated), - - - - - -	4·85	7·00	6·40	6·4
Soluble in ether (quinia), - - - - - -	3·25	4·25	4·75	1·7
Cinchonia and cinchonidia, - - - - - -	1·60	2·75	1·65	4·7
Sulphate of quinia crystallized, - - - - -	3·00	4·00	4·65	1·7

It appears that these barks give a considerably larger product than the average of the genuine red barks of S. America, though, so far as stated, not favoured by the mossing process. Another interesting point is the difference of the yield of the different specimens, not only in relation to the whole alkaloid product, but also to the alkaloids severally; the quinia largely predominating except in the 4th sample, in which it is greatly exceeded by the two others jointly. The result is probably connected with natural diversities in the tree, such, for example, as that noticed by Markham, referred to above in this note; and it will no doubt be important to study these varieties in regard to practical results. The root-bark of this species was also examined, and found to contain the alkaloids in proportion, not very different from the bark of the stem. (*Pharm. Journ. and Trans.*, Nov. 1867, p. 239.)—*Note to the thirteenth edition.*

conclusion, considers it as one of the best characterized species of the genus. According to this author, the scrobiculi at the axils of the veins on the under surface of the leaf, which are one of the most prominent of its peculiarities, are not usually found in C. micrantha, as stated in its description; but what have been taken for them, in the latter species, are simply small bundles of hairs. The tree was seen by Humboldt and Bonpland, forming large forests near the city of Jaen de Bracomoros; and Weddell states that it is met with also in the Peruvian provinces of Cuzco and Carabaya. Large quantities of the bark were formerly collected at Jaen, and sent to the coast to be shipped for Lima. At present the traders in this bark are said by Weddell to be chiefly at Cuzco. The bark of the younger branches has been ranked with the pale or gray barks; that of the larger branches has been sometimes employed to adulterate the Calisaya.

6. *C. lancifolia.* Mutis, *Period. de Santa Fé*, p. 465; Lindley, *Flor. Med.* 415. This is one of the species discovered by Mutis in New Granada, and by the disciples of that botanist was considered as embracing many trees which had received distinct specific designations. By the London College it was long recognised as the source of one of the officinal barks, under the impression, probably, that it was identical with *C. Condaminea*, which was known to yield one of the most highly valued varieties. It is, however, a native of New Granada; and, as none of the barks recognised by the Pharmacopœias come from Carthagena, its product, which must be shipped from that port, cannot be considered as ranking among them. It yields the *orange bark* of Mutis, or *fibrous Carthagena bark* of present pharmacologists. This bark, at one time much neglected, has within a few years come into extensive use, having been found to yield the alkaloids in very large proportion.

7. *C. cordifolia.* Mutis, in *Humb. Magaz. Berlin*, 1807, p. 117; Lindley, *Flor. Med.* 839; Carson, *Illust. of Med. Bot.* i. 51, pl. 43. This is a spreading tree, fifteen or twenty feet high, with a single, erect, round stem, covered with a smooth bark, of a brownish-gray colour. It was first discovered by Mutis in the mountains about Santa Fé de Bogota, in New Granada, and grows at elevations varying from 5800 to 9500 feet. It was formerly considered by the British Colleges as the source of their *yellow bark;* but has been ascertained not to produce the officinal bark, which never comes from the region where it is known to grow. Guibourt found that the *quina amarilla* or *yellow bark of Santa Fé*, which is probably produced by C. cordifolia, is identical with *hard Carthagena bark*. Weddell states that the tree grows also in Peru, and yields the white and ash-coloured barks of Loxa.

8. *C. Boliviana.* Weddell, *Hist. Nat. des Quinquinas*, p. 50, t. 9. This tree was discovered and named by Weddell, who found it growing in Bolivia and Peru, extending somewhat further northward than C. Calisaya, but not so far towards the south. In the northern parts of Bolivia the two species frequently grow together. The bark of C. Boliviana is generally mixed in commerce with the proper Calisaya, from which it cannot always be easily distinguished. This is less to be regretted, as, according to Weddell, the properties of the two barks are not essentially different. It is said that this botanist now considers his C. Boliviana as scarcely more than a variety of C. Calisaya; and Mr. Markham, who joins in this opinion, proposes to designate the plant *Cinchona Calisaya*, var. *Morada*. (*Pharm. Journ.*, Sept. 1863, p. 108.) The close resemblance of the products of the two trees is a strong evidence of their specific identity.

9. *C. ovata.* Ruiz and Pavon, *Fl. Peruv.:* Weddell, *Hist. Nat. des Quinquin.* p. 42, t. xi. and xii. This species grows in close groves, in warm places at the foot of the Andes, near Pozuzo and Panao, about ten leagues from Huanuco. Lindley considers it quite distinct from *C. pubescens* of Vahl, and *C. cordifolia* of Mutis, with both of which it has been confounded. Ruiz calls its bark *cascarillo pallido* or pale bark, and states that it was not to be found in commerce. Von Bergen, however, upon comparing a specimen of the *cascarillo pallido* in the collection of Ruiz with the Jaen bark, found them identical. From Weddell's statements it would seem that this species is widely diffused in Peru and

Bolivia, and varies extremely in the character of its bark in different situations. In the parts visited by him, the finer qualities pass for Calisaya bark; and in the Peruvian province of Carabaya, bordering on Bolivia, it is habitually employed to sophisticate that bark. He believes also that much of the quilled bark of Loxa and Huanuco must be referred to this species. The *C. ovata*, var. *erythroderma*, is now known to be the source of the officinal red bark, and has been raised to the position of a species, under the name of C. succirubra. (See p. 268.)

10. *C. Pitayensis.* Weddell. For figures of the leaves, flowers, and fruit of this species, the reader is referred to a paper by Mr. J. E. Howard, in the *Pharm. Journ. and Trans.* (Aug. 1864, p. 48). They were drawn from specimens collected by Mr. Jervise. From specimens of the bark gathered by Mr. Robert Cross in the lofty mountain ridges near Popayan, where the temperature varies from 30° to 60° F., there can be no doubt that this tree is the source of the finest red-coloured Pitaya bark, which is among the most valuable now collected, having yielded as high a percentage as 8·6 of alkaloids. As described by Mr. Cross, the tree, though 60 or 70 feet high, is relatively very slender, having a diameter of the stem rarely exceeding 18 inches or 2 feet. The branches are also slender, and the leaves small and lanceolate, and always, before falling, of a deep-red or purple colour. The range of the tree is rather limited, being confined to a few square miles of the steep forest-covered slopes, northward of the volcano Purace, belonging to the central Cordillera. The bark of the root is more valuable than that of the trunk and branches; the former yielding 5 per cent. of quinia, the latter only 4 per cent. Its produce is already becoming scarce; but, as the tree is easily cultivated, and grows very rapidly, there is reason to believe that it may hereafter become more abundant. (See *Am. Journ. of Pharm.*, Nov. 1865, p. 473.)

In addition to the species above mentioned, the following, for a description of which we refer to Lindley's Flora Medica, yield barks possessing febrifuge properties. — 11. *C. nitida* of the Flora Peruviana, incorrectly confounded, according to Lindley, with C. lanceolata by De Candolle, and C. Condaminea by Lambert, grows in groves, in cold situations upon the Andes, in the Peruvian provinces of Huanuco, Tarma, Huamilies, and Xuaxa, and is probably the source of the finest variety of commercial *Lima bark*. — 12. *C. lucumæfolia* of Pavon, confounded by Lambert with C. Condaminea, grows near Loxa, and probably contributes to the Loxa or pale barks. — 13. *C. lanceolata* of the Flora Peruviana is found at Cuchero, and various other places fifteen or twenty leagues distant from Huanuco, where it forms groves in lofty cold situations upon the Andes. Its bark is said by Ruiz and Pavon to be called *yellow bark*, from the colour of its inner surface, and to resemble Callisaya bark in flavour. — 14. *C. ovalifolia* of Humboldt and Bonpland, the *C. Humboldtiana* of Römer and Shultes, and of De Candolle, is a shrub from six to nine feet high, inhabiting the province of Cuença, where it forms considerable forests. It probably contributes to the Loxa barks, although its product is said to be of inferior quality. — 15. *C. pubescens* of Vahl, considered by Lindley as identical with *C. purpurea* of the Fl. Peruv., is a tree of considerable magnitude, distinguished by the violet tint of its large leaves, and the purple colour of its flowers. It occurs in groves on the lower mountain ridges in the provinces of Loxa, Jaen, Pantahuas, &c., was seen by Pöppig at Cuchuo, and is stated to grow also in New Granada. The bark is inferior, and is said to be employed for adulterating the better kinds. A specimen taken to Europe by Pöppig was found by Reichel to be identical with the Huamilies bark. By Weddell it is stated to be the bark known in French commerce as *Cusco bark*, and closely to resemble that of C. cordifolia. — 16. *C. hirsuta* of the Fl. Peruv. grows on wooded mountains in the province of Panatahuas near Huanuco, and is said to yield a good bark, called formerly *quina delgadilla* or *delgada*, now scarcely collected. — 17. *C. glandulifera* of the Fl. Peruv. is a shrub of about twelve feet, flourishing on the mountains N. W. of Huanuco, and yielding an excellent bark, unknown in commerce, called by the inhabitants *cascarillo negrillo* from its blackish epidermis. In its flowering

season, it perfumes the forest by the scent of its blossoms.—18. *C. Mutisii* of Lambert (*C. glandulifera* of Lindley) is considered among the best characterized species. It grows in Loxa, but its bark is unknown.

Besides the above species, Lindley enumerates, 19. *C. rotundifolia* of Ruiz and Pavon, growing in the province of Loxa; 20. *C. villosa* of Pavon (C. Humboldtiana of Lambert), growing at Jaen of Loxa; and 21. *C. caduciflora* of Bonpland, growing near Jaen de Bracomoros; not to mention the species joined by Weddell to his now admitted genus of Cascarilla. None of the species referred to in this paragraph are known to yield bark to commerce. To these must now be added, 22. *C. amygdalifolia* of Bolivia and Peru; 23. *C. australis* of Bolivia, the most southern of all the known species, growing as far south as the 19th degree of latitude; 24. *C. purpurascens;* 25. *C. Chomeliana;* 26. *C. asperifolia*, also of Bolivia; and 27. *C. Carabayensis* of Carabaya; all of which were discovered and described by Weddell; but from none of which is commercial bark procured. *C. dichotoma* of the *Fl. Peruv.*, *C. macrocalyx* of De Candolle, *C. crassifolia* of Pavon, in De Candolle's Prodromus, *C. pelalba* of the same authority, and *C. Muzonensis* of Goudot in De Candolle's Prodromus, are considered by Lindley as uncertain species.*

Perhaps too much importance has been attached to the study of particular species of Cinchona. The character of the product of any one species varies much according to the part of the plant decorticated, and the circumstances of its growth. Weddell has made some observations on this point, which, if confirmed, may lead to important practical results.†

Commercial History.

For more than a century after Peruvian bark came into use, it was procured almost exclusively from the neighbourhood of Loxa. In a memoir published

* The addition of *C. Pahudiana*, of Howard, must now be made; as this species, so nearly valueless in its native country, and when first taken to India, where it was extensively planted, found so unproductive as greatly to disappoint the hopes that had been entertained, has, under the process of mossing the trunk, so far improved as to give hope that it may yet take rank among the valuable species. Mr. Howard has extracted from a specimen of the bark recently sent to him 1·60 per cent. of crystallized sulphates. (*Pharm. J. and Trans.*, Nov. 1867, p. 243.)—*Note to the thirteenth edition.*

† The fundamental idea is, that the chemical character of the bark is connected with peculiarities in its intimate structure, and that by knowing the latter we may ascertain, with an approach to certainty, the former also; and thus, as the virtues of the bark depend on its chemical constitution, we may have reliable criteria of its value. Now in the different barks there are three varieties of structure; the dead exterior layers being left out of the question. *First*, as in the *Calisaya bark*, which consists of the inner bark or liber, the whole substance is filled with short fusiform fibres, which, whether viewed in a longitudinal or transverse section, are seen, with the aid of the microscope, to be isolated by a cellular tissue, in the midst of which they are regularly disposed in parallel lines, lying end to end without absolute junction. It is known that this bark abounds in quinia, and owes its virtue to that constituent.

In the *second variety*, such as the flat bark of *C. scrobiculata*, a cellular coat exists outside of the liber. In this, under the microscope, the inner layer is seen to consist of fibres more closely arranged, more numerous and much larger than in the preceding, and firmly attached at their extremities; and they suddenly diminish in number as we approach the outer surface, where the bark consists solely of cells.

The *third variety*, of which the bark of *C. pubescens* is an example, consists chiefly of cellular tissue, with a few irregular series of fibres in the inner half; and these fibres are three or four times as large as in the other varieties. In the two latter barks cinchonia is the predominant alkali; but it is not very abundant in either, and least so in the one last mentioned. The inference is, that quinia is most largely developed in those barks in which the fibres are short and intimately mixed with cells; while the cinchonia is more especially deposited in the tissue exclusively cellular. The fracture in the first variety is, from its structure, fibrous, but short-fibrous throughout; that of the second and third is smooth where cells exist exclusively, and with long fibres where fibres exist. A short, smooth fracture, therefore, as in the young barks, or a fracture partly smooth and partly long-fibrous, as in the older barks which have not thrown off their cellular layer, indicates a cinchona bark, and one comparatively feeble; while a fracture uniformly short-fibrous indicates a variety abounding in quinia and energetic; and, in proportion as a bark approaches this latter condition, will it prove to be efficacious. (*Note to the ninth edition.*)

A.D. 1738, La Condamine speaks of the bark of Rhiobambo, Cuença, Ayavaca, and Jaen de Bracomoros. Of these places, the first two, together with Loxa, lie within the ancient kingdom of Quito, at the southern extremity; the others are in the same vicinity, within the borders of Peru. The drug was shipped chiefly at Payta, whence it was carried to Spain, and thence spread over Europe. Beyond the limits above mentioned, the Cinchona was not supposed to exist, till, in the year 1753, a gentleman of Loxa discovered it, while on a journey to Santa Fé de Bogota, in numerous situations along his route, wherever, in fact, the elevation of the country was equal to that of Loxa, or about 6500 feet above the level of the sea. This discovery extended through Quito into New Granada, so far as two degrees and a half north of the equator. But no practical advantage was derived from it; and the information lay buried in the archives of the vice-royalty, till subsequent events brought it to light. To Mutis belongs the credit of making known the existence of the Cinchona in New Granada. He first discovered it in the neighbourhood of Bogota, in 1772. A botanical expedition was afterwards organized by the Spanish government, with the view of exploring this part of their dominions, and the direction was given to Mutis. Its researches eventuated in the discovery of several species of Cinchona in New Granada; and a commerce in the bark soon commenced, which was carried on through the ports of Carthagena and Santa Martha.

To these sources another was added about the same time, A.D. 1776, by the discovery of the Cinchona in the centre of Peru, in the mountainous region about the city of Huanuco, which lies on the eastern declivity of the Andes, northeast of Lima, at least six degrees south of the province of Loxa. To explore this new locality, another botanical expedition was set on foot, at the head of which were Ruiz and Pavon, the distinguished authors of the Flora Peruviana. These botanists spent several years in that region, during which time they discovered numerous species. Lima became the entrepot for the barks collected around Huanuco; and hence probably originated the name of Lima bark, so often conferred, in common language, not only upon the varieties received through that city, but also upon the medicine generally.

Soon after the last-mentioned discovery, two additional localities of the Cinchona were found; one at the northern extremity of the continent near Santa Martha, the other very far to the south, in the provinces of La Paz and Cochabamba, then within the vice-royalty of Buenos Ayres, now in the republic of Bolivia. These latter places became the source of an abundant supply of excellent bark, which received the name of Calisaya. It was sent partly to the ports on the Pacific, partly to Buenos Ayres.

The consequence of these discoveries was a vast increase in the supply of bark, which was now shipped from the ports of Guayaquil, Payta, Lima, Arica, Buenos Ayres, Carthagena, and Santa Martha. At the same time the average quality was probably deteriorated; for, though many of the new varieties were possessed of excellent properties, yet equal care in superintending the collection and assorting of the bark could scarcely be exercised in a field so much more extended. The varieties now poured into the market soon became so numerous as to burden the memory, if not to defy the discrimination of the druggist; and the best pharmacologists found themselves at a loss to discover any permanent peculiarities which might serve as the basis of a proper and useful classification. This perplexity has continued more or less to the present time; though the discovery of the alkaline principles has presented a ground of distinction before unknown. The restrictions upon the commerce of South America, by directing the trade into irregular channels, had also a tendency to deteriorate the character of the drug. Little attention was paid to a proper assortment of the several varieties; and not only were the best barks mixed with those of inferior species and less careful preparation, but the products of other trees, bearing no resemblance to the Cinchona, were sometimes added, having been artificially prepared so as to deceive a careless observer. The markets of this country were peculiarly ill-furnished. The supplies, being derived chiefly, by means of a con-

traband trade, from Carthagena and other ports on the Spanish Main, or indirectly through the Havana, were necessarily of an inferior character; and most of the good bark which reached us was imported by our druggists from London, whither it was sent from Cadiz. A great change, however, in this respect, took place, after the ports on the Pacific were opened to our commerce. The best kinds of bark were thus rendered directly accessible to us; and the trash which formerly glutted our markets is now in great measure excluded. Our ships trading to the Pacific run along the American coast from Valparaiso to Guayaquil, stopping at the intermediate ports of Coquimbo, Copiapo, Arica, Callao, Truxillo, &c., from all which they probably receive supplies. Much good bark has of late also been imported from Carthagena, and other ports of the Caribbean Sea, being brought down the Magdalena river from the mountainous regions of New Granada; and, since the completion of the railroad across the Isthmus, large quantities reach this country by way of Panama, to which place they are brought chiefly from the Pacific Ports of Buenaventura and Guayaquil. An additional source of supply has recently been opened through the Amazon; a considerable quantity of bark having been taken to the London market from the port of Para, in Brazil, brought down that river, probably from the Peruvian province of Huanuco. According to Mr. Howard, the bark thus obtained is of inferior quality, yielding but a small proportion of alkaloids. (*Pharm. Journ.*, Dec. 1863, p, 248.)*

The persons who collect the bark are called in South America *Cascarilleros*. Considerable experience and judgment are requisite to render an individual well qualified for this business. He must not only be able to distinguish the trees which produce good bark from those less esteemed, but must also know the proper season and age at which a branch should be decorticated, and the marks by which the efficiency or inefficiency of any particular product is indicated. The bark gatherers begin their work with the setting in of the dry season in May. Sometimes they first cut down the tree, and afterwards strip off the bark from the branches; in other instances they decorticate the tree while standing. The former plan is said to be the most economical; as, when the tree is cut down, the stump pushes up shoots which in the course of time become fit for decortication, while, if deprived of its bark, the whole plant perishes. The operator separates the bark by making a longitudinal incision with a sharp knife through its whole thickness, and then forcing it off from the branch with the back of the instrument. Other means are resorted to, when the trunk or larger limbs are decorticated. According to Pöppig, the bark is not separated until three or four days after the tree is felled. It must then be speedily dried, as otherwise it becomes deteriorated. For this purpose it is taken out of the woods into some open place, where it is exposed to the sun. In drying it rolls up, or becomes quilled; and the degree to which this effect takes place is proportionate directly to the thinness of the bark, and inversely to the age of the branch from which it was derived. In packing the bark for exportation, it often happens that several different kinds are introduced into the same case. The packages are, in commercial language, called *seroons*. As found in this market they are usually covered with a case of thick and stiff ox-hide, lined within by a very coarse cloth, apparently woven out of some kind of grass.

The Cinchona forests, being in very thinly inhabited districts, do not, for the most part, belong to individuals, but are open to the enterprise of all who choose to engage in the collection of the bark. The consequence is, that the operations are carried on without reference to the future condition of this important interest; and the most wasteful modes of proceeding are often adopted. Nevertheless, the great extent to which the Cinchona forests prevail, spreading, as they do, with some interruptions, over thirty degrees of latitude, and occupying regions which can never be applied to agricultural purposes, almost precludes the idea of their even remote extinction.

* An interesting history of the commerce in the Cinchona barks, by Dr. H. A. Weddell, will be found in the *American Journ. of Pharm.* (xxvi. 539, Nov. 1854), originally from his *Voyages dans le Nord de la Bolivie*, Paris, 1853.

The bitterness of the Cinchona is not confined to its bark. The leaves and flowers also have this property, which in the former is associated with acidity, in the latter with a delicious aroma, which renders the air fragrant in neighbourhoods where the trees abound. The wood is nearly tasteless; but the bark of the root has the same virtues as that of the trunk: and rich mines of underground treasure may await future explorers, in regions which have been stripped of their trees either by fire or the axe.

It was at one time supposed that the leaves might have sufficient of the active principles of the bark to justify their use in medicine; but, though they have proved useful as a tonic, experiment has not shown them to be possessed of decided antiperiodic powers, and, on chemical examination, they have yielded but a small proportion of the characteristic alkaloids.

Classification.

To form a correct and lucid system of classification is the most difficult part of the subject of bark. An arrangement founded on the botanical basis is liable to the objection, that the product of the same species may vary according to the age of the bark and the situation of the tree; and, besides, is at present scarcely practicable; as, though our knowledge of the source of the several varieties has very much extended, it is still defective on some points.

The Spanish merchants adopted a classification, dependent partly on the place of growth or shipment, and partly on the inherent properties, or supposed relative value of the bark. So long as the sources of the drug were very confined, and the varieties few, this plan answered the purposes of trade; but at present it is quite inadequate; and, though some of the names originally conferred upon this principle are still retained, they are often uncertain or misapplied.

Perhaps, on the whole, the best arrangement for pharmaceutical and medicinal purposes is that founded upon difference of colour. It is true that dependence cannot be placed upon this property alone; as barks of a similar colour have been found to possess very different virtues; and, between the various colours considered characteristic, there is an insensible gradation, so that it is not always possible to decide where one ends and the other begins. Still it has been found that most of the valuable barks may be arranged, according to their colour, in three divisions, which, though mingling at their extremes, are very distinctly characterized, in certain specimens, by peculiarity not only in colour, but also in other sensible properties, and even in chemical constitution. The three divisions alluded to are the *pale*, the *yellow*, and the *red*. This arrangement has been adopted in the U. S. and British Pharmacopœias; and as, until recently, almost all the highly esteemed barks were brought from the Pacific coast of South America, and those from the northern coast were deemed inferior, it is only the former that are recognised under the three divisions referred to. In describing, therefore, the different kinds of bark, we shall treat first, under the officinal titles of *pale*, *yellow*, and *red*, of those originally brought only from the ports of the Pacific; while those coming to us from the northern ports of New Granada and Venezuela will be subsequently considered under the heading of *non-officinal* or *Carthagena barks*, by the latter of which names they have been generally known in commerce. The commercial name will be given whenever a knowledge of it can be useful. It is proper to state that the different barks are often mingled in the same package, and that, in deciding upon the character of a seroon, the druggist is guided rather by the predominance than the exclusive existence of certain distinctive properties.

1. Pale Bark.

The epithet *pale*, applied to the barks of this division, is derived from the colour of the powder. The French call them *quinquinas gris*, or gray barks, from the colour of the epidermis. They come into the market in cylindrical pieces, of variable length from a few inches to a foot and a half, sometimes singly, sometimes doubly quilled, from two lines to an inch in diameter, and from half

a line to two or three lines in thickness. The kinds which were formerly deemed the finest are about the size of a goosequill; but experience has shown that the young barks are not the most efficient. Their exterior surface is usually more or less rough, marked with transverse and sometimes with longitudinal fissures, and of a grayish colour, owing to adhering lichens. The shade is different in different samples. Sometimes it is a light gray, approaching to white, sometimes dull and brown, sometimes a grayish fawn, and frequently diversified by the intermixture of the proper colour of the epidermis with that of the patches of lichens. The interior surface, in the finer kinds, is smooth; in the coarser, occasionally rough and somewhat ligneous. Its colour is a brownish-orange, sometimes inclining to red, sometimes to yellow, and, in some inferior specimens, of a dusky hue. The fracture is usually smooth, with some short filaments on the internal part only. In the coarser barks it is more fibrous. The colour of the powder is a pale fawn, which is of a darker hue in the inferior kinds. The taste is moderately bitter and somewhat astringent, without being disagreeable or nauseous. Authors speak also of an acidulous and aromatic flavour. The better kinds have a feeble odour, which is distinct and agreeably aromatic in powder and decoction. The pale barks are chemically characterized by containing *a much larger proportion of cinchonia and quinidia or cinchonidia than of quinia;* and their infusion does not yield a precipitate with solution of sulphate of soda. Their appearance generally indicates that they were derived from the smaller branches. They are collected in the provinces about Loxa, or in the country which surrounds the city of Huanuco, northeast of Lima, and are probably derived chiefly from Cinchona Condaminea, C. nitida, and C. micrantha.

There are several commercial varieties of pale bark, obtained from different sources, and differing more or less in properties. The most highly esteemed of these is the *Loxa bark*, the finest specimens of which are sometimes called *crown bark of Loxa*, from the impression that they have the same origin and character with the bark, formerly selected with great care for the use of the King of Spain and the royal family. The pale bark collected about Huanuco is named either *Lima bark*, because taken to that city for commercial distribution, or *Huanuco bark*, from its place of collection. The former name has been more common in this country, where, indeed, this commercial variety has not unfrequently been confounded with the Loxa bark. Other pale barks are the *Jaen* and *Huamilies barks*, which are scarcely known as distinct varieties in the United States.*

* The following description of the several varieties of *pale bark* has been derived mainly from the works of Von Bergen, Guibourt, and Pereira, probably the highest European authorities on this subject; the first in Germany, the second in France, and the third in England. We have consulted also other pharmacological writers, and have derived advantage from the recent observations of Dr. Weddell and M. Delondre, and of Mr. J. E. Howard, of London, who has carefully examined the rich collection of Pavon deposited in the British Museum, and compared the specimens with the barks of commerce. Our remarks are put in the form of a note; as the information in relation to these varieties can be of little use to the student, though it may aid the druggist.

For a proper understanding of the subject, the reader should have some idea of the general structure of the bark. In the young barks there are four layers, viz.: 1. the *epidermis* or outer coat, often covered or incorporated with lichens; 2. the *periderm* or suberous coat, sometimes of a cork-like character; 3. the *cellular coat* or *green layer*, often containing resin; and 4. the *liber*, or inner coat, which is more or less fibrous.

1. *Loxa Bark. Crown Bark.—Quinquina de Loxa*, Fr.—*Loxa China*, *Kron-China*, Germ. —The following is Von Bergen's description of this variety, contained in his splendid work upon bark, entitled *Versuch einer Monographie der China*, published in Hamburg in the year 1826. This bark is in cylindrical tubes, strongly rolled, from six to fifteen inches long, from two lines to an inch in diameter, and from half a line to two lines thick. The outer surface is more or less rough, seldom much wrinkled longitudinally, but marked with numerous transverse fissures, which usually run round the bark, and divide it into rings, the edges of which are somewhat elevated. In the smallest quills these fissures are not very obvious; in the larger, they are distant and apt to be interrupted. In the largest the surface is sometimes very rough and even warty. The proper colour of the epidermis is dark-gray, sometimes almost black, sometimes ash-coloured, and occasionally inclining to fawn; but frequently diversified by whitish lichens, which are in some instances so numerous as to cover almost the whole exterior of the bark, and to give it a light-gray

In this country, the pale bark has fallen into disuse. As it yields little *quinia*, it is not employed in the manufacture of the sulphate of that alkaloid, which has

appearance. The inner surface is smooth and uniform, and of the colour of cinnamon, with occasionally a reddish tinge. The fracture in the smaller quills is quite smooth, in the larger somewhat fibrous. The bark is of a rather firm consistence, and when cut transversely exhibits a resinous character. Its odour is compared by Guibourt to that perceived in damp woods, by Von Bergen to that of tan. Its taste is acidulous, astringent, and bitterish. The powder is of a dull cinnamon colour.

Guibourt, in the edition of his *Histoire des Drogues* published in 1850, describes four chief varieties of Loxa bark, under the names severally of 1. *Quinquina de Loxa gris compacte*, 2. *Quinquina de Loxa brun compacte*, 3. *Quinquina de Loxa rouge fibreux de roi d'Espagne*, and 4. *Quinquina de Loxa jaune fibreux*. Of these the first two appear to be embraced in the description above given from Von Bergen. The third is distinguished from the common Loxa bark by its eminently fibrous texture, and its slight astringency to the taste. It is scarcely to be found in commerce. The fourth was almost the only variety of Loxa bark known in the French market. It is in quills, very thin, and usually very much rolled, but slightly rough externally, with minute transverse fissures, generally covered with a thin whitish coat which gives it a light-gray colour, reddish and very smooth internally, and of a very finely fibrous fracture. Its taste is astringent and bitter, and its odour sufficiently marked. The pieces from the trunk are much larger, and may even have a thickness of two lines, with some resemblance to the Calisaya; but its outer surface, scarcely rough, and often longitudinally wrinkled, the fineness of its texture, and the smoothness of its inner surface readily distinguish it. Guibourt has no hesitation in referring it to *C. macrocalyx*.

English druggists distinguish Loxa bark into 1. the *picked crown bark*, which consists of the finest, thinnest, and longest quills; 2. the *silvery crown bark*, somewhat larger in size, and characterized by a whitish silvery appearance of the epidermis, derived from adhering lichens; and 3. the *leopard crown bark*, named from its speckled appearance, depending on whitish lichens alternating with the dark-brown epidermis. Dr. Pereira, in the last edition of his work on Materia Medica, the publication of which was completed after his death (A.D. 1853), distinguishes the following varieties of Loxa bark.—1. *Original or old Loxa Bark*. This is the original *crown bark*, and derived its name from the circumstance, that parcels of it were found on board a captured Spanish vessel returning from S. America, put up with peculiar care, and marked as for the royal family. It was in slender quills, thirteen inches long, tied up in bundles about three inches in diameter. Similar bundles were afterwards imported, and still occasionally come in the seroons of commercial crown bark. This bark is believed to have been derived from *C. Condaminea*, variety *vera* of Weddell; but, as the tree is nearly exhausted, little is obtained from it at present; and what is commonly called Loxa, or crown bark, is derived from other varieties of C. Condaminea, or from other species.—2. *White Crown Bark*. This is in small and large quills; the former having a silvery appearance from the presence of crustaceous lichens, and exhibiting numerous transverse cracks; the latter without these transverse fissures, but ragged externally from longitudinal rents in the epidermis, with a satin-like lustre of the surface thus exposed. It is the produce of *C. Condaminea*, var. *lucumæfolia* of Weddell, *C. lucumæfolia* of Pavon.—3. H.O. *Crown Bark*. This is the variety usually found in commerce, and has been named from the brand H.O. with a crown, adopted in the time of the Spanish government in S. America. It is in quills from six to fifteen inches long, from two lines to an inch in diameter, and from one-third of a line to two lines thick. Some of the quills are without lichens, thin, externally brown and shrivelled, with numerous longitudinal wrinkles, but with few transverse fissures. The internal surface is cinnamon-coloured, and the fracture pale-yellow. Others are larger, coarser, grayish externally from lichens, with many transverse fissures, some of which quite surround the quills. Others again are twisted, and have a patchy black and white appearance from the adhering lichens. The botanical origin of this bark is not certainly known; though Howard ascribes it to *C. glandulifera*. (*Pharm. Journ.*, xii. 128.) It comes from the port of Payta.—4. *Ashy Crown Bark*. This is in quills about the size of the fingers, having an external surface mottled with white, gray, and black or soot-like patches of powdery and crustaceous lichens, sometimes also marked with rusty fungoid warts. The epidermis has longitudinal wrinkles and transverse fissures; the internal surface is of an orange or cinnamon colour. Mr. Howard found it identical with the bark, in Pavon's collection, ascribed to *C. rotundifolia* of that botanist, *C. cordifolia*, var. *rotundifolia* of Weddell. It is stated to be imported from Lima; and, according to Mr. Howard, large quantities are used for pharmaceutical purposes. (*Ibid.*, 126.)—5. *Wiry Loxa Bark*. This is in very slender, wire-like quills, internally smoothish and brown, in some places slightly gray, without lichens, and almost destitute of transverse fissures. Many of the quills are lined within with a thin shaving of pale-yellow wood. The fracture is short and resinous. The taste is very astringent and but slightly bitter, and, as the bark is almost destitute of alkaloids, it is very nearly worthless. It is brought from Payta; but its botanical source is unknown.

The earlier analyses gave as constituents of the Loxa barks cinchonia and quinia, gene-

almost superseded the bark as a remedy in intermittents; and the red or yellow bark is preferred by physicians when it is necessary to resort to the medicine in

rally with a predominance of the former alkaloid. Since the discovery of *quinidia* and *cinchonidia*, these also have been found, sometimes in considerable proportion. The different varieties vary much in their yield of alkaloids; the larger barks, in all the varieties affording more than the smaller. An average of several results, stated by Geiger, gives about 0·48 per cent. of cinchonia, and 0·06 of quinia. In the thickest pieces, Thiel found 1·0 per cent. of cinchonia, and 0·03 of quinia. According to Soubeiran, one pound of Loxa bark yields from a drachm and a half to two drachms of sulphate of cinchonia. From some fine old Loxa bark, not now in the market, Mr. Howard obtained 0·714 per cent. of quinia, 0·514 of quinidia (or cinchonidia), and 0·04 of cinchonia. From the *H.O. crown bark*, which is at present the variety usually found in commerce, he got from small quills 0·57 per cent. of quinidia and 0·6 of cinchonia, and from larger 1·05 of the former and 0·8 of the latter, and no quinia from either. (Pereira, *Mat. Med.*, 3d ed., p. 1639.) From the *ashy crown bark* the same chemist got 0·418 per cent. of quinia and quinidia jointly, and 0·914 of cinchonia. (*Pharm. Journ.*, xii. 126.) From these results it would appear either that the older Loxa barks contained much more quinia than the modern, or that what was supposed to be quinia was really the then unknown alkaloid quinidia or cinchonidia. The strong reaction of a solution of gelatin with the infusion of Loxa bark indicates the presence of much tannic acid.

2. *Lima* or *Huanuco Bark. Cinchona Cinerea, Gray Bark, Silver Bark*, Ed.—*Quinquina de Lima*, Fr.—*China Huanuco, Graue China*, Germ.—Lima or Huanuco bark was introduced into notice about the year 1779, after the discovery of Cinchona trees in the central regions of Peru; but Pöppig says that the trade in it began in 1785. The first name originated from the circumstance that the bark entered into commerce through the city of Lima; the second was derived from the name of the city (Huanuco or Guanuco) in the more immediate neighbourhood of which the trees were found. There would seem to be two varieties of this bark, which come either in separate packages, or mixed together in the same. They are distinguished in England as *fine* and *coarse* gray barks, and have a different botanical origin; the former having been ascertained by Mr. Howard to belong to *C. nitida*, and the latter being ascribed to *C. micrantha*, probably with justice.

Fine Gray Bark.—Quinquina Rouge de Lima. Guibourt. The dimensions of this variety do not materially differ from those of the preceding, although in the largest pieces the diameter is somewhat greater. Many of the smaller quills have a more or less spiral form. At the edge of most of the complete quills, a sharp oblique cut with a knife is observable. The epidermis is usually adherent. The exterior surface is marked with longitudinal wrinkles or furrows, which in the thick pieces often penetrate quite through the outer coating of the bark. Transverse fissures are also generally observable; but they never run wholly round the quill, often not more than a quarter or half round, and do not exhibit elevated borders. In some pieces the epidermis is rubbed off, either wholly or in spots; and in a few the entire thickness of the external layers is here and there removed, exhibiting the proper bark in patches. The colour externally is very light-gray, almost milk-white, with occasionally bluish-gray and darkish spots intermingled. Where the outer crust which imparts this whitish colour is wanting, the surface is grayish-fawn or reddish-gray, and in the thicker pieces of a dark cinnamon colour. The inner surface, though in the smaller quills sometimes tolerably uniform, is generally more or less uneven, fibrous, or splintery, especially in the larger pieces, in which may often be observed adhering yellowish-white splinters of wood. The colour is usually a rusty brown inclining somewhat to red, with occasionally a purplish tinge. The transverse fracture is smooth exteriorly, fibrous or splintery interiorly. The longitudinal fracture is generally somewhat uneven, without being splintery, and exhibits here and there minute shining spots. The inner layers of the bark are usually soft and friable. The colour of the powder is a full cinnamon-brown. The odour of the bark is like that of clay, and in this respect different from that of all other varieties. The taste is at first acidulous, astringent, and slightly aromatic, and ultimately bitter and adhesive.

Coarse or Inferior Gray Bark. The characters of this bark as a distinct variety were first given by Guibourt, who calls it *quinquina de Lima gris brun*. The following is his description. "It is in the form of long tubes, well-rolled, from the size of a quill to that of the little finger, offering very often longitudinal wrinkles, formed by desiccation. The exterior surface is, moreover, moderately rugose, often nearly destitute of transverse fissures, having a general deep-gray tint, but with black or white spots, and bearing here and there the same lichens as the Loxa barks. The inner bark is of a deep-brownish yellow, and formed as it were of agglutinated fibres." (*Hist. des Drogues*, 4e ed., iii. 108.) Mr. Howard says of this bark that its predominant feature is its general *woody texture*, a feature very observable on reducing it to powder, while the only hard portion of the former variety is a resinous circle existing between the inner and outer coats. He further states, as distinctions between the two varieties, that the one now described is thinner than the former; that its prevailing superficial colour, independently of the white lichenous covering, is *glaucous green*, and the colour of its substance *rusty yellow*, while the *fine gray*, as regards the inner surface, varies superficially from a maroon colour to rust

substance. There is no doubt, however, that *cinchonia* possesses febrifuge properties little inferior to those of *quinia*; and the same is probably the case with

and as regards the outer is brown, the substance of the bark being red: that a decoction of the former is pale, and gives a small flocculent deposit on cooling, while one of the latter is brown, and lets fall a copious sediment. (*Pharm. Journ.*, xii. pp. 15 and 16.)

The Edinburgh College referred the Lima bark, which it denominated *cinchona cinerea* or *gray bark*, to *C. micrantha*. There is at present little room to doubt, from the observations of Guibourt, Pereira, and Howard, that it is only the *coarse or inferior variety* that belongs to that species; while the *fine gray bark* must be ascribed to *C. nitida*, which also grows in the neighbourhood of Huanuco.

The Lima or Huanuco barks contain a considerable proportion of the alkaloids, though cinchonia predominates over quinia, and the latter is said to exist in a form in which it is difficultly crystallized, at least in the fine variety. Howard gives, as the result of his analysis of the *fine gray bark* (C. nitida), 1·4 per cent. of cinchonia, 0·571 of quinia, and 0·142 of quinidia (or cinchonidia), amounting altogether to 2·113 per cent. (*Pharm. Journ.*, xii. 12.) It also contains much tannic acid. (*Ibid.*, p. 161.) In the *inferior kind* (*C. micrantha*) he found 1·25 of cinchonia, 0·243 of quinia, 0·28 of quinidia (or cinchonidia), together 1·773 per cent. (*Ibid.*, p. 14.) Geiger gives as the average of several results, in relation to Lima or Huanuco bark, 1·72 per cent. of cinchonia and 0·29 of quinia. Von Santen got from the best specimens, as the maximum, 2·73 per cent. of cinchonia, and no quinia. Delondre obtained from the different varieties from 0·2 to 0·6 per cent. of sulphate of quinia, and from 0·8 to 1·2 of sulphate of cinchonia. (*Quinologie*, pp. 27, 28.) It would, therefore, appear that this variety of bark must become valuable, if cinchonia should come into general use.

3. *Jaen Bark. Ash Bark. — China Jaen, Blasse Ten-China*, Germ. — *Quinquina de Loxa cendré* of Guibourt. This variety probably derives its name from the province of Jaen de Bracomoros, near Loxa, where large quantities of bark have been collected. The Jaen bark is always in quills, which do not differ much in size from those of the Loxa bark, but are distinguishable by being frequently curved longitudinally, or bent in different directions, and somewhat spiral. The outer coat is often partially or entirely rubbed off, leaving the surface smooth and soft to the touch. When the epidermis is perfect, it exhibits small, irregular, transverse fissures, with sometimes faint longitudinal fissures and wavy wrinkles, and here and there a few warts, but no deep furrows. The colour varies from light or ash-gray to light yellow, diversified with blackish and brownish spots. When the outer coat is rubbed off, it inclines still more to yellow. Considered in mass, the bark always appears somewhat yellowish or straw-coloured. The exterior layers are soft and rather spongy, and may be readily scraped by the nail. The inner surface is exceedingly diversified, sometimes smooth, sometimes uneven and splintery. It is usually of a dull-cinnamon colour. The bark is very brittle, and the fracture smooth in the smaller quills, more or less uneven and sometimes splintery in the larger, and in neither having a resinous appearance. The odour is sweetish, and is compared to that of tan. The taste is acidulous, slightly astringent, and bitter, without being disagreeable. The colour of the powder is cinnamon-brown. The bark is very deficient in alkaloids. Some experimenters have found none, or only traces, while the highest product obtained was 80 grains of quinia and 13 grains of cinchonia from a pound. M. Munzini, of Paris, extracted from it an alkaline principle which he believed to be peculiar, and named *cinchovatin;* but others believe that it is identical with the *aricina* of Pelletier; and Mr. Howard can discover no difference between it and quinidia. (*Pharm. Journ.*, xii. 127.) Mr. Howard does not coincide in the general opinion of the great poverty of the *ash bark* in alkaloids. He found in a mean-looking specimen 0·86 per cent. of cinchonia, and 0·61 of quinidia (or cinchonidia). (*Ibid.*, p. 127.) Delondre obtained, on the large scale, 0·4 of sulphate of cinchonia and 1·0 of sulphate of quinia. (*Quinologie*, p. 29.) Von Bergen believes this bark to be the product of C. ovata; and Mr. Howard confirms this reference.

Von Bergen describes a variety of pale bark, under the name of *dark Jaen bark* (*dunkele Ten-China*), or *pseudo Loxa*, which resembles the Loxa, but may be distinguished by the oblique or bent shape of the quills, and the uneven, fibrous, or splintery appearance of the inner surface. It seldom comes in large pieces. Pereira considers it identical with the *ashy crown bark* already described. (See *page* 277.)

4. *Huamilies Bark. — China Huamilies*, Germ. This bark is little known as a distinct variety. Its commercial name was derived from the province of Huamilies, in the interior of Peru, northward of Huanuco, and a part of the region explored by the botanical expedition under Ruiz and Pavon. It came into notice in Germany about the beginning of the present century. It is in quills and flat pieces. The quills are from three lines to an inch and a half in diameter, from five to sixteen inches long, and from half a line to three lines thick. The flat pieces, which are usually only fragments of the largest quills, are from one to two inches broad, and six to twelve inches long. In general all the layers of the bark are present, but sometimes the outer coat, and even the whole of that part usually called the epidermis in our descriptions of bark (including those outer layers which in the tree are destitute of vitality, having been thrown outward by the annually renewed layers beneath them), are wanting in spots, though very seldom entirely absent.

quinidia and *cinchonidia;* so that, should the source of quinia begin to fail, the pale bark may come into more extensive use for the preparation of the other alkaloids.

2. Yellow Bark.

The officinal term yellow bark is applicable only to the valuable variety of the drug called commercially *Calisaya*, a name which has been said, though erroneously, to be derived from a province in Bolivia, near the city of La Paz, where the bark is collected.* By the druggists *Calisaya bark* is arranged in two sub-varieties, the quilled and the flat, which sometimes come mixed together in the same seroon, sometimes separate. It is called by the French *quinquina jaune royal* (royal yellow bark), from its resemblance to a variety of bark formerly collected for the Spanish king.

The *quilled Calisaya* (*Calisaya arrolada* of the Spanish Americans) is in pieces from three inches to two feet long, from a quarter of an inch to two or three inches in diameter, and of equally variable thickness. The epidermis is of a brownish colour, diversified or concealed by silvery-white, whitish, or yellowish lichens, is marked by longitudinal wrinkles and transverse fissures, and is often partially separated, and generally easily separable from the proper bark. In the larger kinds, it is thick, rough, deeply indented by the transverse fissures, which often surround the quills, and is composed of several layers, separated from each other by a reddish-brown membrane. The epidermis yields a dark-red powder, and is tasteless and inert. It is desirable, therefore, to get rid of it before the bark is powdered, as the medicine is thus procured of greater strength. The bark itself, without the epidermis, is from one to two lines in thickness, compact, of a short-fibrous texture, and when broken presents shining points, apparently the termination of small fibres running longitudinally, which, examined by the microscope, are found, when freed from a salmon-coloured powder that surrounds them, to be yellow and transparent. When the bark is powdered, they readily separate, in the form of spicula, which, like those of cowhage, insinuate themselves into the skin, and produce a disagreeable itching and irritation. The colour of the bark is brownish-yellow with a tinge of orange, the taste less astringent than that of the pale bark, but much more bitter; and the

The epidermis is comparatively thin, very brittle, soft, and spongy. The outer surface, in the small and middling quills, is sometimes nearly smooth, but usually marked with wavy longitudinal wrinkles, and beset here and there with warts. These warts are abundant upon the thick pieces, which they sometimes almost entirely cover. Transverse fissures are seldom found, and only in the thick pieces. The colour of the epidermis is usually grayish-fawn, here and there passing into a rusty brown; but in the thicker pieces, in which the warts are abundant, it is between a liver and chestnut colour, often mixed with a tinge of purple. When the epidermis is wanting, the colour is often a full ochre-yellow. The inner surface is sometimes uniform and almost smooth, sometimes slightly fibrous, rarely splintery. The colour of this surface is rusty-brown, occasionally reddish and in the fibrous or splintery pieces of an ochre-yellow. The fracture in the smaller quills is rather even, in the larger presents short fibres, and is sometimes even splintery. The odour of the bark is feeble but agreeable, the taste somewhat aromatic, bitterish, and slightly astringent. The powder is of a full-cinnamon colour. The average product of cinchonia and quinia, as stated by Geiger, is 0·67 per cent. of the former, and 0·25 of the latter; so that the bark, though dissimilar in appearance to the other varieties of pale bark, agrees with them in containing more cinchonia than quinia. Von Santen obtained, as the maximum, 1·2 per cent. of cinchonia, and little or no quinia. Huamilies bark, on the authority of Reichel, has been referred to *C. pubescens* (*C. purpurea* of the *Flor. Peruv.*); but Dr. Pereira and Mr. Howard agree in believing it to be the product of *C. Condaminea*, variety *Chahuarguera* of De Candolle, considered by Weddell as identical with his *C. Condaminea*, variety *vera*. The bark here described is noticed by Guibourt, who names it *quinquina Huamilies ferrugineux*. The same author makes four other varieties of Huamilies bark; viz. the *gris terne*, *mince et rougeâtre*, *blanc*, and *jaune de Cuença*. (*Note to the tenth edition.*)

*No such province exists in Bolivia. According to M. Laubert, the name is a corruption of *colisalla*, said to be derived from *colla*, a remedy, and *salla*, a rocky country. (*Journ. de Pharm.*, xxii. 614.) Weddell refers the origin of the name to the words *colli* and *saya*, which in the Quichua language signify *red* and *sort*, and have probably been applied from the redness which the outer denuded surface of the bark assumes in drying, or from the red colour which the leaves sometimes exhibit.

bitterness is somewhat peculiar. The external part of the proper bark is more bitter and astringent, and consequently stronger in medicinal power, than the internal. The odour is faint, but, when the bark is boiled, resembles that of the pale varieties. The small quills closely resemble some of the pale barks, but may be distinguished by their very bitter taste.

The *flat Calisaya* (*Calisaya plancha* of the Spaniards), which is derived from the large branches and trunk, is in pieces of various lengths, either quite flat, or but slightly curved, and generally destitute of the epidermis, which has been obviously removed through its own want of adhesiveness to the proper bark, and not by a knife, as is the case with some inferior barks in other respects resembling the Calisaya. The inner surface is like that of the quilled pieces; the outer is irregular, marked with confluent longitudinal furrows and ridges, and somewhat darker coloured than the inner, being of a brownish fawn, frequently diversified with darker stains. The bark is of uniform fracture throughout, generally thicker than the quilled, more fibrous in its texture, less compact, less bitter, and possessed of less medicinal power. Though weaker than the proper bark of the quills, it is usually, in equal weight, more valuable than that variety, because free from the useless epidermis.

The officinal yellow bark is characterized by its strongly bitter taste, with little astringency; by its fine brownish-yellow, somewhat orange colour, which is still brighter in the powder; and by *containing a large proportion of quinia with very little cinchonia.* The salts of quinia and lime are so abundant, that a strong infusion of it instantly affords a precipitate when crystals of sulphate of soda are added. (Guibourt, *Hist. des Drogues*, 4ème ed., iii. 131.)*

* *Calisaya bark* is described by Von Bergen, under the name of *China Regia* or *König's China.* We present a brief abstract of his description, omitting the form and dimensions, which are given in the text. The epidermis,† which in many of the small quills is partly wanting, in the flat pieces usually quite wanting, is very thick and brittle, constituting from a third to one-half of the bark, and, in some of the largest quills or partially quilled pieces, even two-thirds. In the latter case, it often consists of six or eight different layers. The quills are generally marked with longitudinal wrinkles and furrows, and always with transverse fissures. These fissures, which often form complete circles round the quills, have usually an elevated border, and sink so deeply in many of the larger pieces, that they are observable upon the proper bark. In the smaller pieces they are often faint, but usually crowded. The colour of the epidermis varies from whitish-gray to bluish-gray; but it is very much diversified by lichens, so as to present yellowish-white, ash-gray, and blackish spots. When the outer layer of the epidermis is wanting, as is not unfrequently the case to a greater or less extent, the colour is somewhat sooty-brown or almost liver-brown. The outer surface of the pieces without epidermis is of a colour between cinnamon-brown and dark rusty-brown. The inner surface, in the pieces of all dimensions, is uniform and almost smooth, but exhibits fine longitudinal fibres closely compressed. Splinters of wood are never found adhering to the inner surface. The prevailing colour of this surface is a rather dark or full-cinnamon brown, passing sometimes into a rusty brown, but seldom reddish. This bark breaks more easily in the longitudinal direction than any other variety, exhibiting a chestnut-brown colour in the part answering to the epidermis, a more or less dark cinnamon-brown in that answering to the proper bark. The transverse fracture of the epidermis is rather even, that of the inner bark fibrous or splintery. A resinous layer may be seen beneath the epidermis, which usually remains when the latter is removed, and communicates to the flat pieces the dark colour which distinguishes their external surface. Small sharp splinters, which in the longitudinal fracture appear like shining points, are apt to insinuate themselves into the skin when the bark is handled. The odour is feebly tan-like; the taste slightly acidulous, strongly but not disagreeably bitter, somewhat aromatic, feebly astringent, and rather durable. The powder is of a fine cinnamon hue.

Weddell speaks of a variety of Calisaya bark having a dark-coloured external surface, which is often wholly of a vinous black, and of another which has a less uneven surface, sometimes semi-cellular, and of a paler colour. The former, he says, is denominated in Bolivia *Calisaya zamba*, *C. negra*, or *C. macha;* the latter *Calisaya blanca.*

Thiel obtained from the flat Calisaya 2·3 per cent. of quinia, and 0·08 of cinchonia;

† By the epidermis is here understood the whole of the external layers which are accumulated upon the outer surface of the bark by the annual renewal of the cortical layers, and the consequent separation of those of former years, which remain, but without life, attached to the external surface. A different meaning is attached to the term by Von Bergen; but, as we have taken pains to make the description in every instance correspond with our definition, we do not misrepresent his meaning.

Until the recent most valuable researches of Weddell, nothing was known with certainty as to the particular species which yields Calisaya bark. At present

Michaelis from the flat 3·7 per cent., and from the quill 2·0 per cent. of quinia, but no cinchonia; *Von Santen* from the flat, an average of 2·0 per cent. of quinia, and little or no cinchonia; *Wittstock*, on an average, 3·0 per cent. of sulphate of quinia, and 0·12 of cinchonia. (*Geiger.*) Riegel obtained as the lowest product 2·18 per cent., and the highest 3·8 per cent. of quinia. (*Pharm. Journ.*, xii. 249.) MM. Delondre and Bouchardat have obtained from the flat Calisaya, without epidermis, from 3·0 to 3·2 per cent. of sulphate of quinia, and 0·6 to 0·8 per cent. of sulphate of cinchonia; and from the quilled with epidermis 1·5 to 2·0 per cent. of the former, and from 0·8 to 1·0 per cent. of the latter. (*Quinologie*, pp. 23 and 26.) M. Guilliermond has recently obtained the very large product of 6 per cent. of quinia from a specimen of quilled Calisaya, without epidermis (*Journ. de Pharm.*, Janvier, 1862, p. 42); and still more recently, Mr. Howard has, in one or two selected specimens, obtained 7 or 8 per cent. of sulphate of quinia. (*Am. Journ. of Pharm.*, Sept. 1866, p. 420.) Calisaya bark without epidermis should yield from 3 to 3·5 per cent. of officinal sulphate of quinia.

False or Spurious Calisaya Barks.

The great value of Calisaya bark has led to the substitution for it, or fraudulent admixture with it, of other varieties bearing a more or less close resemblance to it in character or appearance. Some of these are not much inferior to the genuine bark, others of little value; and it is highly important that they should be distinguished. We give below a brief notice of such as are described in pharmacological works, or have come under our own observation. Weddell states that the characters by which the true Calisaya bark may be best distinguished from all others are, 1. the shortness of the fibres in the whole surface of its transverse fracture, 2. the facility with which these may be separated, 3. the uniform fawn colour, without any white marking in its thickness, 4. the *great density* of the bark, which is such that, when the nail is drawn across it, a shining track is often left, 5. the depth of the depressions on its outer surface, and the prominence of the ridges that separate them. These remarks refer to the flat variety. The quills are not so easily distinguished, as they closely resemble certain other varieties, especially the bark of C. scrobiculata and C. rufinervis, and the fracture does not give signs so precise as in the older barks. The surest test is the greater bitterness of the genuine. From their deficiency in compactness, spurious Calisaya barks are called by the French *Calisaya légere*, or *light Calisaya*.

1. *Bark of C. Calisaya*, variety *Josephiana* of *Weddell*. This is not known as a distinct variety in Europe or this country; but it is very probably mingled more or less with the genuine, as it is collected in Bolivia. It is in quills, of a brown, grayish-black, or slate colour on the outer surface, which is also covered with pale lichens. The inner surface is irregular, in consequence of the difficulty with which it is separated from the wood. From the *roots of the same variety*, which are probably the remains of former forest trees, is obtained another kind of bark, in short pieces, flattish, undular, or more or less contorted, destitute of epidermis, internally fibrous or almost smooth, slightly cellular externally, of a uniform ochreous yellow, and of a decided bitterness, though not so strong as that of good Calisaya, which it resembles in its internal structure. The Peruvians call it *ichucascarilla*. (Weddell.) These barks can scarcely be considered as adulterations, as they have the virtues of the genuine.

2. *Bark of C. Boliviana.* Weddell states that this is almost always mixed in commerce with genuine Calisaya, from which it is often difficult to distinguish it. This is of the less consequence, as it is probably not much inferior in virtue. The following is Weddell's description. The quilled is in all points similar to the quilled Calisaya. The flat consists exclusively of the inner bark. It is generally not so thick as the Calisaya, but of equal density. The furrows on the outer surface are not so deep, and the ridges which separate them more rounded. The colour of this surface is a brownish-yellow fawn, with here and there greenish shades, of the inner, a somewhat reddish or orange fawn. The fracture is like that of the Calisaya, but exhibits spots of a light almost white colour, which are never seen in that variety. The taste is a strong and agreeable bitter, which is developed more quickly than that of the Calisaya.

3. *Bark of C. ovata* var. *rufinervis* of Weddell. This variety of C. ovata inhabits Bolivia and the southern province of Peru called *Carabaya*, where the bark is said by Weddell to be largely employed for adulterating the Calisaya. It is known in Peru by the name of *Cascarilla Carabaya*. It sometimes so closely resembles Calisaya as to be with difficulty distinguished. In the *quilled*, the outer coating sometimes differs only in being somewhat less thick. In other instances it has but a few annular fissures, is finely wrinkled longitudinally, and varies in colour from a light gray to a deep brown, being often completely covered with mosses and lichens. It is generally easily separable from the inner coat, the uncovered surface of which is of a light-brownish fawn, and smooth, or marked with longitudinal depressions corresponding to rents in the outer coat. The inner surface is grayish or reddish-yellow, and finely fibrous; the transverse fracture fibrous; the resinous circle scarcely observable; the taste quickly bitter and astringent. The *flat* kind is of

there is no variety of which, in this respect, we have more accurate knowledge. The genuine bark is derived from the newly described species, named *C. Cali-*

variable form, often closely resembling the Calisaya, but generally much lighter. Sometimes it consists solely of the inner bark, but more frequently has a portion greater or less of the cellular coat attached. The outer surface is sometimes smooth, with a few linear transverse depressions, and wholly cellular; in other instances, uneven, with roundish depressions, fibrous at bottom; and is of a grayish-fawn or reddish colour, sometimes marbled with darker shades. The inner surface is of a dull grayish-yellow, or brilliant orange, with fine parallel fibres. The transverse fracture is more or less corky exteriorly, and fibrous-stringy within, or of the latter character in the whole thickness. It has considerable bitterness, which is rapidly developed in the recent barks.

Carabaya Bark. Under this name a bark has within a few years been introduced into the commerce of this country and Europe, derived from the province of Carabaya, through the port of Islay, or that of Arica. Dr. Pereira describes it as follows. — It is thin and flimsy, of a more or less rusty colour, and in some of the pieces very similar to the *Huamalies*. The *quills* are about as thick as the finger, and of variable length, sometimes even two feet, coated, or uncoated; the coated having a dull-rusty, or grayish-rusty, warty surface, marked by longitudinal furrows, but rarely by transverse; the uncoated sometimes presenting a dark or more or less tea-green tint. The *flat pieces* consist of the liber alone, or of this with a portion of the cellular coat. The outer surface of the liber, in some of the uncoated pieces, is blackish, with rusty, round, flattish warts. Sometimes it looks as if dusted over with a yellowish powder. The liber itself is more or less orange; but some pieces resemble red bark in colour. Whether this is the product of *C. ovata* is uncertain; but, taking its source into consideration, and the fact stated by Weddell that the bark of that species is gathered largely in Carabaya, and known by the same name in Peru, the probabilities seem to be greatly in favour of this opinion. Pereira states that its total yield of alkaloids, including quinia, cinchonia, and quinidia, is from 3 to 4 per cent. In the *Quinologie* of MM. Delondre and Bouchardat (p. 26), the product of the better specimens is stated to be from 1·5 to 1·8 per cent. of sulphate of quinia, and 0·4 to 0·5 per cent. of sulphate of cinchonia. It is, therefore, a valuable bark.

A variety of *flat bark*, imported into the U. States as *Carabaya*, is in irregular pieces, some very small, the largest about 9 inches in length, generally very thin; for the most part destitute of epidermis, but sometimes with portions of the outer coat attached; on the *outer surface*, when uncoated, of a dull-cinnamon hue, with spots of a different colour sometimes much darker, more or less irregular from slight elevations and shallow depressions, somewhat furrowed longitudinally, seldom so transversely; on the *inner surface*, of a lighter hue than on the outer, smooth and somewhat shining when viewed obliquely, with fine compact straight fibres; with a decided fibrous fracture, sometimes smooth toward the outer edge; and, when handled, readily yielding spicula, which penetrate the fingers like those of Calisaya. In one specimen shown us by Messrs. Powers and Weightman, the outer surface was almost completely covered with the subepidermic layer, with little or none of the epidermis itself, and was remarkably uniform in its aspect, though sometimes presenting numerous slight longitudinal wrinkles from drying, and a few shallow transverse impressions. We are informed that this variety contains more cinchonia than quinia, and have little doubt that it is the bark referred to by Weddell as the product of *C. ovata*, var. *rufinervis*.

4. *Bark of C. scrobiculata.* The younger bark of this tree has, we think, undoubtedly been imported among the pale or gray barks. The larger or flat pieces have been fraudulently substituted for Calisaya. Of these, according to Pereira, there are two varieties, derived from different varieties of the tree.

a. *Cusco Bark. Red Bark of Cusco.* (*Delondre and Bouchardat*, Quinologie, p. 26.) *Bark of St. Ann. Bark of C. scrobiculata*, var. *Delondriana.* This is collected in the province of Cusco, in the south of Peru; and the town of Cusco is said by Weddell to be the centre of its commerce. It is the kind to which Guibourt has attached the name of *light Calisaya*. Weddell thus describes it: "Less dense than the Calisaya; consisting generally of the liber and a thin layer of the cellulo-resinous tissue; thickness from 5 to 10 millimetres (2 to 4 lines). Outer surface obscurely *red*, smooth, with some linear transverse impressions, or more or less irregular; exhibiting often superficial cavities filled with fungous detritus; raised in other instances into asperities or irregular warts, or more rarely presenting an exfoliation of the cellular coat, as complete as in the Calisaya, with digital confluent furrows fibrous at bottom, and the ridges which separate them. *Interior surface* uniform, of fine and straight grain, and of a handsome *reddish-orange* colour. *Transverse fracture* more or less cork-like on the outside, according to the thickness of the cellular portion; on the inside very fibrous, with long, pliable, stringy fibres, and of a lighter colour than the outer part. *Longitudinal fracture* presenting numerous splinters with shining points, less marked than in the Calisaya, and medullary rays more numerous and visible. *Taste* bitter, strong and quickly developed in the middling sized barks, with perceptible astringency. This bark yields from 0·7 to 0·8 per cent. of sulphate of cinchonia, and from 0·3 to 0·4 of sulphate of quinia." (*Hist. Nat. des Quinquinas*, pp. 44, 45.)

saya; but the bark of *C. Boliviana*, another of the species discovered by Weddell, is sometimes mixed with it in the same seroons. It is produced exclusively

b. *Peruvian Calisaya.* Bark of *C. scrobiculata*, var. *genuina*, Weddell. This is imported from Lima. Pereira describes it as occurring in flat pieces, closely resembling the genuine Calisaya in colour, for which it is often sold. They are thicker and denser than the last-mentioned variety, from which they also differ in colour. Externally the bark is smoother than the Calisaya; and the ridges between the furrows are more rounded. The fracture is fibrous, and the taste, in the larger pieces, less bitter than that of Calisaya. (*Mat. Med.*, 3d ed., p. 1629.)

This bark is probably the same with that referred to in the eighth and ninth editions of this Dispensatory (p. 236 of the 9th), as having been imported into the United States about the year 1848; having been consigned to a manufacturing chemist of this city by a commercial house in Valparaiso, with the information that it had been sent to them by Dr. J. Villamil, and had been gathered in the forests of Huanuco in Peru. The pieces are generally without the epidermis, which appears to have separated spontaneously, and, when retained, has the transverse fissures and longitudinal furrows characteristic of the Calisaya. The colour and consistence of the bark are the same as in the genuine; and it even presents the shining spicula which characterize the latter, though they are less numerous, and do not so readily penetrate the fingers. The taste is very bitter. Examined chemically by Professor Procter, it was found to afford a precipitate with sulphate of soda, in consequence of containing kinate of lime, and thus in another point approaches the Calisaya; but he could not detect in it a trace of quinia. The only alkaloid it was found to contain was cinchonia, of which there was the large proportion of 2·8 per cent.; so that this must rank with the valuable barks. For a more particular account of it, the reader is referred to a paper by Prof. Procter in the *American Journal of Pharmacy* (xix. 178).

5. *Bark of Cinchona pubescens*, var. *Pelleteriana* of Weddell. *Cusco Bark. Arica Bark.* This was first known in France by the name of Arica bark, from the port at which it was shipped; but, both in French and English commerce, this name has given way to the more appropriate one of *Cusco Bark*, derived from the Peruvian province in which it is collected. Dr. Pereira says that it was first introduced into Europe in 1829 as yellow or Calisaya bark. From the statements of Weddell, there seems to be little doubt that it is the product of the tree referred to at the heading of this paragraph; as specimens collected by himself in the mountains of Cusco were found identical with the bark as known in Europe. The following is his description condensed. — In the *quilled*, the outer coat is thin, very adherent, almost smooth, sometimes with traces of annular fissures, of a uniform dirty-gray colour, or marbled with darker shades. The proper bark is, without, of an obscure yellow, sprinkled with little brown spots when artificially denuded, and marked with some superficial longitudinal wrinkles; within, is obscurely yellow and a little reddish, coarsely fibrous, and often rough to the touch. The transverse fracture is exteriorly corky and quite short, without a resinous circle, and inwardly with a few short thick fibres. *The flat pieces* are very dense, and consist about equally of cellular coat and liber. The outer surface is smoothish, sometimes slightly wrinkled longitudinally, of an ochre-yellow more or less brownish, and frequently marbled with grayish or silvery spots, which are the remains of the epidermis. The inner surface is brownish or reddish, thick, and fibrous. The transverse fracture is cork-like outwardly, of short woody fibres inwardly. A fresh cut surface in the same direction shows inwardly rows of large isolated semitranslucent points, corresponding to the section of the cortical fibres, agglutinated in bundles. The longitudinal fracture is almost without splinters. The epidermis, when it remains on the large barks, is thin, unequal, sometimes warty, of an obscure gray, and more or less brownish or even greenish in some spots. When it has been scraped, the bark sometimes presents deep-brown spots, which are the points where the prominences in the cellular coat had raised the epidermis so as to form the little warts referred to. These are sometimes decayed, and upon falling leave roundish depressions. The taste of the bark is bitter, astringent, and somewhat pungent. (*Hist. Nat. des Quinquin.*, p. 56.)

Von Bergen says that this bark somewhat resembles the fibrous Carthagena. Inexperienced persons might mistake it for the Calisaya. Guibourt says that it may be readily distinguished by a more regularly cylindrical form, its smoother outer surface, the remains of the white and fungous layer, by its two shades of colour, orange or brownish externally, and whitish or very pale internally, and by not yielding a precipitate with sulphate of soda.

Pelletier supposed that he had found a new alkaloid in this bark, which he named *aricina;* but the substance he obtained is now thought to have been some modification of one of the other alkaloids. The chief alkaloid in the bark is cinchonia. Frank obtained 48 ounces of it from 100 lbs. of the bark, and only a trace of quinia; Winckler, 256 grains from 16 ounces of a good specimen, and only 77 grains from the same quantity of an inferior one. Guibourt estimates the proportion at a drachm for every pound, and observes that the bark is rich in cinchonic red.

6. Bark of *C. micrantha*, var. *rotundifolia* of Weddell. As this variety grows in Bolivia, and the flat bark derived from it simulates Calisaya, it is very probable that its product has been sometimes used to adulterate the latter bark. Weddell says of it that

in Bolivia, formerly upper Peru, and in the southern portion of the adjoining Peruvian province of Carabaya. Before these countries were separated from Spain, it was shipped as well from Buenos Ayres as from the ports on the Pacific; but at present it comes only from the latter. As first announced in this work, from information derived from merchants long personally engaged in commercial transactions on the Pacific coast of South America, the bark is brought from the interior to the port of Arica, whence it is sent to various other ports on the coast. The interior commerce in the drug has its centre chiefly in the town of La Paz. The trade in this bark has been much diminished, in consequence partly of its greater scarcity, partly of restrictions by the Bolivian government.

It is generally supposed to have been first introduced into commerce towards the end of the last century, and it was probably not known by its present name till that period; but La Condamine states that the Jesuits of La Paz, at a period anterior to the discovery of the febrifuge of Loxa, sent to Rome a very bitter bark by the name of *quinaquina*, which, though supposed by that traveller to have been derived from the Peruvian balsam tree, was very probably, as conjectured by Guibourt, the true cinchona. Besides, Pomet, in his *History of Drugs*, published in 1694, speaks of a bark more bitter than that of Loxa, obtained from the province of Potosi, which borders upon that of La Paz; and Chomel also states that the cinchona tree inhabited the mountains of Potosi, and produced a bark more esteemed than that which grew in the province of Quito. (Guibourt, *Journ. de Pharm.*, xvi. 235.) It is possible that, though known at this early period, it may have gone out of use; and its reintroduction into notice, towards the end of the last century, may have been mistaken for an original discovery.*

it has little density, and consists of the liber alone, or of this and the cellular coating, which is generally semi-fungous and imperfectly exfoliated. The *external surface* is unequal, presenting superficial concavities similar to those of Calisaya, and separated by irregular corky eminences, but sometimes though rarely smooth from the persistence of the whole cellular coating, and is of a bright and grayish orange-yellow. The *internal surface* is considerably fibrous, of the same colour as the external, but of a more lively tint. The *transverse fracture* is stringy; the *longitudinal* but slightly splintery, and of a dull surface. The *taste* is decidedly bitter and quickly developed, a little pungent, scarcely astringent. (*Hist. Nat. des Quinquin.*, p. 53.)

7. Bark of *C. amygdalifolia.* This species also inhabits Bolivia, and its bark may possibly sometimes contaminate the Calisaya, as it has been largely collected. Pereira states that it is imported alone or mixed with other Bolivian barks, both quilled and flat. According to the same author, it is distinguished from the Calisaya by its lightness, its more orange colour, the presence of the cellular coat in the pieces deprived of epidermis, the stringy transverse fracture, the splintery longitudinal fracture, the want of marked annular fissures in the epidermis, and the astringent and but slightly bitter taste. Mr. Howard obtained from a portion of the quills 0·7 per cent. of quinidia and a trace of cinchonia; from the flat 0·23 of quinidia and the same of cinchonia. (Pereira's *Mat. Med.*, 3d ed., p. 1629.)—*Note to the tenth edition.*

Yellow Bark of Guayaquil. Under this name MM. Delondre and Bouchardat describe a bark, occurring in very long rolls, of a colour like that of Chinese cinnamon, with the outer surface marked by rather close but shallow longitudinal furrows, with traces of a very thin, white epidermis; the inner surface browner, uniform, and compact; the fracture resinous exteriorly, and shortly fibrous interiorly. The bitterness is strong, without astringency. Delondre obtained from it 3·0 per cent. of sulphate of cinchonia, and 0·3 to 0·4 of sulphate of quinia. (*Quinologie*, p. 32.) This bark is scarce in commerce; but we have been told that portions have been brought from Guayaquil, across the Isthmus of Panama. It will be very valuable, should cinchonia come, as it ought to do, into general use.

A *false bark* has been sometimes mixed with the genuine Calisaya, which it resembles so closely as not to be easily distinguished by the eye. According to Weddell, it is the bark of *Gomphosia chlorantha*, a lofty tree, growing in the same forests where the *Calisaya* is found. It is distinguished by a peculiar odour, and by exhibiting in its transverse section, under the microscope, "a peculiar fasciculate disposition of the cortical fibres, and some vessels gorged with a ruby-coloured juice." It does not contain a particle of alkaloid, but yields a volatile oil on which its odour depends. (Howard, *Pharm. Journ.*, xiv. 318.)—*Note to the eleventh edition.*

* The great value of Calisaya bark will justify us in giving a brief account of its mode of collection, as described by Weddell from personal observation. The tree producing it grows in the Bolivian provinces Enquisivi, Yungos, Larecaja, and Caupolican. At present

3. Red Bark.

The name of this variety is very appropriately applied; as the colour is usually distinct both in the bark and the powder. In South America it is called *cascarilla roxa* and *colorada*. Some writers have divided it into several subvarieties; but, in relation to the true red bark, there does not seem to be ground for such division in any essential difference of properties. Like the *Calisaya*, it comes in quills and flat pieces, which are probably derived from different parts of the same tree. It is imported in chests.

Some of the pieces are entirely rolled, some partially so, as if they had been taken from half the circumference of the branch; others are nearly or quite flat. They vary greatly in size, the quill being sometimes less than half an inch in diameter, sometimes as much as two inches; while the flat pieces are occasionally very large and thick, as if derived from the trunk of a tree. They are covered with a reddish-brown or gray, sometimes whitish epidermis, which is rugged, wrinkled longitudinally, and in the thicker pieces marked with furrows, which in some places penetrate to the surface of the proper bark. In many specimens, numerous small roundish or oblong eminences, called warts, may be observed upon the outer surface. Beneath the epidermis is a layer, dark-red, brittle and compact, which possesses some bitterness and astringency, but much less than the interior parts. These are woody and fibrous, of a more or less lively brownish-red colour, which is usually very distinct, but in some specimens passes into orange and even yellowish-brown; so that it is not always possible to distinguish the variety by this property alone. The taste is bitter and astringent, and the odour similar to that of other good barks. Red bark is chemically distinguished by *containing considerable quantities of both quinia and cinchonia*. It yields a turbid salmon-coloured decoction with water. Mr. Howard, in examining slender sections of a fine specimen of red bark under the microscope, noticed numerous stellate groups of crystals diffused irregu

it is necessary to travel for eight or ten days from the nearest inhabited place, in order to reach the forests where it is found of a size and in numbers which will repay the trouble of gathering the bark. The Cascarilleros are persons educated from infancy to the business. Several of them are engaged in the service of a merchant or small company, by whom they are sent, at any period of the year except during the rains, upon an expedition under the charge of a leader called a Mayordomo. Having previously received information which governs the direction of their journey, they proceed to the vicinity of their intended operations, and establish a camp in a convenient position. Henceforward the neighbourhood is considered as belonging exclusively to the party, and no other bark-gatherers pretend to interfere. From the camp the Cascarilleros are despatched singly or in small bands, in different directions into the forests, through which they have to make their way, often with great labour and fatigue. Each man carries with him provisions for a long absence. The trees do not form forests of themselves, but are scattered singly or in groups more or less close. From some convenient point of view the explorer scans the top of the forest, and is able to recognise, at a great distance, from the peculiarity of its aspect, not only one of the Cinchonas, but the particular species of which he is in search. Sometimes he is directed by the appearance of the dry leaves upon the ground. Having found a suitable tree, he first fells it, cutting as near the soil as possible, then lops off the branches, and detaches by blows with a wooden mallet, or the back of his axe, the outer or dead layers of the bark, which easily separate. He next makes incisions through the bark, so as to isolate pieces usually fifteen to twenty inches long by three or four broad, which he removes by means of a knife or other instrument. The branches are decorticated without separating the epidermis. The pieces obtained from these are simply allowed to dry in the sun, and, rolling themselves up, form the quilled variety. The pieces from the trunk are disposed in square piles, one being placed over the other, and the whole kept down by some heavy body. They are thus prevented from rolling as they dry. When sufficiently dried they are carried to the camp on the back of the gatherer, who often consumes several days in his returning journey, and undergoes incredible fatigue. At the camp, the bark is assorted, and the portion deemed fit for commerce is sent to the town, on the backs of men or of mules, where it is packed in bales or seroons, covered with fresh hides. The most wasteful methods of collecting the bark prevail, the only object being present convenience. Not only is the tree felled, but the bark is frequently removed from the stump down into the very earth, so as to prevent the growth of sprouts, which would otherwise spring up from the old roots, and in the course of time afford another crop. (*Note to the ninth edition.*)

larly throughout its substance, which he believed to consist of kinovate of quinia, formed during the drying of the bark. He also noticed other crystalline forms which he ascribed to the kinovates severally of cinchonia, quinidia, and cinchovidia. (*Pharm. Journ. and Trans.*, May, 1865, p. 584.)*

The species of Cinchona which produces red bark has been unknown until very recently. The notion derived from Mutis, and once generally prevalent, that it was obtained from the *C oblongifolia* of that botanist, was long since demonstrated to be incorrect. For the proofs upon this point, which have now

* The *red bark* is described by Von Bergen under the name of *China rubra* or *rothe China*. The following is an abstract of his description. The quills are from two lines to an inch and a quarter in diameter, from one-third of a line to two lines thick, and from two to twelve inches or more in length. The smaller quills are often spiral. The flat pieces are from one to two inches broad, from three-eighths to a quarter of an inch thick, and of the same length as the quills. In the smaller and middling-sized quills, the external surface exhibits longitudinal wavy wrinkles. In the thicker pieces, these wrinkles, between which are here and there longitudinal furrows, often elevate themselves into roundish or oblong warts, which are of a somewhat friable and granular consistence. The longitudinal furrows sometimes penetrate to the bark. Transverse fissures seldom occur. The colour in the smaller quills varies from a fawn-gray to a dull reddish-brown, in the larger is reddish-brown or chestnut-brown with a tinge of purple. When the wrinkles and warts are rubbed off, the peculiar brownish-red colour of the bark appears. The pieces are often in part or almost wholly covered with a whitish-gray or yellowish-white coat, either belonging to the epidermis or consisting of lichens. In some of the quills the epidermis is wanting in spots, which exhibit a dirty reddish-cinnamon colour. The inner surface is delicately fibrous and almost uniform in the small quills, but becomes more fibrous and uneven in the larger, and in the flat pieces is splintery and very irregular. Its colour varies with the size of the pieces, being a reddish-rusty brown in the least, redder in the larger, and a full brownish-red in the largest. The inner surface is also sometimes yellowish, or brownish, or of a dirty appearance. It becomes darker when scraped with the nail. The fracture exhibits the different colours of the epidermis, the inner bark, and a resinous layer between the two. It is usually smooth in the smaller quills, fibrous in the larger, and at the same time fibrous and splintery in the largest pieces. The fracture of the epidermis, however, is in all either smooth, or only here and there somewhat granular. The odour is like that of tan, and earthy; the taste strongly but not disagreeably bitter, somewhat aromatic, and not lasting. The powder is of a dull brownish-red colour.

Experiments upon many different specimens of red bark, as stated by Pfaff, give as an average product 1·7 per cent. of pure cinchonia, and 0·44 of sulphate of quinia. The highest product obtained was 3·17 per cent. of cinchonia, and 0·15 of sulphate of quinia. Another specimen yielded 1·21 per cent. of the former, and 1·33 of the latter. Pelletier and Caventou obtained 0·8 per cent. of cinchonia, and 1·7 of quinia. (*Geiger.*) Dr. E. Riegel, of Carlsruhe, obtained from one specimen of the best red bark 4·16 per cent. of alkaloids (2·65 of quinia and 1·51 of cinchonia), and from another 3·85 per cent. (*Pharm. Journ.*, xii. 250.) Delondre obtained from the genuine red bark, "*bright red*," 2·0 to 2·5 per cent. of sulphate of quinia, and 1·0 to 1·2 of sulphate of cinchonia; from the "*pale red*" 1·5 to 1·8 of the former, and 0·5 to 0·6 of the latter. (*Quinologie*, p. 30.) It appears, therefore, that the proportion of the alkalies is exceedingly different in different specimens; and it is highly probable that some of the barks experimented upon were inferior red barks, not properly belonging to this variety. The degree of bitterness is, perhaps, the best criterion of their efficacy.

Guibourt divides the red bark into two principal varieties, which he distinguishes by the names of *quinquina rouge verruqueux*, and *quinquina rouge non verruqueux*, from the presence or absence of the warts upon the outer surface. There is, however, no real distinction between the varieties, as they possess the same virtues, and differ only in being derived from different parts of the same tree; the warty, it is asserted, being derived from the root and trunk, the non-warty from the branches. (Howard, *Pharm. Journ.*, xvi. 210.) He describes also four other red barks; 1. *Rouge orangé verruqueux*, differing from the true warty kind by its more orange colour, its very thin epidermis, its finer fibres, and the less thickness of the large barks; 2. *Rouge blanchissant à l'air*, characterized by the whitening of its fracture in the air, and by its little bitterness; 3. *Rouge de Lima*, with a whitish epidermis, an ochreous reddish liber, and of excellent qualities (see *Fine Gray Bark*, p. 278); and 4. *Rouge pâle à surface blanche*, resembling the first of these varieties, but distinguishable by its whiter epidermis, and generally lighter colour. Under the same head may be ranked his *quinquina de Jaën ou de Loxa rougeâtre*, which has a dark-gray epidermis, and a uniform fibrous proper bark, reddish or deep-brown, and of a very astringent taste with little bitterness. (*Note to the second, fourth, ninth, and twelfth editions.*)

A specimen of bark in our possession, brought by Dr. Dillard, of the U. S. Navy, from the Pacific, and labelled *red bark of Cuença*, has a thick epidermis like that of the ordinary red bark, is of a very deep dark-red colour, and possesses little bitterness.

ceased to have any practical importance, the reader is referred to the article CINCHONA, section RED BARK, in early editions of this work. It has been supposed that red bark may be derived from the same species with one or more of the pale barks, but taken from the larger branches of the trunk. This opinion received some support from a statement made by La Condamine, in his memoir upon cinchona. We are told by this author that three kinds of bark were known at Loxa; the white, the yellow, and the red. The white, so named from the colour of the epidermis, scarcely possessed any medicinal virtue, and was obtained from a tree entirely distinct from that which yielded the two other varieties The red was superior to the yellow; but he was assured, on the very best authority, that the trees producing them grew together, and were not distinguishable by the eye. Of the three varieties mentioned by La Condamine, the white, which was probably one of the inferior barks with micaceous epidermis, does not reach us; and that which he calls yellow is probably identical with the pale variety of the Pharmacopœias, as this grows abundantly about Loxa. At the date of the publication of the last edition of this work, it had been rendered extremely probable by Mr. Howard, that the genuine red bark is derived from the trunk and larger branches of the *Cinchona ovata*, var. *erythroderma* of Weddell, growing on the western slopes of the mountains Assuay and Chimborazo, eastward of Guayaquil, in about 2° of south latitude. (*Pharm. Journ.*, xvi. 207.) Since that period, this ascription has been found to be correct, though the variety referred to has been raised to the dignity of a species, C. *succirubra*, which is now generally admitted to be the source of the officinal red bark.

NON-OFFICINAL OR CARTHAGENA BARKS.

Under this head may be classed all the Cinchona barks brought from the northern Atlantic ports of South America. In commerce, they are variously called *Pitaya*, *Bogota*, *Carthagena*, *Maracaybo*, and *Santa Martha barks*, according to the place in the vicinity of which they are collected, or the particular port at which they may be shipped. Formerly these barks were for the most part of inferior quality, and were therefore not recognised in the Pharmacopœias; but the deficient supply and consequent high price of Calisaya have directed enterprise into other quarters; and within a few years large quantities of very good bark have been imported from New Granada, derived chiefly from the neighbourhood of Bogota and Popayan, and brought down the river Magdalena. Since the completion of the railroad across the Isthmus of Panama, considerable quantities have been brought to us by that route, being shipped from the port of Buenaventura, on the Pacific coast. There can be little doubt that the commerce in these barks will continue and increase; as some of them are inferior in their yield of alkaloids only to the Calisaya, if even to that variety, and the region from which they are procured is almost virgin soil. It has appeared to us, from an examination of such of them as have come under our notice, that they may all, at least with one exception, be referred without violence to some one or another of the varieties of Carthagena bark already recognised; but these better kinds formerly seldom reached the market; because, partaking of the general reputation of the inferior barks from the same region, it was feared that they might not pay the cost of importation. Most of the Carthagena barks are characterized by a soft, whitish or yellowish-white epidermis, which may be easily scraped by the nail, and which, though often more or less completely removed, almost always leaves behind traces sufficient to indicate its character. Those of them which may, in other respects, bear some resemblance to Calisaya, are in general readily distinguishable by this character of the epidermis when it remains, and, when it is wanting, by the peculiar appearance of the outer surface, showing that the exterior coating has been scraped off, or shaved off with a knife. They all contain the alkaloids in greater or less proportion, though they differ much in this respect. In reference to the relative proportion of the different alkaloids, they have nothing in common, except perhaps that they yield proportionably more cinchonia, cinchonidia, and quinidia than the Calisaya, resembling, in this respect,

the pale and red barks. Inferior barks, with the soft, white epidermis, are found on the western coast of South America, where they are known as *white barks;* but they seldom reach us. In the state of powder, the inferior Carthagena barks were formerly, and are still, to a certain extent, kept in the shops, and sold for tooth-powder, &c., under the name of *common bark.* They have not unfrequently been substituted, either fraudulently or by mistake, for the better kinds.

The Carthagena barks were formerly classified, according to their colour, into the *yellow, orange, red,* and *brown;* but this mode of distinction must now be abandoned; for these varieties of colour may be found in barks identical in other respects, and derived from the same species of Cinchona. The well characterized Carthagena barks may all be referred to one of the three following varieties.

1. *Hard Carthagena Bark. Hard Yellow Carthagena Bark. Yellow Bark of Santa Fé. Common Yellow Carthagena Bark. — China flava dura.* Von Bergen. — *Quinquina de Carthagène jaune pale.* Guibourt. This is in pieces of various size and form, sometimes wholly or partially quilled, and sometimes flat; and the flat pieces present the appearance of having been warped in drying, being frequently curved longitudinally backward, and sometimes also in the transverse direction or spirally. The quills are from three to eight lines in diameter, from half a line to a line and a half thick, and from five to nine and rarely fifteen inches long. The flat pieces are thicker, from half an inch to two inches broad, and from four to eight and sometimes twelve inches in length. As found in this market, the bark is sometimes in small, irregularly square or oblong, flattish, and variously warped pieces, from one to four inches long, and from one to three lines in thickness, mixed with small quills or fragments of quills; the former appearing as if chipped from the trunk or large branches, the latter evidently derived from the small branches. In this shape it was treated of in some former editions of this work, as a distinct variety, under the name of *Santa Martha Bark,* which it at one time held in the market; but a closer examination has convinced us that it is the same bark as the one above described, though collected in a different manner. The quills are generally more covered with the whitish epidermis than the flat pieces, in which it is often nearly or quite removed. The inner surface of the latter, though sometimes smooth, is often rough and splintery, as if forcibly separated from the wood. The colour of the proper bark is a pale, dull, brownish-yellow, darker in parcels which have been long kept; and the surface often appears as if rubbed over with powdered bark. The texture is rather firm and compact, and the fracture abrupt, without being smooth or presenting long splinters. The taste is bitter and nauseous This variety of bark is now universally ascribed to C. cordifolia.*

2. *Fibrous Carthagena Bark. Fibrous Yellow Carthagena Bark. Spongy Carthagena Bark. Bogota Bark. Coquetta Bark. — Quinia naranjanda.* Mutis. — *Quinquina orangé.* Humboldt. — *China flava fibrosa.* Von Bergen. — *Quinquina Carthagène spongieux.* Guibourt. This is in quills or half-quills, or is slightly rolled; and there are comparatively few pieces which are quite flat, even among the largest barks. The quills are from half an inch to an inch and a half in diameter, and of extremely variable length, with a yellowish-brown

* We introduce, in the form of a note, more detailed and precise information on the subject of the Carthagena barks than our space allows in the text; because, in the present condition of the manufacture of the cinchona alkaloids, it is important to be able to distinguish the several varieties, and estimate their value.

Hard Carthagena Bark. The following is a somewhat precise description of this variety, taken from Von Bergen. The account of the dimensions and shape of the pieces, given in the text, is sufficiently particular. The epidermis is in many pieces partially or almost wholly wanting. The outer surface is on the whole rather smooth, though it usually exhibits a few faint longitudinal furrows and transverse fissures, and pieces are occasionally found with hard warts or protuberances. In the flat pieces, the epidermis, when present, has somewhat the consistence of cork, and is composed of several layers. The colour of the epidermis varies from yellowish-white to ash-gray, and is sometimes diversified by bluish-gray or blackish lichens. When it is wanting, the colour is between a dark cinnamon and brownish-yellow. These shades, however, are seldom clear, and the flat pieces have usually a somewhat dusty aspect. The inner surface of the quills is tolerably uniform,

epidermis, often covered with crustaceous lichens so as to render the surface of the bark whitish and smooth, and exhibiting not unfrequently longitudinal and transverse fissures. The larger barks, which are much the most frequent in commerce, are usually from six to twelve inches long, from one to two inches broad, and from two to five lines in thickness; but they often vary much from these dimensions, being sometimes in the smallest fragments, and sometimes forming semi-cylinders four or five inches in diameter, a foot and a half long, and nine lines thick. They are usually without epidermis, which has been scraped off, or pared off with a knife, leaving the surface smooth and uniform in the former case, and somewhat angular in the latter. Sometimes, however, the epidermis either partially or wholly remains, when it generally exhibits the soft whitish surface characteristic of most of the Carthagena barks. The bark is very fibrous, presenting generally, when broken, long, sometimes stringy splinters, though the outer edge of the fracture is occasionally short from the cellular, or remains of the suberous coat. Its texture is loose, soft, and spongy under the teeth, and the bark itself is usually light. The colour both of the trimmed outer surface, and the inner, and of the bark itself, varies from an ochreous or light brownish-yellow, to orange, and red; but, for the most part, it presents more or less of the orange tint, which induced Mutis to give it the title of *orange bark*. The red colour is found especially in the largest barks. The larger pieces are sometimes marked on the outside with a deep spiral impression, produced probably by a climbing plant winding around the stem of the tree. The colour of the powder is yellowish, with not unfrequently an orange tint. The taste is more or less bitter; but varies in this respect extremely; some barks being almost insipid, while others have a very decided taste. There can be little doubt that these barks are all derived from the Cinchona lancifolia of Mutis. It is asserted that the red variety of the bark is obtained from trees which grow side by side with those which yield the yellow or orange.

The productiveness of the fibrous bark in alkaloids varies greatly in the different specimens. Thus, while some have scarcely yielded any product, others have been found to afford more than three per cent. They probably contain all the cinchona alkaloids; but some have been found more abundant in one, and others in another. Thus, the red is said to be especially rich in quinidia (cinchonidia); a Pitaya bark, which we believe to belong to the fibrous Carthagena, has yielded a very large product of quinia; while, in not a few specimens which have been examined, the cinchonia predominates. (*Am. Journ. of Pharm.*, xxv. 308.) It is probable that the richness in these principles depends in some degree on the natural position of the plants; those growing in low situations being less productive than those higher on the mountains.*

A specimen labelled *yellow bark of Loxa*, brought from South America several years since by Dr. Dillard, of the U. S. Navy, and said to be used in Loxa for making extract of bark, presents characters closely analogous to those of fibrous Carthagena bark, sufficiently so to justify the supposition that it was derived from the same species of Cinchona; and we have seen a specimen sent

that of the flat pieces uneven or faintly furrowed and even splintery, the points of the splinters often projecting. Its colour, which is almost always dull, as if the surface were dusty, varies between a light cinnamon and a dull ochre-yellow, and in some pieces is rusty-brown, or fawn-gray, or even whitish-yellow. The bark does not readily break in the longitudinal direction. The transverse fracture presents short splinters, and is sometimes fibrous. When cut transversely, the bark obscurely exhibits a very small darker-coloured resinous layer beneath the epidermis. The odour is feeble, the taste astringent and bitter, but not strongly so. The powder is of the colour of cinnamon. This bark yielded, according to Von Bergen, on an average of two experiments, 0·57 per cent. of cinchonia, and 0·33 of sulphate of quinia. Goebel and Kirst found in a pound 56 grains of quinia and 43 of cinchonia. Dr. Pereira states that it contains quinidia (cinchonidia).

* Karsten states that the bark of C. lancifolia, which on the average yields 2·5 per cent. of sulphate of quinia and from 1·0 to 1·5 per cent. of sulphate of cinchonia, often yields neither, and sometimes 4·5 per cent. of the two. The bark of the young branches yields much less than that of the trunk. (*Am. Journ. of Pharm.*, xxx. 534.)

hither from Guayaquil, which has the same character, and is so rich in alkaloids as to be worked with advantage.*

* *Fibrous Carthagena Bark.* The following is an abbreviation of Von Bergen's description of this variety. In shape and dimensions, it does not materially differ from the preceding; but the flatter pieces are almost always a little rolled, or curved laterally. The epidermis is in general either in part or wholly rubbed off. When it is present, the outer surface is nearly smooth, only marked here and there with faint irregular transverse fissures and longitudinal furrows. Its colour varies from a dirty-whitish gray to yellowish, but is sometimes more or less dark. When the outer surface is rubbed off, as is almost always the case in the flat pieces, the colour is nearly pure ochre-yellow. Where the whole thickness of the outer coat is wanting, as happens here and there in spots, the surface is dark-cinnamon, or dark ochre-yellow, and commonly dull or powdery. The inner surface is usually even, but sometimes irregular and splintery, and always harsh to the fingers, leaving small splinters sticking in the skin when drawn over it. It is of a nearly pure ochre-yellow colour, and is very powdery. The fracture distinguishes this variety from the preceding, and from all others. The longitudinal fracture is strikingly fibrous, and in the flat pieces the fragments still hang together by connecting fibres. The bark, moreover, breaks obliquely, and the fracture even of the outer coat, which in other varieties is almost always smooth, is here uneven or rough-grained. The transverse fracture exhibits very long and thin splinters or fibres, which are very flexible, and may almost be said to be soft. No traces of a resinous appearance are observable in the fracture. The odour is feeble, the taste at first woody and flat, afterwards slightly bitter and astringent, and weaker in this than in any other variety of bark. The colour of the powder is intermediate between that of cinnamon and yellow ochre. The highest product of this bark in alkaloids was about 0·59 per cent. of cinchonia, and 0·52 of sulphate of quinia.

The above description does not embrace all the varieties of this bark which have since been introduced into commerce: nor does it by any means represent the finest specimens. The *highly fibrous character of the bark, its looseness of texture, relative lightness, and sponginess under the teeth*, are properties common to all the specimens; but in appearance and virtues they vary considerably; so much so, indeed, that it is only of late that they have been united under one name, and traced to one source.

In the edition of this work of 1843, we described a kind of bark of which large quantities had then recently been imported in a vessel from *Maracaybo*, and which, from its possession in a high degree of the properties just referred to, we were disposed to rank with this variety; and subsequent observation has tended to prove the correctness of this reference. In general aspect it bore some resemblance to the flat Calisaya, particularly in the appearance of its inner surface; but it differed in being thicker, less hard, compact, and heavy, and much more fibrous, and especially in the character of its outer surface, which had the appearance as though the exterior coating had been removed by scraping or cutting with a knife, and not spontaneously separated at the natural juncture, as in the Calisaya. The pieces were considerably larger than those we had previously seen of the fibrous Carthagena, and differed somewhat in colour, having much more of the orange tint, especially in the outer portion, where it was decidedly reddish in some of the pieces. Though less bitter than the Calisaya, and without the property of precipitating sulphate of soda, it nevertheless had a decided bitterness; and its infusion afforded a copious precipitate with infusion of galls, indicating the presence of no inconsiderable portion of the alkaline principles.

Recently we have had opportunities, through the kindness of Messrs. Powers & Weightman, of examining several varieties of the fibrous bark brought from Bogota and Popayan, which have proved of great value as sources of the cinchona alkaloids, and which we propose briefly to describe, in connection with a statement, derived from the same highly respectable source, of their yield of these valuable principles.

Bogota Bark. Fusagasuga Bark. Coquetta Bark. The first of these names is derived from the entrepot of the trade in this bark; the second, from the particular district where it is collected. Of the origin of the third, by which it is known in English commerce, we are not informed. The bark is in pieces of various lengths, often exceeding a foot, sometimes nearly flat, but generally more or less rolled, and occasionally forming semi-cylinders more than an inch in diameter. It is often either partially or wholly covered with the whitish, soft, micaceous epidermis characteristic of Carthagena barks. In other instances this has been removed by scraping, or sometimes by chipping, and the deep strokes of the knife or hatchet are not unfrequently observable. The pieces are often of considerable thickness, usually rather firm, though very fibrous, and spongy under the teeth. The colour is brownish-yellow with a tinge of red. Mr. Weightman obtained from it from 1 to 1·3 per cent. of sulphate of quinia, and from 0·3 to 0·4 per cent. of sulphate of cinchonia. An inferior variety of Bogota bark, not designated as Fusagasuga, yielded him only 0·4 of sulphate of quinia. In the *Am. Journ. of Pharm.* (xxv. 308) is a statement of results obtained in the examination of the Bogota (Fusagasuga) bark, which were, on the average of four specimens, 0·95 per cent. of cinchonia or quinidia or both, 1·45 of sulphate of quinia (equivalent to about 1·09 of the uncombined alkaloid), and 1·0 of extractive

3. *Hard Pitaya Bark.*—*Pitaya Condaminea Bark.* Pereira.—*Quinquina brun de Carthagène. Quinquina Pitaya, ou de la Colombia, ou d'Antioquia.* Guibourt. This bark, though seen by Guibourt so long since as 1830, has come into general notice only within the last ten or twelve years. Much of it has been imported into Philadelphia, coming sometimes through Carthagena, and sometimes over the Isthmus of Panama, whither it is brought from Buenaventura. The following description is drawn from an examination of the bark contained in several seroons that have come under our notice. It is in small irregular pieces, from less than an inch to about four inches long, which are obviously the fragments of larger pieces both quilled and flat. Dr. Pereira states that he had pieces more than a foot in length. In thickness it varies from less than a line to four or five lines. Most of the fragments are covered with the whitish, soft epidermis, characteristic of the Carthagena barks; but some of them have a dark-brown epidermis, rugose with innumerable cracks in all directions; and others are partially or wholly destitute of the outer covering, presenting generally, in the denuded part, a dark uniform or somewhat wrinkled surface. The inner surface is finely and compactly fibrous, and of a dull yellowish-brown colour with a reddish tinge; and the whole of the liber or true bark has the same colour and texture. But outside of the liber there is in many pieces a very distinct resinous layer, which is sometimes of considerable thickness, and, when cut across by a knife, exhibits a dark reddish-brown, shining surface. The resinous layer is the most striking peculiarity of the bark, though not present in all of the pieces, which sometimes consist of the liber alone. The fracture is towards the interior shortly fibrous, towards the exterior often smooth, in consequence of the layer just referred to. The whole bark is rather hard, compact, and heavy; differing in this respect very decidedly from the last mentioned variety. It has more resemblance to the hard Carthagena, from which, however, it differs by its deeper and redder colour, its much more developed resinous coat, and its occasional grater-like epidermis. The taste is very bitter, and the yield in alkaloids considerable. Mr. Weightman informed us that he had obtained from it an average product of 1·6 per cent. of sulphate of quinia, and 0·34 of sulphate of cinchonia, independently of the amorphous or uncrystallizable alkaline matter. It must, therefore, be ranked among the efficient barks,

residue, which is presumed to consist mainly of amorphous quinia; so that the whole of the alkaline ingredients amounted to about 3·04 per cent.

Soft Pitaya Bark. Calisaya of New Granada (*Delondre and Bouchardat*, Quinologie, p. 33). This, though said to be brought from the Pitaya mountain near Popayan, is wholly different from the *hard Pitaya* described in the text as one of the varieties of Carthagena bark. It is imported from Carthagena, whither it is brought down the Magdalena river, and from the Pacific port of Buenaventura, whence it is sent to us by the Isthmus of Panama. From the specimens we have seen of the soft Pitaya, we have no hesitation in classing it with the fibrous Carthagena barks, though superior to the others, probably in consequence of the more elevated site of its growth. It comes broken up into small irregular fragments of larger pieces, either quilled, partially rolled or flat. Few of the fragments exceed four inches in length, and many are very minute. Indeed, in some of the seroons, much of their contents seem to be almost in the state of a very coarse powder. This condition of the bark no doubt depends partly on its great fragility; but it is probable that it is purposely broken up for the convenience of close package in the hide seroons. The fragments are almost all destitute of epidermis, but when portions of it remain, it has the usual whitish, soft, micaceous character, common to all these barks. The outer surface, which consists of a thin sub-epidermic suberous layer, is remarkably uniform and smooth, apparently from the careful scraping to which it has been subjected. By far the greater part of the bark consists of the liber, which is highly fibrous, though very soft, easily broken, and yielding with great facility under the teeth. The colour is externally and internally a uniform fine brownish-yellow, with an orange tint, and is brighter than in most others of the analogous barks. The taste is very bitter. Mr. Weightman obtained from ordinary specimens of this bark 2·0 per cent. of sulphate of quinia, and 0·05 of sulphate of cinchonia; from a very fine specimen, 3·0 per cent. of the former, and but a trace of the latter. It is, therefore, one of the most valuable varieties of bark, scarcely yielding in productiveness to Calisaya. The results stated in the *Am. Journ. of Pharm.* (xxv. 308) even exceed these. The average yield of four different specimens, including the uncrystallizable product, was 4·42 of alkaloids, probably in the state of sulphates, and, without the uncrystallizable matter, about 3·4 per cent. (*Note to the tenth and eleventh editions.*)

though not so productive as the fine variety of fibrous bark denominated soft Pitaya. It contains also a large proportion of resin.

This bark comes from the mountain of Pitaya near Popayan, and the particular seroons examined by ourselves were said to have been brought down the Magdalena river from the town of Honda. It is referred by Dr. Pereira and Mr. Howard to the *Cinchona Condaminea*, var. *Pitayensis* of Weddell, of which that author has more recently made a distinct species, under the name of *Cinchona Pitayensis*. (*Ann. des Sci. Nat.*, May, 1849.)*

False Barks.

Before dismissing the subject of the varieties of cinchona, it is proper to observe that numerous barks have at various times been introduced into the market, and sold as closely resembling or identical with the febrifuge of Peru, which experience has proved to differ from it materially, both in chemical composition and medical virtues. These barks are generally procured from trees formerly ranked among the Cinchonas, but now arranged in other genera. They are distinguished from the true Peruvian bark by the absence of its peculiar alkaloids. Among them are 1. a bark known to the French pharmaceutists by the name of *quinquina nova* or *new bark*, which, though at one time thought to be possessed of some virtues, has been proved to be worthless, and was ascertained by Guibourt to be the produce of the *C. oblongifolia* of Mutis, now ranked in Weddell's genus Cascarilla;† 2. the *Caribæan bark*, from Exostemma Caribæa; 3. the *St. Lucia*

* *Hard Pitaya Bark.* The following is Guibourt's description of this bark. "In the young barks, the crust is fine, whitish externally, fissured, almost like the young red Lima barks. In the large barks, and in the parts not worn by rubbing, the crust is always whitish exteriorly, but interiorly it is rust-coloured and fungous. The liber presents a very fine fibrous texture, joined to a considerable density and hardness; the internal surface is smooth and reddish; its taste is very bitter and disagreeable, and its watery infusion strongly precipitates with sulphate of soda. It yields largely of the alkalies, but proportionably more cinchonia than quinia." Guibourt obtained 2·3 per cent. of cinchonia, and 1·15 of sulphate of quinia; or about 3·16 per cent. of pure alkaloids. (*Hist. Nat. des Drogues*, 3ème ed., iii. 141.)

Under the title of *Pitaya-Condaminea Bark*, Pereira describes this variety as follows. "Bark consisting of single or double quills, or half-rolled pieces. I have specimens which are more than a foot in length. Some samples, however, which I have received, consist of pieces not more than two or three inches in length, sometimes entirely, at others only partially coated; the partially coated pieces consist of the suberous and cellular coats and liber. Epidermis, when present, dark-brown, frequently coated by crustaceous lichens, marked by numerous, closely set, transverse cracks, with prominent or slightly everted borders, which give the bark a grater-like feel; and here and there presenting round or oval warts, or fungoid rusty tubercles, varying in size from a grain of wheat to a seed of coffee, and usually marked like the latter with a longitudinal, sometimes also with a transverse fissure. The suberous coat in some pieces much developed, spongy or fungous, fawn-yellow, sometimes brown in the interior, and yellow externally and internally. Resinous tissue on the inside of the suberous coat, from which it is definitely separated, shining, of a dark-reddish colour. Liber gradually passing into the resinous coat, hard, dense, dark, reddish-brown: cortical fibres small and short. Pitaya-Condaminea bark is firm and heavy, and has a very bitter, rather disagreeable taste, which is slowly developed." It contains cinchonia, quinidia (cinchonidia), and quinia. (*Mat. Med.*, 3d ed., p. 1643.)—*Note to the tenth edition.*

† This was formerly called *red Carthagena bark*, but must not be confounded with the genuine red Carthagena bark, which belongs to the *fibrous Carthagena*, already noticed. As described by Guibourt, it is in pieces a foot or more long, rolled when small, open or nearly flat when larger, in general perfectly cylindrical, with a whitish, thin, uniform epidermis, showing scarcely any fungi, and but a few transverse fissures, which are sometimes quite wanting; one to three lines thick without the epidermis; of a pale carnation, becoming deeper in the air, especially upon the outer surface, which, when destitute of epidermis, is always reddish-brown; of a fracture which is foliaceous in the outer part, and short-fibrous in the inner; and exhibiting under the microscope, between its fibres, and especially between the lamine, a great abundance of two granular matters, of which one is red and the other whitish. In some pieces the fracture exhibits, nearer the external than the internal surface, a yellow, transparent, resinous or gummy exudation. The taste is flat and astringent like that of tan, the odour feeble, between that of tan and of the pale barks. The powder is decidedly red. It contains neither quinia nor cinchonia. Its most interesting constituents are a *peculiar tannic acid*, *kinic acid*, *kinovic acid* discovered by Winckler, and a peculiar red colouring matter called *kinovic red*. (Hlasiwetz, *Chem. Gaz.*, ix. 421 and 441.)

bark, or *quinquina piton* of the French, derived from Exostemma floribunda; and 4 a bark of uncertain botanical origin, called in France *quinquina bicolore*, and in Italy *china bicolorata*, and sometimes erroneously named *Pitaya bark*. Of these the last only is known in this country. A considerable quantity of it was some time since imported into New Orleans, whence a portion reached this city. The specimen in our possession is in quills, for the most part singly, but in some instances doubly rolled, from eight or ten inches to more than two feet in length, and from a quarter of an inch to an inch or more in diameter. The outer surface is of a dull grayish-olive colour, with numerous large oval or irregular spots, much lighter coloured, sometimes even whitish and slightly depressed beneath the general surface, as if a layer of the epidermis had fallen off within their limits. It is to this appearance that the bark owes the name of *bicolorata*. The colour of the internal surface is deep-brown or almost blackish; that of the fresh fracture, brownish-red. The bark is hard, compact, and thin, seldom as much as a line thick, and breaks with a short rough fracture. It is inodorous, and has a very bitter taste, not unlike that of some of the inferior kinds of cinchona.*

The inner bark of an India species of *Hymenodictyon*, formerly considered as a Cinchona, and named *C. excelsa*, has been supposed to possess properties analogous to those of genuine cinchona. It has been chemically examined by Mr. Broughton, who succeeded in obtaining from it a pure crystalline principle, ascertained to be identical with *æsculin*, the characteristic principle of *Æsculus Hippocastanum*, or common horsechestnut. He could find no trace of any of the cinchona alkaloids. (*Pharm. J. and Trans*, March, 1868, p. 418.)

Chemical History.

In the analysis of Peruvian bark, the attention of chemists was at first directed exclusively to the action of water and alcohol upon it, and to the determination of the relative proportions of its gummy or extractive and resinous matter. The presence of tannin and of various alkaline or earthy salts in minute quantities was afterwards demonstrated. Fourcroy made an elaborate analysis, which proved the existence of other principles in the bark besides those previously ascertained. Dr. Westring was the first who attempted the discovery of an active principle in the bark, on which its febrifuge virtues might depend; but he was not successful. Seguin afterwards pursued the same track, and endeavoured, by observing the effects of various reagents, to discover the relative value of different varieties of the drug; but his conclusions have not been supported by subsequent experiment. M. Deschamps, an apothecary of Lyons, obtained from bark a crystallizable salt of lime, the acid of which Vauquelin afterwards separated, and called *kinic acid*. The latter chemist also pushed to a much further extent the researches of Seguin as to the influence of reagents, and arrived at the conclusion that those barks were most efficient which gave precipitates with tannin or the infusion of galls. Reuss, of Moscow, succeeded in isolating a peculiar colouring matter from red bark, which he designated by the name of *cinchonic red*, and obtained a bitter substance which probably consisted in part of the peculiar alkaline principles subsequently discovered. The first step, however, towards the discovery of cinchonia and quinia appears to have been taken by the late Dr. Duncan, of Edinburgh, so early as 1803. He believed the precipitate, afforded by the infusion of cinchona with that of galls, to be a peculiar vegetable principle, and accordingly denominated it *cinchonine*. Dr. Gomez, a Portuguese physician, convinced that the active principle of bark resided in this cinchonine, but mixed with impurities, instituted experiments upon some pale bark, which

* In previous editions of this work, it was stated that this bark had been employed in Italy successfully in intermittents; and that Folchi and Peretti had discovered in it a new alkaloid, which they named *pitayna*. But there is reason to believe that this was a mistake, caused by the confused use of the name Pitaya bark; and that the bark employed in Italy, and analyzed by the chemists mentioned, was that described as *hard pitaya* in a preceding page. It is conjectured that the alkaloid *pitayna* may have been either quinidia or cinchonidia, or a mixture of the two. (*Note to the tenth and eleventh editions.*)

resulted in the separation of a white crystalline substance, considered by him to be the pure *cinchonine* of Dr. Duncan. It was obtained by the action of potassa upon an aqueous infusion of the alcoholic extract of the bark, and was undoubtedly the principle now universally known by the name of *cinchonine* or *cinchonia*. But Dr. Gomez was ignorant of its precise nature, considering it to be analogous to resin. M. Laubert afterwards obtained the same principle by a different process, and described it under the name of *white matter*, or *pure white resin*. To Pelletier and Caventou was reserved the honour of crowning all these experiments, and applying the results which they obtained to important practical purposes. In 1820, they demonstrated the alkaline character of the principle discovered by Gomez and Laubert, and gave it definitively the name of *cinchonine*. They discovered in the yellow or Calisaya bark another alkaline principle, which they denominated *quinine*. Both these bases they proved to exist in the barks, combined with *kinic acid*, in the state of *kinate of cinchonine and of quinine*. It was, moreover, established by their labours that the febrifuge property of bark depends upon the presence of these two principles. In 1833, MM. O. Henry and Delondre discovered a new alkaloid, but afterwards, finding its composition in its anhydrous state the same as that of quinia, concluded that it was a hydrate of that base. About 1844, Winckler announced anew the existence of the same principle, which he considered distinct, and named *chinidine;* and, under the similar title of *quinidine*, it is now generally admitted to a place among the cinchona alkaloids. In 1853, M. Pasteur found that what had been considered as quinidine consisted in fact of two alkaloids, for one of which he retained the name of quinidine, and called the other *cinchonidine;* and, on pushing his investigations further, he ascertained that no less than six alkaloids may be obtained from different varieties of Peruvian bark; namely *quinine* and *quinidine* isomeric with each other, *cinchonine* and *cinchonidine* also isomeric, and two others, derivatives from the preceding through the agency of heat, viz., *quinicine* from quinine, and *cinchonicine* from cinchonine, each being isomeric with the alkaloid from which it is derived. As the termination *a* or *ia* has been generally adopted by American and English chemists to distinguish the organic alkaloids from other organic proximate principles, the names of which terminate in *in* or *ine*, the terms quinine and cinchonine of the French writers have been changed with us into *quinia* and *cinchonia*. On the same principle, *quinidine*, *quinicine*, *cinchonidine*, and *cinchonicine* should be called respectively *quinidia*, *quinicia*, *cinchonidia*, and *cinchonicia*. This method of designating the vegetable alkaloids is uniformly followed in the present work.*

It has before been stated, on more than one occasion, that the three officinal varieties of bark are distinguished by peculiarities of composition. We give the result of the analysis of each variety, as obtained by Pelletier and Caventou. (*Journ. de Pharm.*, vii. 70, 89, 92.)

Pale bark of Loxa contains, 1. a fatty matter; 2. an insoluble red colouring

* Reference has been made in a note to the discovery, by Pelletier and Coriol, of an alkaloid called *aricina* in the Arica or Cusco bark. It was obtained by the same process as that employed in the extraction of quinia from yellow bark. It is white, crystallizable, and distinguisable from cinchonia, which it in many respects resembles, by exhibiting a green colour under the action of nitric acid, and by the property, possessed by its sulphate, of forming a tremulous jelly when a saturated boiling solution of the salt is allowed to cool. Manzini obtained from Jaën bark an alkaline substance which he supposed to be peculiar, and named *cinchovatin;* but the same had been obtained by Bouchardat, and considered by him, as well as by Pelletier, to be identical with *aricina;* and Winckler, having extracted a portion from the bark, and examined it with great care, coincided in this conclusion. (*Journ. de Pharm.*, 3e sér., ii. 95 et 313; *Central Blatt*, A. D. 1844, p. 126.) Much doubt, however, exists on the subject of this supposed alkaloid, and by Mr. Howard it is thought most probably to have been quinidia.

Besides the alkaloids mentioned in the text, the claims of which as characteristic constituents of Peruvian bark are admitted, and besides the aricina of Pelletier, there are others, the discovery of which has been from time to time announced, but of which the pretensions to this rank have not been so satisfactorily determined. Of these mention will be made in notes, as the opportunity offers; our limits not permitting that they should be introduced into the text of the work.

matter; 3. a yellow colouring matter; 4. tannin, or soluble red colouring matter; 5. gum; 6. starch; 7. lignin; 8. kinate of lime; 9. *kinate of cinchonia, with a very minute proportion of kinate of quinia.*

Yellow Calisaya bark contains the fatty matter, the cinchonic red, the yellow colouring matter, tannin, starch, lignin, kinate of lime, and *kinate of quinia, with a comparatively small proportion of kinate of cinchonia.*

Red bark contains the fatty matter, a large quantity of the cinchonic red, the yellow colouring matter, tannin, starch, lignin, kinate of lime, and *a large proportion both of kinate of quinia and of kinate of cinchonia.*

Carthagena bark generally contains the same ingredients with the red bark, but in different proportions. It has less of the alkaline matter, which it also yields with much greater difficulty to water, in consequence of the abundance of insoluble cinchonic red which it contains, and which either involves the salts of quinia and cinchonia so as to prevent the full contact of water, or retains these alkaloids in combination. (*Journ. de Pharm.*, vii. 105.)

Besides quinia and cinchonia, there can be little doubt that two other alkaloids, *quinidia* and *cinchonidia* as they are denominated in this work, exist in Peruvian bark; and it is highly probable that, though found most abundantly in the pale, and some of the Carthagena barks, they are contained at least occasionally, to a greater or less extent, in all; while two others *quinicia* and *cinchonicia*, if they do not pre-exist in the barks, result from the processes employed in the separation of the alkaloids just mentioned.

Another bitter principle was extracted from Calisaya bark by Winckler. He named it *kinovic bitter;* but, having been supposed to possess acid properties, it was afterwards denominated *kinovic acid.* It is thought to exist in the bark in a free state (Schwartz, *Pharm. Cent. Blatt*, 1852, p. 194), as well as combined with one or more of the alkaloids. The nauseous taste of some of the barks has been ascribed to this principle.

By the experiments of Henry jun. and Plisson, it may be considered as established, that the alkaloids of the different varieties of bark are combined at the same time with kinic acid, and with one or more of the colouring matters, which, in relation to these substances, appear to act the part of acids. This idea was originally suggested by Robiquet. (*Journ. de Pharm.*, xii. 282, 369.) The compounds of quinia, cinchonia, &c. with the colouring matter, are scarcely soluble in water, while their kinates are very soluble.

From these statements it appears that the three officinal varieties of bark differ little except in the proportion of their constituents. All contain quinia and cinchonia; the yellow bark most of the first, the pale of the second, and the red a considerable quantity of both. All probably contain, occasionally at least, the other characteristic alkaloids. Gum was found in the pale, but not in the red or yellow. Kinovic bitter, though first discovered in the yellow, probably exists in others.

The odour of bark appears to depend on a *volatile oil*, which Fabroni and Trommsdorf obtained by distillation with water. The oil floated on the surface of the water, was of a thick consistence, and had a bitterish, acrid taste, with the odour of bark.*

The *fatty matter*, which was first obtained pure by M. Laubert, is of a greenish colour as obtained from the pale bark, orange-yellow from the yellow. It is insoluble in water, soluble in boiling alcohol, which deposits a part of it on cooling, very soluble in ether even cold, and saponifiable with the alkalies.

The *cinchonic red* of Reuss, the *insoluble red colouring matter* of Pelletier

* A very careful chemical examination of several varieties of Peruvian bark has been made by Dr. E. Reichardt, the results of which are given in a paper, which received a prize from the Philosophical Society of Jena. The following are the constituents of the barks examined. 1. *Organic constituents;* quinia, cinchonia, ammonia, kinic acid, kinovic acid, cincho-tannic acid, oxalic acid, sugar, wax, cinchonic red, humic acid, and cellulose. 2. *Inorganic constituents;* chloride of potassium, carbonates of potassa, magnesia, and lime, phosphates of lime, alumina, and iron, silicate of lime, sulphate of lime, and oxide of manganese. (*Chem. Pharm. Cent. Blatt*, Sept. 12, 1855, p. 637.)—*Note to the eleventh edition.*

and Caventou, is reddish-brown, insipid, inodorous, largely soluble in alcohol especially when hot, and almost insoluble in ether or water, though the latter dissolves a little at the boiling temperature. The acids promote its solubility in water. It precipitates tartar emetic, but not gelatin; but if treated with a cold solution of potassa or soda, or by ammonia, lime, or baryta, with heat, and then precipitated by an acid, it acquires the property of forming an insoluble compound with gelatin, and seems to be converted into tannin. It is precipitated by subacetate of lead. It is most abundant in the red bark, and least so in the pale. Berzelius supposed it to be formed from tannin by the action of the air. According to Schwartz, it results from the absorption by the tannin of three eqs. of oxygen, and the elimination of two eqs. of carbonic acid and one eq. of water. (*Pharm. Cent. Blatt*, 1852, p. 194.) There is reason to believe that it is also produced by changes in the alkaloids under the influence of light.

The *yellow colouring matter* has little taste, is soluble in water, alcohol, and ether, precipitates neither gelatin nor tartar emetic, and is itself precipitated by subacetate of lead.

The *tannic acid, tannin, cincho-tannic acid*, or *soluble red colouring matter* of Pelletier and Caventou, has been considered as possessing all the properties which characterize the proximate vegetable principles associated together under the name of tannic acid. It has a brownish-red colour and austere taste, is soluble in water and alcohol, combines with metallic oxides, and produces precipitates with the salts of iron, which vary in colour according to the variety of bark, being deep-green with the pale bark, blackish-brown with the yellow, and reddish-brown with the red. It also forms white precipitates with tartar emetic and gelatin, and readily combines with atmospheric oxygen, becoming insoluble. It must, however, differ materially from the tannic acid of galls, which could not exist in aqueous solutions containing cinchonia and quinia without forming insoluble compounds with them.

But the most interesting and important constituents of Peruvian bark are the alkaline and active principles quinia, cinchonia, &c., and the kinic and kinovic acids, with the former of which the latter principles are combined. In relation to these, therefore, we shall be more minute in our details.

Quinia. As usually prepared, quinia is whitish, rather flocculent, and not crystalline; but it may with care be crystallized from its alcoholic solution in silky needles; and Liebig obtained it from a somewhat ammoniacal watery solution in the same form. It is inodorous and very bitter. At about 300° F. it melts without chemical change, and on cooling becomes brittle. By carefully regulated heat, it may be sublimed unchanged, assuming a crystalline form. (Waddington, *Pharm. Journ. and Trans.*, March, 1868, p. 413.) It is soluble in about 400 parts of cold and 250 of boiling water, is very soluble in alcohol and ether, and dissolved by the fixed and volatile oils. The alcoholic solution is intensely bitter. Quinia is unalterable in the air. It forms salts with the acids which readily crystallize. The tannate, tartrate, and oxalate are said to be insoluble or nearly so, but are dissolved by an excess of acid. The acetate, according to Prof. J. M. Maisch, is so slightly soluble that it is precipitated from a solution of the sulphate by the acetates of magnesia and the alkalies. (*Am. Journ. of Pharm.*, xxx. 386.) When recently precipitated quinia, diffused in water, is exposed to the action of a stream of carbonic acid gas, the quinia is dissolved; and, if the solution be exposed, acicular crystals of carbonate of quinia are deposited, which effloresce in the air, are soluble in alcohol, but insoluble in ether, have an alkaline reaction, and effervesce with acids. After the deposition of the crystals has ceased, the solution yields quinia on evaporation. (Langlois, *Comptes Rendus*, Nov. 7, 1853, p. 727.) Freshly precipitated quinia is scarcely soluble to an appreciable extent in an excess of potassa, but is more readily dissolved by ammonia. (Wadgymar, *Am. Journ. of Pharm.*, Sept. 1866, p. 451.)

Quinia and its salts may be distinguished from all other vegetable alkalies and their salts, excepting only quinidia, by the beautiful emerald-green colour which results, when their solution is treated first with solution of chlorine and

then with ammonia, and which changes to a white or violet upon saturation with a dilute acid. The least quantity of quinia may be detected by powdering the substance supposed to contain it, then shaking it with ether, and adding successively the tests just mentioned. Its salts are precipitated by the bichlorides of mercury and platinum, and of a buff colour by the terchloride of gold.

In relation to the property, possessed by quinia, of imparting fluorescence to its watery solution, which is possessed also, though in less degree, by other cinchona alkaloids, there will be occasion to speak under Sulphate of Quinia, in Part II. of this work; in connection with the singular discovery, by Dr. Bence Jones, of London, of a substance normally present in the animal system having analogous properties, and therefore named by him "*animal quinoidine.*"

The composition of quinia is differently given. According to Liebig, it consists of twenty eqs. of carbon, twelve of hydrogen, one of nitrogen, and two of oxygen ($C_{20}H_{12}NO_2$), and its combining number is 162. This formula is based on the supposition that, of the two salts which quinia forms with most acids, the one containing the smallest proportion of acid is a di-salt, consisting of two eqs. of base and one of acid, and the other neutral, consisting of one eq. of each. Another view is, that the first of these salts is neutral, and the second a bi-salt; and, if this be admitted, the above combining number must be doubled. Upon the latter supposition, the formula, according to Laurent, is $C_{38}H_{22}N_2O_4$ and the combining number 310; according to Regnault and Strecker, the former is $C_{40}H_{24}N_2O_4$ and the latter 324, being just double the number of Liebig, and probably correct, at least so far as concerns the relative proportion of the several ingredients.*

There is reason to believe that quinia may become uncrystallizable without change of composition, and impart to its salts the same uncrystallizable character. In this state it is called *amorphous quinia.* This is always among the substances left in the mother-waters after the crystallization of sulphate of quinia, in its preparation from Calisaya bark. More will be said of this under sulphate of quinia in the second part of this work.

Quinia is obtained by treating its sulphate with the solution of an alkali, collecting the precipitate, washing it till the water comes away tasteless, then drying it, dissolving it in alcohol, and slowly evaporating the solution.

The most important artificial salt of quinia is the *sulphate*, the process for procuring which, as well as its properties, will be hereafter described. The *valerianate* has been introduced into the U. S. Pharmacopœia, and the *citrate of iron and quinia* both into this and the British, which give processes for their preparation. The *phosphate, acetate, citrate, lactate, camphorate, ferrocyanate, tannate, arsenite, antimoniate, urate, hypophosphite,* and *chlorate,* have also been employed or recommended; but none of them has yet gained admittance

* Langlois found the carbonate of quinia, deposited from a solution in carbonic acid water, to contain one eq. of acid and one of base, admitting the combining number of the latter to be 162; and, if this salt be considered neutral, the result will tend to confirm the view of Liebig. (*Comptes Rendus*, Nov. 7, 1853, p. 727.) On the contrary, Adolphus Strecker, who has made an elaborate analysis of quinia and its compounds, has adopted the formula $C_{40}H_{24}N_2O_4$ (eq. 324), basing his opinion chiefly on the composition of the double chloride of platinum and quinia, and on the fact, that the only crystallizable nitrate he could obtain coincides with the officinal sulphate, and that in this compound one eq. of oxide of silver may be made to replace one eq. of water, so as to form a nitrate of silver and quinia. (See *Am. Journ. of Pharm.*, xxvii. 241 and 321.) To the same point tends the fact, that the officinal sulphate of quinia is the more permanent of the two sulphates. Upon the whole, we are inclined to the view which considers the formula to be $C_{40}H_{24}N_2O_4$, and the combining number 324. (*Note to the eleventh edition.*)

Oxyquinia. Schutzenberger has ascertained that when sulphate of quinia is boiled with a solution of nitrite of potassa, nitrogen escapes with effervescence, and the liquid, after cooling, deposits, on the addition of ammonia, a white, granular substance, which, when dissolved in alcohol, and obtained in a dry state by the evaporation of the menstruum, assumes a transparent, resinous appearance. By contact with water it becomes crystalline. This substance has alkaline properties, and differs from quinia only in containing two additional eqs. of oxygen. It has, therefore, been named *oxyquinia.* (*Comptes Rendus*, Juillet 12, 1858, p. 81.)—*Note to the twelfth edition.*

into the Pharmacopœias, and none probably is superior to the officinal sulphate. The first five may be prepared by saturating a solution of the acids respectively with quinia, and evaporating the solutions. The *camphorate* is recommended as a substitute for the valerianate. (*Am. Journ. of Pharm.*, July, 1865, p. 254.) The *ferrocyanate* is directed to be made by boiling together two parts of sulphate of quinia and three of ferrocyanide of potassium in a very little water, pouring off the liquor from a greenish-yellow substance of an oily consistence which is precipitated, washing the latter with distilled water, then dissolving it in strong alcohol at 100° F., filtering immediately, and afterwards evaporating the solution. (*Am. Journ of Pharm.*, xii. 351.) M. Pelouze, however, found this preparation to be pure quinia, mixed with a little Prussian blue. (*Archives Gén.*, 3e sér., xv. 236.) The *tannate* may be prepared by precipitating the infusion of bark, or solution of sulphate of quinia, by the infusion of galls or solution of tannic acid, and then washing and drying the precipitate. It has the advantage of possessing little taste, while experience has shown that it is little if at all inferior in antiperiodic powers to the sulphate; but its amorphous condition renders it more liable to adulteration. Either of these salts may be given in the same dose as the sulphate. *Arsenite of quinia* has been recommended by Dr. Ringdon, especially in chronic cutaneous affections. He prepares it by boiling 64 grains of arsenious acid, with half the quantity of carbonate of potassa, in four fluidounces of distilled water until dissolved, adding water enough to make the solution measure four fluidounces, and then mixing five drachms of this solution with two scruples of sulphate of quinia, previously dissolved in boiling distilled water. The arsenite of quinia is thrown down in the form of a white curdy precipitate, which is to be washed on a filter and dried. It is uncrystallizable, insoluble in water, and soluble in alcohol. The dose is one-third of a grain, given at first twice a day, and afterwards three and four times a day. (*Prov. Med. and Surg. Journ.*, Aug. 25, 1847.) *Antimoniate of quinia* has been recommended by Dr. La Camera, of Naples, as a febrifuge, being especially applicable to cases of doubtful periodicity. It unites, he thinks, the evacuant properties of the antimonials with the antiperiodic property of quinia. The dose is two or three grains, four times a day. (*Journ. de Pharm.*, 3e sér., xxv. 471.) The *urate of quinia* is thought by Dr. Pérayre, of Bordeaux, to be peculiarly efficacious in obstinate intermittents. It is prepared by boiling 10 parts of crude quinia in water, adding gradually 20 parts of crystallized uric acid, and, after sufficient ebullition, filtering and evaporating. A yellow salt is obtained, sometimes amorphous, more frequently crystalline, soluble in hot and less so in cold water, and, according to the author, capable of curing intermittent fever in smaller doses than the sulphate, with less cerebral disturbance, less bitterness, and easier tolerance by the stomach. (*Journ. de Pharm.*, 3e sér., xxxvii. 139.) The *hypophosphite of quinia* has been brought into notice by Dr. J. Lawrence Smith, of the University of Louisville, who prepares it by mixing, in a large porcelain capsule, 50 ounces of sulphate of quinia, 2 gallons of distilled water, and 2 ounces of hypophosphorous acid, heating the mixture to 200°, and then adding a solution of hypophosphite of baryta sufficient to produce complete decomposition, an excess of the latter salt being scrupulously avoided. Sulphate of baryta and hypophosphite of quinia are formed, the latter in solution. The solution is filtered while hot, and on cooling deposits the salt in crystals. If the sulphate of baryta be washed, the washings added to the mother-waters of the first crystallization, and the mixed liquors carefully evaporated, a fresh crop of crystals will be obtained. The salt consists of one eq. of quinia (admitting the double numbers) and one of hypophosphorous acid, with two eqs. of water of crystallization. (*Am. Journ. of Pharm.*, Sept. 1860, p. 410.)*

* The *chlorate of quinia* is best prepared, according to Mr. C. R. C. Tichborne, from chlorate of baryta. He mixes in a porcelain dish 310 grains of chlorate of baryta dissolved in a little boiling water with 2 ounces avoird. of sulphate of quinia, and 12 ounces of hot water, at 194° F.; a slight excess of the sulphate being used to ensure the precipitation of all the barium. Owing to this excess, a slight pellicle of sulphate of quinia floats on the surface. Apply heat, and gradually add a very little precipitated carbonate of

Cinchonia. This, when pure, is white, crystallizable from its alcoholic solution in four-sided prisms with oblique terminal facets, soluble in 2500 parts of boiling water, almost insoluble in cold water, soluble in boiling alcohol which deposits a portion upon cooling, and slightly soluble in ether and in the fixed and volatile oils.* Its bitter taste, at first not very obvious in consequence of its difficult solubility, is developed after a short time by the solution of a minute portion in the saliva. Its alcoholic, ethereal, and oleaginous solutions are very bitter. By heat it is melted and partially changed, and, if the heat be cautiously increased, sublimes into a matted tissue of fine crystals, which have the same formula as the pure alkaloid. (Hlasiwetz, *Chem. Gaz.*, ix. 90.) Waddington found it to sublime readily, without change, and in perfectly characteristic crystals. (*Pharm. J. and Trans.*, March, 1868, p. 414.)† Its alkaline character is very decided, as it neutralizes the strongest acids. Of the salts of cinchonia, the sulphate, nitrate, muriate, phosphate, and acetate are soluble in water. The neutral tartrate, oxalate, and gallate are insoluble in cold water, but soluble in hot water, alcohol, or an excess of acid. Winckler has shown that cinchonia is rendered uncrystallizable or amorphous by sulphuric acid in excess, aided by heat; a fact of importance in the preparation of the sulphate of this alkaloid. (*Chem. Gaz.*, March 15, 1848.) Cinchonia is but little more soluble in carbonic acid water than in pure water, and does not, like quinia, yield crystals of the carbonate on exposure of its carbonic acid solution. (*Comptes Rendus*, Nov. 7, 1853, p. 727.)

Several processes have been employed for the preparation of cinchonia. One of the simplest is the following. Powdered pale bark is submitted to the action of sulphuric or muriatic acid very much diluted, and the solution obtained is precipitated by an excess of lime. The precipitate is collected on a filter, washed with water, and treated with boiling alcohol. The alcoholic solution is filtered while hot, and deposits the cinchonia when it cools. A further quantity is obtained by evaporation. If not perfectly white, it may be made so by converting it into a sulphate with dilute sulphuric acid, then treating the solution with animal charcoal, filtering, precipitating by an alkali, and redissolving by alcohol in the manner already mentioned. It may also be obtained from the mother-waters of sulphate of quinia by diluting them with water, precipitating with ammonia, collecting the precipitate on a filter, washing and drying it, and then dissolving it in boiling alcohol, which deposits the cinchonia in a crystalline form upon cooling. It may be still further purified by a second solution and crystallization.

The same remarks in relation to equivalent composition apply to cinchonia as those already made in reference to quinia. According to the view which considers the salts as basic and neutral, cinchonia consists of twenty eqs. of carbon, twelve of hydrogen, one of nitrogen, and one of oxygen ($C_{20}H_{12}NO$); and its combining number is 154. This is the formula of Liebig. The other view would double these numbers; the formula being $C_{40}H_{24}N_2O_2$, and the eq. 308.

Exposed to the air, cinchonia does not suffer decomposition, but very slowly

baryta till the coating of sulphate is replaced by a slight oily pellicle of alkaloid. The chlorate of quinia is now obtained by evaporation and crystallization. For a mode of preparing the chlorate of baryta, see a communication from Dr. C. Lewis Diehl, in the *Amer. Journ. of Pharm.* (March, 1868, p. 101).

The chlorate crystallizes from its solution in fungoid tufts, consisting of filiform, snow-white crystals, radiating from a centre. It melts with heat, and in the air at length takes fire, burning vividly, and if dry sometimes with explosion, leaving a carbonaceous residue. It is very soluble in boiling water, but sparingly in cold, and is deposited from its hot solution on cooling. Gently warmed with muriatic acid, it emits chlorine copiously; and ammonia now added in excess occasions an emerald-green colour; thus showing that it is a compound of chloric acid and quinia. (*Pharm. Journ. and Trans.*, 2d ser., viii. 135.)—*Note to the thirteenth edition.*

* According to Hesse, cinchonia is soluble at 68° F. in 3670 parts of water, in 125·7 parts of alcohol of 0·852, and in 371 parts of ether of 0·7305. (See *Am. Journ. of Pharm.*, xxxv. 54.)—*Note to the twelfth edition.*

† It is asserted that the muriates of quinia, cinchonia, and quinidia, heated on a slip of platinum, short of combustion, emit a purple vapour like iodine. Neither the alkaloids nor their sulphates have this property; but the addition of one-tenth of muriate will cause the evolution of the coloured vapour. (*J. de Pharm. et de Chim.*, 4e sér, iii. 397).—*Note to the thirteenth edition.*

absorbs carbonic acid, and acquires the property of effervescing slightly with acids. It is precipitated of a sulphur-yellow by the terchloride of gold. Chlorine water dissolves it or any of its salts without change; but if ammonia be now added, a white precipitate is produced. It is thus distinguishable from quinia. Dr. J. W. Bill, U. S. A., proposes ferrocyanide of potassium as a very delicate test of cinchonia. If added to the solution of a salt of this alkaloid, it produces a yellowish-white curdy precipitate, which is dissolved upon the application of a gentle heat, but is again deposited, when the liquid cools, as an abundant crop of golden-yellow crystals. No other alkaloid exhibits the same reaction. A cloudy precipitate is produced by the same reagent with a salt of quinia, but this does not happen when the ferrocyanide is in excess, and, if the precipitate is dissoved by heat, no subsidence takes place on cooling. Hence, in the application of this test to cinchonia, a slight excess of the ferrocyanide should be added. (*Am. Journ. of Sci. and Arts*, July, 1858, p. 108.)

Sulphate of cinchonia (*disulphate* of Liebig), the only salt of this base which has been employed in a separate state, is now one of the U. S. officinals, and will be treated of in the second part of this work among the *Preparations*.

Quinidia (*quinidine*) and *Cinchonidia* (*cinchonidine*). It has been already stated that the substance, at one time considered as a peculiar alkaloid, and denominated quinidia or quinidine, has been ascertained to be generally complex, and to consist of two distinct alkaloids in variable proportions. For one of these, in consequence of its similarity in chemical constitution to quinia, Pasteur retained the name of quinidine (quinidia), while he called the other, from a similar resemblance to cinchonia, cinchonidine (cinchonidia). It is unfortunate that Pasteur's quinidine is the alkaloid which in general constitutes the smaller proportion of the complex substance formerly so named; his cinchonidine existing in it much more largely, and sometimes, there is reason to believe, constituting almost the whole of it. Nevertheless, it is necessary to adopt the nomenclature of Pasteur, as corresponding strictly with the chemical relations of the several substances concerned. The student will, therefore, take care not to confound the quinidia as formerly described with the pure alkaloid of the same name, and to recollect that the former substance corresponds more closely with cinchonidia (the cinchonidine of Pasteur), and sometimes probably consists of it exclusively, or nearly so.

Quinidia (*quinidine*, Pasteur) is isomeric with quinia, having the constitution $C_{40}H_{24}N_2O_4$, or $C_{20}H_{12}NO_2$. It crystallizes readily in rhombic prisms, which contain four eqs. of water, and effloresce on exposure to the air. It is sublimable by heat without change, and is condensed in a crystalline form. (*Waddington.*) It resembles quinia not only in composition, but also in its chemical relations with chlorine and ammonia, being rendered green by the successive action of those agents. According to Dr. Herapath, it resembles quinia also in causing a fluorescent appearance when dissolved in water, which is not the case with either cinchonia or cinchonidia, or is so at least in a much less degree. (See *Am. Journ. of Pharm.*, xxix. 245.) It differs, however, in its greater facility of crystallization, in its much less solubility in ether, and in its influence on polarized light, quinidia producing deviation to the right, and quinia to the left. De Vry, of Rotterdam, states, as the result of his observation, that quinidia (of Pasteur) forms a salt of very difficult solubility with hydriodic acid; and, consequently, when a solution of iodide of potassium is added to a solution of sulphate of quinidia, a white precipitate takes place. By this test quinidia may be distinguished from the other cinchona alkaloids, and detected when mixed with them in solution; no other yielding a precipitate with iodide of potassium. (See *Am. Journ. of Pharm.*, xxix. 233.) Dr. Herapath proposes another test to distinguish this alkaloid from quinia. If to a solution of sulphate of quinia in acetic acid tincture of iodine be added, and the mixture heated and then allowed to cool, a beautiful emerald-green compound is formed; while sulphate of quinidia treated in the same way, yields a brown precipitate. When the mixture of this alkaloid with cinchonidia is exposed to hot air, the crystals

of quinidia effloresce, and may be distinguished from the others by their opaque whiteness. For practical purposes this separation is unnecessary; for there is probably no appreciable difference in their effects as remedial agents.*

Cinchonidia (*cinchonidine*, Pasteur) is isomeric with cinchonia, having the constitution $C_{40}H_{24}N_2O_2$, or $C_{20}H_{12}NO$, and agrees also with that alkaloid in forming anhydrous crystals, and in not producing the green colour with chlorine and ammonia. It differs in being more soluble in ether, and in producing deviation to the left in its influence on polarized light; cinchonia producing deviation to the right. (Regnault, *Cours Élément. de Chim.*, 4e ed., iv. 314.) If, on exposure to hot air, white effloresced crystals show themselves, it may be taken for granted that there is an admixture of quinidia. It sublimes readily unchanged, assuming a more or less crystalline form, and, with a carefully regulated heat, perfect crystals may be obtained. (*Waddington.*)

As the two preceding alkaloids have not been thoroughly investigated, in their perfectly pure and isolated state, in reference either to their chemical or practical relations, it will be proper to state what has been made known of the commercial quinidia, in which they are believed to exist, in general conjointly.

Commercial quinidia, consisting generally of proper quinidia with a much larger proportion of cinchonidia, and sometimes, there is reason to believe, exclusively, or nearly so, of the latter alkaloid, was, carefully examined by H. G. Leers, from whose paper, published originally in the *Ann. der Chem. und Pharm.* (May, 1852), the following account of its properties has been chiefly derived. It readily crystallizes from its alcoholic solution, by spontaneous evaporation, in hard, shining, colourless crystals, which are easily pulverized, and yield a snow-white powder. They melt without decomposition or loss of water at 347° F., and on cooling concrete into a grayish-white crystalline mass. At a higher heat they take fire, and burn with the odour of kinole, and volatile oil of bitter almonds. Their taste is bitter, but less intensely so than that of quinia. Quinidia is soluble, according to Leers, in 2580 parts of water at 62°, and in 1858 parts at 212°, in 143 (169 Winckler) of ether, and 12 of alcohol of 0·835, both at 62° F.; but its solubilities must, of course, vary more or less according to the quantities of its two components, quinidia proper and cinchonidia, contained in it. With the acids it forms salts, most of which are beautifully crystallizable, and much more soluble than those of quinia. There are, as of quinia and cinchonia, two sets of the salts of quinidia, which may be considered either as neutral and acid, or as basic and neutral. When treated first with chlorine and then with ammonia, it does not like quinia yield a green colour, nor like cinchonia a white one, but remains unaffected. It differs from quinia also by its much less solubility in ether. From the aqueous solution of its salts, the alkalies, their carbonates, and bicarbonates throw down pulverulent precipitates not soluble in an excess of the precipitant. With phosphate of soda, nitrate of silver, and bichloride of mercury it forms white, with terchloride of gold light-yellow, and with bichloride of platinum orange-yellow

* Cinchonia, quinia, quinidia, and strychnia, when heated with caustic potassa, yield acrid vapours, which condense into an oily liquid having alkaline properties, for which the name of *quinolëin* was proposed by its discoverer Mr. Gerhardt, and which is also called *cincholin*. It has a peculiar odour, not unlike that of the bean of St. Ignatius, and an extremely acrid and bitter taste; is slightly soluble in water, and freely so in alcohol, ether, and the volatile oils; forms crystallizable salts with the acids; and is characterized by producing a yellow crystalline precipitate with chromic acid. It results also from the dry distillation of quinia. (*Journ. de Pharm.*, 3e sér., ii. 341.) Dr. A. W. Hofmann has found that the substance called *leucol*, existing in coal-gas naphtha, is identical with cincholin. (*Chem. Gazette*, June, 1845, p. 251.) More recently Mr. C. Greville Williams has shown that the alkaline matter called cincholin is complex, and that several volatile alkaloids result from the decomposition of cinchonia by potassa with heat, analogous to those found in coal-gas tar. (*Ibid.*, Aug. 15, 1855, p. 301. See also *Gregory's Chemistry*, 4th ed., Lond., p. 400.) Dr. Stenhouse proposes, as a test of the presence of alkaline principles in bark, to macerate with dilute sulphuric acid, precipitate with solution of carbonate of potassa or soda in excess, and distil the precipitate with a great excess of caustic potassa or soda. Cincholin will distil over in oily drops, recognisable by its peculiar odour and strong alkaline properties. (*Philos. Mag.*, xxvi. 199.)

precipitates. It may be obtained by first precipitating it from the solution of one of its salts by an alkali, and then repeatedly dissolving in alcohol and crystallizing, until it is entirely freed from a greenish-yellow resinous substance which is apt to attend it. From quinia it may be separated by repeated washing with ether, until the ethereal solution no longer affords evidence of the presence of quinia by the test of chlorine and ammonia. In this state it must be looked on as unmixed cinchonidia. One of the distinctive characters of this complex alkaloid is, according to Guibourt, that, while *oxalate of quinia* is quite insoluble in water, *oxalate of quinidia* (*commercial*) is very soluble, and easily crystallizable by refrigeration or evaporation. (*Journ. de Pharm.*, 3e sér., xxii. 414.)

Sulphate of quinidia (*commercial*) is, according to one view, neutral, consisting of one eq., each, of quinidia, sulphuric acid, and water; according to another, basic, containing two eqs. of base, one of acid, and one of water, and therefore a disulphate. It is in long, shining, silky acicular crystals, soluble in 130 parts of water at 62° F., in 16 parts at 212°, readily soluble in alcohol, but almost insoluble in ether. It is obtained from the quinidia (strictly, cinchonidia) barks by the same process as that by which sulphate of quinia is procured from the Calisaya. When the two alkaloids are contained in the same bark, the sulphate of quinidia (commercial) remains in the mother-waters in consequence of its greater solubility. By the addition to its solution of a quantity of sulphuric acid equal to that which it contains, it is converted into the bisulphate (sulphate on the basic view), crystallizable in fine acicular crystals like asbestos.

Quinicia (*quinicine*) and *Cinchonicia* (*cinchonicine*). When quinia and cinchonia, or quinidia and cinchonidia, or their salts, are exposed to heat, these alkaloids have been found by Pasteur to be changed into other but isomeric alkaloids; quinia and quinidia into quinicia, isomeric with themselves; and cinchonia and cinchonidia into cinchonicia, isomeric with its own antecedents. These new alkaloids are, therefore, products rather than educts, and generally result, in greater or less proportion, from the processes employed in extracting the other alkaloids from bark; though it is not impossible that they may pre-exist in bark to a certain extent, being formed by a natural process, from the same original alkaloids, either in the living tree, or in the barks while drying, after separation from the tree.

Quinicia is almost insoluble in water, but very soluble in alcohol, and differs from quinia in causing deviation of the plane of polarization to the right instead of the left (*Regnault*), and in being apparently uncrystallizable.

Cinchonicia is also insoluble in water and soluble in alcohol. It agrees with cinchonia, from which it is derived, in producing deviation of the plane of polarization to the right; but differs from cinchonidia in this respect; and differs from both of these alkaloids in being amorphous or uncrystallizable.

The *amorphous quinia* of Liebig (*quinoidine* or *quinoidia*) is probably when pure identical with quinicia; but, as it occurs in commerce, it is generally a mixture of this with cinchonicia. For a particular account of it, see *Sulphate of Quinia*, in the *second part* of this work.*

Kinic Acid (*called also Cinchonic or Quinic Acid*), *and the Kinates of*

* *Cinchonidia of Wittstein.* Wittstein has announced the discovery of a new alkaloid in a variety of bark belonging probably to the division of barks here considered under the name of fibrous Carthagena barks. He calls the alkaloid *cinchonidine;* but it must not be confounded with the cinchonidine of Pasteur. (*Am. Journ. of Pharm.*, xxix. 115.) From the researches of Dr. Herapath it appears that its claims to be considered as a distinct alkaloid are well founded; its iodo-sulphate being readily distinguishable by the eye from the other iodo-sulphates examined by him. (*Pharm. Journ.*, xvii. 468.) It ought, therefore, to receive another designation, in order to prevent confusion.

β. cinchonine of Schwabe. Still another cinchona alkaloid has been brought into notice by Schwabe, who extracted it from quinoidine. He calls it *β. cinchonine* (*β. cinchonia*), and obtained it by dissolving quinoidine in dilute muriatic acid, precipitating with ammonia, washing the precipitate successively with cold and hot water and drying it, treating it with cold alcohol for 24 hours, then exhausting it successively with alcohol and water, and finally dissolving it in dilute sulphuric acid. The solution was heated, and, carbonate of soda being added till a pellicle began to form, was set aside to cool. Sulphate of *β.* cinchonia was now deposited in crystals, from which the pure alkaloid was obtained by precipitating an acidulated solution with ammonia. It differs from the other

Cinchonia and Quinia. It may be desirable to procure the alkaline principles in the state of saline combination in which they exist in the bark; as it is possible that they may exert an influence over the system in this state, somewhat different from that produced by their combinations with the sulphuric or other mineral acid. As it is impossible to procure the kinates immediately from the bark in a pure state, it becomes necessary first to obtain the kinic acid separately, which may thus become of some practical importance. We shall, therefore, briefly describe the mode of procuring it, and its characteristic properties. By evaporating the infusion of bark to a solid consistence, and treating the extract with alcohol, we have in the residue a viscid matter consisting chiefly of mucilage with kinate of lime, which is insoluble in alcohol. If an aqueous solution of this substance be formed, and allowed to evaporate at a gentle heat, crystals of the kinate will be deposited, which may be purified by a second crystallization. The salt thus obtained, being dissolved in water, is decomposed by means of oxalic acid, which precipitates the lime, and leaves the *kinic acid* in solution. This may be procured in the crystalline state by spontaneous evaporation, though as usually prepared, it is in the form of a thick syrupy liquid. The crystals are transparent and colourless, sour to the taste, and readily soluble in alcohol and in water. The kinates of cinchonia and quinia may be obtained either by the direct combination of their constituents, or by the mutual decomposition of the sulphates of those alkalies and kinate of lime. *Kinate of cinchonia* has a bitter and astringent taste, is very soluble in water, is soluble also in alcohol, and is crystallized with difficulty. *Kinate of quinia* is also very soluble in water, but less so in rectified alcohol. Its taste is very bitter, resembling exactly that of yellow bark. It crystallizes in crusts of a mammillated form, and opaque or semi-transparent. The salt is with difficulty obtained free from colour, and only by employing the ingredients in a state of extreme purity. (*Ann. de Chim. et de Phys.*, Juillet, 1829.)* Lauteman found, in experiments upon himself, that

cinchona alkaloids in the shape of its crystals, solubilities, and chemical properties. For an account of some of these properties, see *Am. Journ. of Pharm.* (March, 1861, p. 174). O. Hesse, however, having compared the β. cinchonia of Schwabe with cinchonia obtained directly from bark, believes them to be identical. (*Ibid.*, Jan. 1863, p. 54.) There seems also to be a discrepancy in the account of the alkaloid given in the journal from which this sketch is extracted, which tends to invalidate the conclusions of the paper. Thus, the alkaloid is said to be soluble in 173 parts of cold alcohol; yet is also said to be procured from the quinoidine after having been completely exhausted by water and cold alcohol.

Huanochine. This was extracted by Erdmann from a variety of bark imported into Bremen, seventeen or eighteen years since, supposed to be flat Huanuco bark, derived from Cinchona nitida. He obtained it by boiling the bark with water acidulated with muriatic acid, treating the decoction with caustic soda in slight excess, washing the precipitate thus obtained and dissolving it in diluted acetic acid, again precipitating with caustic soda, digesting the precipitate with alcohol, decolorizing with animal charcoal, filtering, evaporating and crystallizing. The substance obtained was found to be an alkaloid, isomeric with quinia, yet differing from this and all the other cinchona alkaloids in properties. It crystallized in small prisms, which were tasteless, almost insoluble in water, soluble in 400 parts of alcohol of 80 per cent. at 62° F. and in 110 parts at the boiling point, in 600 parts of ether at 62° and 470 parts of boiling ether, readily fusible and volatilizable, and inflammable, burning with a smoky flame, and without residue. Though tasteless itself, its salts were very bitter. The alkaloid was found efficient as an antiperiodic. To us, however, it seems most probable, from the method of obtaining the alkaloid, that it is a mixture of cinchonia with one or more of the other known cinchona alkaloids. (See *Am. Journ. of Pharm.*, xxix. 553.)—*Note to the twelfth edition.*

* When kinic acid is mixed with sulphuric acid and deutoxide of manganese, and distilled, a neuter substance called *kinoïle* or *kinone* is obtained, in crystalline needles, of a beautiful golden-yellow colour and high lustre, fusible and volatilizable without change, and having a peculiar odour. The production of this substance, when a concentrated decoction of a bark is distilled with half its weight of sulphuric acid and deutoxide of manganese, has been proposed as a test of the presence of kinic acid in the bark, and consequently of its belonging to the cinchona barks. If there be the least quantity of that acid, the first portion of liquid distilled will have a yellow colour and the odour of kinone, and will become bright-green on the addition of chlorine water. (*Philos. Mag.*, xxvi. 198.) The test, however, cannot be fully relied on; as it has been ascertained that caffeic acid also yields kinone, when treated as above with sulphuric acid and deutoxide of manganese. (Stenhouse, *Am. Journ. of Pharm.*, xxvi. 249, from *Philos. Mag.*)

kinic acid, when taken into the system, undergoes a conversion into hippuric acid, and in this state escapes with the urine. (*Ann. der Chem. und Pharm.*, cxxv. 9.) Kinic acid is said by Zwenger to have been found in the leaves of *Vaccinium Myrtillus*. (*Am. Journ. of Pharm.*, March, 1861, p. 128.)

Kinovic Bitter. Kinovin. Kinovic Acid. Originally discovered in the false bark called quinquina nova or new bark, this substance has since been found in the Calisaya bark, and probably exists, in greater or less proportion, in all the Cinchona barks. It was detected by Dr. De Vry not only in the bark, but also in the wood and leaves of C. Calisaya and C. lucumæfolia. (*Journ. de Pharm.*, Avril, 1860, pp. 225 and 258.) It is white, uncrystallizable, almost insoluble in water, but readily dissolved by alcohol and ether. It is very bitter, and, as it is asserted to have no febrifuge virtues, may on this account mislead the judgment in relation to the activity of the bark in which it may be found. Some barks are said to owe their bitterness mainly to this ingredient. It consists of carbon, hydrogen, and oxygen; its formula being, according to Hlasiwetz and Gilm, $C_{60}H_{48}O_{16}$. It has been supposed to possess acid properties, and a solution of its combination with magnesia is said to precipitate solutions of acetate of lead, bichloride of mercury, and the salts of cinchonia. Winckler gives, as a certain test of its presence in any bark, the sulphate of copper, which is indifferent to infusion of bark containing none of this principle, but detects the smallest proportion of it by producing a dirty-green colour, soon followed by the deposition of a fine similarly coloured powder. This is a salt of copper, and has a very bitter and metallic taste. (See *Am. Journ. of Pharm.*, xxv. 343.) Hlasiwetz and Gilm deny the acid properties of this substance, considering it a glucoside, capable of being resolved, through the action of muriatic acid on its alcoholic solution, into a peculiar acid, and a kind of sugar which they consider as identical with the mannitan of Berthelot. This acid they propose to call *kinovic acid*, adopting the name which has been given to the kinovic bitter under the impression of its acid character. Its formula is $C_{48}H_{38}O_4$. It is white, in rhomboidal crystals, insoluble in water, but slightly soluble in ether, somewhat more so in boiling alcohol, but very soluble in ammonia and the fixed alkalies. All its solutions are decidedly bitter. Its acid properties are feeble, yet it is capable of decomposing the alkaline carbonates. (*Journ. de Pharm.*, Nov. 1859, p. 386.) These results have been confirmed by Dr. De Vry, who proposes the following method of isolating the *kinovic bitter*. Macerate powdered cinchona with a very weak solution of caustic potassa or soda, precipitate the filtered liquid with an acid, redissolve the precipitate in milk of lime to separate the cinchonic red, filter and precipitate the solution boiling hot with muriatic acid, separate the precipitate, wash it, express as much as possible, and lastly dry it on porous stones, and powder it. Thus prepared, the kinovic bitter forms soluble compounds with magnesia and lime, and has been employed, in this mode of combination, as a tonic, in the hospital of Batavia, with encouraging success. (*Ibid.*, Avril, 1860, p. 258.)

Incompatibles. Of the relations of bark to the several solvents employed in pharmacy we shall speak hereafter, under the heads of its infusion, decoction, and tincture; where we shall also have an opportunity of mentioning some of the more prominent substances which afford precipitates with its liquid preparations. It is sufficient at present to state that all the substances which precipitate the infusion of bark do not by any means necessarily affect its virtues; as it contains several inert ingredients which form insoluble compounds with bodies that do not disturb its active principles. As *tannic acid* forms with the alkaloids compounds insoluble in water, it is desirable that substances containing this acid, in a free state, should not be prescribed in connection with the infusion or decoction of bark; for, though these insoluble tannates might be found efficacious if administered, yet, being precipitated from the liquid, they would be apt to be thrown away as dregs, or at any rate would communicate, if agitated, an unpleasant turbidness. The same may be said of the *tincture* and *compound solution of iodine*, which form insoluble compounds with all

the cinchona alkaloids, and of the *alkalies*, *alkaline carbonates*, and *alkaline earths*, which precipitate these alkaloids from their aqueous solution.

Estimation of Value. It is evident, from what has been said, that an infusion of bark, on account of the tannin-like principle which it contains, may precipitate gelatin, tartar emetic, and the salts of iron, without having a particle of cinchonia, quinia, or other alkaloid in its composition; and that consequently any inference as to its value, drawn from these chemical properties, would be fallacious; but, as the active principles are thrown down by the tannic acid of galls, no bark can be considered good which does not afford a precipitate with the infusion of this substance.*

It is impossible to determine, with accuracy, the relative proportion of the active ingredients in the different varieties of cinchona; as the quantity is by no means uniform in different specimens of the same variety. The results of the most recent experiments have been already stated under the head of the several varieties of bark described. But it is highly important, in relation to any particular sample of bark, to be able to ascertain its medicinal efficiency, which is measured by the quantity of the peculiar cinchona alkaloids it may contain. The following is Winckler's process, which he prefers to all others. In determining the value of a large quantity of bark, it is necessary first to ascertain whether it may not consist of more than one variety, and if it do, to assort it, and act on each kind separately. The pieces are to be reduced to a fine powder, of which 1000 grains are to be digested with six ounces of alcohol of 80 per cent., by means of a water-bath, until completely exhausted. The tincture, when cold, is to be strained through thin but close linen; and the residue to be again digested with 3 ounces of alcohol, and strained as before. The residue now obtained is to be once more treated in like manner with alcohol. The tinctures are then to be united, filtered, and treated, at common temperatures, with a mixture of equal parts of fresh-slaked lime and crude well-burnt animal charcoal, of which about 500 grains will be required. The mixture is to be frequently shaken, and the maceration to be continued until the supernatant liquid is rendered colourless. In most of the genuine barks the decolorization is soon effected; but in those containing kinovic acid it is imperfect. The decolorized liquid is to be separated, and the residue to be repeatedly shaken with small quantities of alcohol, washed on a filter with the same liquor, and dried. The alcoholic liquids are to be mixed, and the alcohol distilled off. The whole of the alkaloids is contained in the residue, with a peculiar fatty matter, cinchonic red, and any kinovic acid which may have existed in the bark. To remove these, the matter is to be transferred to a small evaporating basin from the distilling vessel, which is to be washed with a little water acidulated with sulphuric acid, and the liquid thus obtained to be added to the rest. A slight excess of sulphuric acid is now to be dropped into the mixture, which is to be heated, allowed to cool, and then filtered, so as to remove the precipitated kinovic acid and other impurities. From the filtered acidulated solution, the alkaloids are to be precipitated by a slight excess of ammonia, and the mixture evaporated by a gentle heat to dryness. The sulphate of ammonia is to be removed by a small quantity of very cold water, and the residual alkaloid matter dried and weighed. Though not absolutely pure, it is sufficiently

* A test of the cinchona barks, containing one or more of their characteristic alkaloids, has been proposed by Grahe. It is founded on the fact, that, when these barks are exposed to destructive distillation, a product is obtained of a bright carmine colour, which is yielded by no other bark under the same circumstances, and not by cinchona unless it contain one or more of its peculiar alkaloids. Nor do the pure alkaloids afford it; but, if mixed with a little acetic, kinic, tannic, citric, or tartaric acid, they exhibit the reaction, showing that in the bark it takes place between the alkaloids and organic acids contained in it. Grahe applies the test by heating a piece of the bark weighing from five to ten grains in an ordinary test-tube, and gradually increasing the heat to redness. Whitish smoke, and watery vapour condensing on the surface of the tube, are first given off, which are soon followed by the appearance of redness in the fumes, and by the deposition, an inch above the heated part, of a red pulverulent film, which is gradually changed into a thick, oily liquid, running down the glass in drops or streaks of a fine carmine colour. (*Chemisches Central Blatt*, Feb. 17, 1858, p. 97.)—*Note to the twelfth edition.*

so for the purposes of the investigation. (*Am. Journ. of Pharm.*, xxv. 343.) Winckler states that the barks will yield to the manufacturer quite as much as is obtained in this way, and generally from one-eighth to one-quarter of one per cent. more, in consequence of the loss in working being less on a large scale.*

The quantity of alkaloid matter obtained by the above process will measure the efficacy of the bark; for all the organic alkaline principles contained in it are efficient as medicines, and in all probability in a nearly equal degree. But, for manufacturing purposes, it is necessary to push the investigation further, and ascertain the proportion of the several alkaloids in the mixture. This is most conveniently done by means of ether. Cinchonia is scarcely soluble in ether, quinidia is soluble in small proportion, quinia is freely soluble. When, therefore, a mixture of these alkaloids is treated with that menstruum, quinia and quinidia are dissolved, and cinchonia left. The two former may be separated by allowing the ethereal solution to evaporate. Quinidia crystallizes from the solution, and quinia is obtained uncrystallized, as the last product of the evaporation of the ether. These remarks apply to quinidia, as it was understood before the investigations of Pasteur.†

* M. Rabourdin has proposed chloroform as an agent for testing the alkaloid richness of barks. The following is the method applied to the Calisaya. Five drachms of the powder, previously passed through a fine hair sieve, are to be exhausted by water, acidulated with hydrochloric acid (2 drachms of acid to a pound of water), in a percolation apparatus, the liquid being added until it passes colourless and tasteless. Five or six ounces of liquid are thus obtained, to which a drachm and a half of caustic potassa and five drachms of chloroform are to be added. These are to be agitated for a short time, and then allowed to stand. A dense whitish deposit forms, consisting of the alkaloids and chloroform. Sometimes the separation is complete and effected in an instant, leaving a red transparent liquid floating on the surface, which is to be immediately poured off. The chloroformic solution is then washed with water, put into a capsule, and allowed to evaporate. The alkaloids remain behind in a pure state.

Red bark is to be treated as the Calisaya; but for the pale or cinchonia barks the process is to be carried further. The matter left after the evaporation of the chloroform contains cinchonic red as well as cinchonia. It is to be treated with water acidulated with hydrochloric acid, which dissolves all the alkaloid, and a portion of the cinchonic red. The liquid is to be filtered, and solution of ammonia, diluted with 15 or 20 parts of water, added drop by drop, with constant stirring, until a white cloud appears which is not removed by the agitation. The cinchonic red is thus precipitated without the alkaloid. It is easy to know when to stop this part of the process; as the cinchonic red is precipitated in reddish-brown flakes, the cinchonia in white curdled flakes. The liquid is now to be filtered, the filter washed with a little distilled water, and the united liquors precipitated by an excess of ammonia. The precipitate is the pure alkaloid. (See *Am. Journ. of Pharm.*, xxiii. 249.)

M. Guillermond employs another test, which, as last improved by himself, is as follows. Take 20 grammes (about ℥v) of yellow bark, powder it without residue, pour on the powder sufficient alcohol of 76° (sp. gr. 0·872) to form a soft paste, which is to be heated for some minutes on a salt-water bath, so that the particles may be thoroughly penetrated by the liquid; then add 10 grammes of hydrated lime, finely powdered, mix it thoroughly with the paste, and dry the mixture on a plate till quite free from moisture. Introduce the resulting powder into a percolator, pack it firmly, and pour upon it 100 grammes of rectified ether. This, in passing, carries with it all the quinia. The filtered liquid, rapidly evaporated at the temperature of boiling water, leaves a residue consisting of quinia, with a little colouring matter, which is altogether insignificant. The weight of this residue, when entirely dried, will represent the quinia strength of the bark employed. By afterwards passing alcohol through the mass remaining in the percolator, the cinchonia may also be obtained. (*Annuaire de Thérap.*, A.D. 1859, p. 149.)—*Note to the twelfth edition.*

† Mr. Robert Howard employs the following method of ascertaining the presence or absence of these alkaloids, severally, in any mixture of their sulphates, founded on the fact, that ten grains of sulphate of quinia dissolve in sixty drops of ether, but only one grain of sulphate of quinidia. Ten grains of the salt are put into a strong test-tube, ten drops of dilute sulphuric acid (one of acid and five of water) with fifteen drops of water are added, and a moderate heat applied till the salt is dissolved. When the solution has quite cooled, sixty drops of officinal ether with twenty of spirit of ammonia are added, and the mixture is well shaken, the tube being closed by the thumb. After this the tube is closely stopped with a well-fitting cork, and gently shaken from time to time. If the salt contain only quinia, or not more than 10 per cent. of quinidia, it will be completely dissolved, while, at the surface of contact of the two clear liquids, only mechanical impurities will be seen. After some time the layer of ether becomes gelatinous, and then no further observation can be made. Ten grains of the salt examined may contain one grain of quinidia, and yet be

From the most recent and carefully conducted experiments, it appears that the best officinal yellow Calisaya bark, the finest red bark, and the finest fibrous Carthagena bark (*soft Pitaya*) are about equal in their amount of alkaloids, each containing from 3 to 4 per cent.; while between these and the barks of lowest value there is every grade of productiveness, down to a mere trace of alkaline matter.*

completely dissolved by the ether and ammonia; but in this case the quinidia will soon begin to crystallize in the layer of ether. The least trace of quinidia may be detected by employing, instead of ordinary ether, the same fluid previously saturated with quinidia, in which case all the quinidia must remain undissolved. It is necessary, in the last experiment, to observe, after the shaking, whether or not all has dissolved; for, owing to the great tendency of quinidia to crystallize, it may again separate, and thus become a source of error. If more than a tenth of quinidia, or if cinchonia be present in the salt, an insoluble precipitate will be seen between the layers of the two fluids. If it be quinidia, it will be dissolved on the addition of proportionately more ether; while, if cinchonia, it will remain unaffected. (*Pharm. Journ.*, xi. 394.)

Dr. J. E. De Vry uses the following method of ascertaining the alkaloid strength of cinchona, and of obtaining the several alkaloids separate. Having dried a portion of powdered bark at 212° F., and weighed it, mix with it one-fourth of slaked lime, and boil for five minutes with ten times its weight of alcohol of sp. gr. 0·85. Put the whole on a filter, and exhaust by adding successively portions of boiling alcohol, until the whole weight of the spirit used equals twenty times that of the bark. Acidulate the tincture with dilute acetic acid so that it shall redden litmus, and then evaporate on a water-bath till all the alcohol is expelled. Treat the residue separately with water till the filtered liquid is no longer made turbid by an alkali. The solution thus obtained contains all the alkaloids; the kinovic acid, resin, fat, and other impurities remaining on the filter. If the filter and its contents be treated with milk of lime, the quantity of kinovic acid can be determined. The watery solution is now to be reduced by evaporation on a water-bath to a small bulk, and then mixed with an excess of slaked lime, by which the alkaloids are precipitated. Now throw the whole on the smallest possible filter, and wash with the minimum of cold water. If proper care be taken, the amount of water necessary to remove the colouring matter is so small, that the loss of alkaloids through their slight solubility in lime-water may be disregarded. After the filter has been duly washed, and dried, boil it repeatedly with alcohol of 0·82, till this will dissolve nothing more; then filter, evaporate the slightly coloured alcoholic solution in a weighed platinum vessel, and heat the residue on a water-bath till it ceases to lose weight. The amount of alkaloids is now known. Sometimes a trace of colouring matter is left undissolved. If this is sufficient to be weighed, it must be deducted from the amount of the alkaloids; but generally the quantity is insufficient to merit notice.

To ascertain their character, dissolve in the smallest quantity of very dilute acetic acid. Put the solution in a closed funnel, provided with a cork, agitate with a slight excess of caustic soda, and a quantity of ether equal to fifteen times the weight of the alkaloids, and let the mixture stand for six hours; for though cinchonidia and quinidia are sparingly soluble in ether, a considerable amount is dissolved on the first agitation, which separates in crystals in a few hours. Now evaporate the ethereal solution, and dry the residue on a water-bath till the weight remains constant. The residue is quinia, with traces of cinchonidia, quinidia, and cinchonia; and in many cases a large amount of a still unknown fusible alkaloid. By the known reactions of chlorine and ammonia, and by the preparation of Herapathite, the real nature of this residue can be ascertained.

The alkaloids which have not been dissolved by the ether are now again to be dissolved in the smallest quantity of dilute acetic acid, and the solution mixed with a few drops of a concentrated solution of iodide of potassium. After stirring with a glass rod, a sandy crystalline precipitate will occur if quinidia is present. In such a case, the hydriodate of quinidia is collected on a filter, dried at 212°, and weighed, and the quantity of quinidia ascertained by calculation; 100 grains of the hydriodate being equivalent to 71·68 of quinidia, according to the formula $C_{40}H_{24}N_2O_4,HI$.

The liquid separated by filtration from the hydriodate is precipitated by caustic soda, and the precipitate will be either cinchonia, or a mixture of this with cinchonidia.

The presence of cinchonia or quinidia among the alkaloids may be conjectured at the time of the treatment with ether; for, if one of these is present, it is partially deposited in a crystalline state after some time.

While the presence of quinidia can easily be ascertained by iodide of potassium even in small quantities, that of cinchonidia can be determined with certainty only by the polarizing apparatus, by which Dr. De Vry has detected the cinchonidia of Pasteur even in the bark of the C. paludiana of Java. (*Pharm. Journ. and Trans.*, vi. 51, July, 1864.)—*Note to the thirteenth edition.*

* To obviate the disadvantages arising from the variable strength of bark, M. Guillermond recommends to fix on an appropriate strength, as indicated by the percentage of quinia, below the highest yet much above the lowest, and either to select bark of this

Medical Properties and Uses.

This valuable remedy was unknown to the civilized world till about the middle of the seventeenth century, though the natives of Peru are generally supposed to have been long previously acquainted with its febrifuge powers. Humboldt, however, is of a different opinion. In his Memoir on the Cinchona forests, he states that it is unknown as a remedy to the Indians inhabiting the country where it grows; and, as these people adhere pertinaciously to the habits of their ancestors, he concludes that it never was employed by them. They have generally the most violent prejudices against it, considering it poisonous, and in the treatment of fever prefer the milder indigenous remedies. Humboldt is disposed to ascribe the discovery of the febrifuge powers of the bark to the Jesuits, who were sent to Peru as missionaries. As bitters had been chiefly relied on in the treatment of intermittent fevers, and as bitterness was observed to be a predominant property in the bark of certain trees which were felled in clearing the forests, the missionaries were naturally led to give it a trial in the same complaint. They accordingly administered an infusion of the bark in the tertian ague, then prevalent in Peru, and soon ascertained its extraordinary powers A tradition to this effect is said by Humboldt to be current at Loxa. Ruiz and Pavon, however, ascribe the discovery to the Indians; and Tschudi states, in his Travels in Peru (*Am. ed.*, ii. 280), that the inhabitants of the Peruvian forests drink an infusion of the green bark as a remedy in intermittent fever.* The Countess of Cinchon, wife of the Viceroy of Peru, having in her own person experienced the beneficial effects of the bark, is said, on her return to Spain in the year 1640, to have first introduced the remedy into Europe. Hence the name of *pulvis Commitissæ*, by which it was first known. After its introduction, it was distributed and sold by the Jesuits, who are said to have obtained for it the price of its weight in silver. From this circumstance it was called *Jesuits' powder*, a title which it long retained. It had acquired some reputation in England so early as the year 1658, but, from its high price, and from the prejudice excited against it, was at first little used. At this early period, however, its origin and nature do not seem to have been generally known; for we are told that Sir John Talbot (Sir Robert Talbor, *Pereira*), an Englishman, having employed it with great success in France, in the treatment of intermittents, under the name of the English powder, at length, in the year 1679, sold the secret of its origin and preparation to Louis XIV., by whom it was divulged.

When taken into the stomach, bark usually excites in a short time a sense of warmth in the epigastrium, which often diffuses itself over the abdomen and even the breast, and is sometimes attended with considerable gastric and intestinal irritation. Nausea and vomiting are sometimes produced, especially if the stomach was previously in an inflamed or irritated state. Purging, moreover, is not an unfrequent attendant upon its action. After some time has elapsed, the circulation often experiences its influence, as exhibited in the somewhat increased frequency of pulse; and, if the dose be repeated, the whole system becomes more or less affected, and all the functions undergo a moderate degree of excitement. Its action upon the nervous system is often evinced by a sense of tension, or fulness, or slight pain in the head, singing in the ears, and partial deafness, which are always experienced by many individuals when brought completely under its influence. The effects above mentioned entitle bark to a place among the tonics, and it is usually ranked at the very head of this class of medicines. But, besides

strength, or to bring that employed to the medium strength, by adding a stronger or weaker bark, as the case may require, in due proportion. He recommends as this standard the yield of 3·2 per cent. of sulphate of quinia. This is to be treated by alcohol till entirely exhausted, and the tincture evaporated so as to yield an extract which shall exactly represent the virtues of the bark, and shall always have the same strength. From this extract all the preparations of bark are to be made, which will thus always be uniform in strength. (*Journ. de Pharm.*, Août, 1863, p. 124.)

* Tschudi also observes that he has found the fresh bark more efficacious than the dried; as, in less than half the usual dose, it not only effects cures in a short time, but ensures the patient against the return of the disease.

the mere excitation of the ordinary functions of health, it produces other effects upon the system, which must be considered peculiar, and independent of its mere tonic operation. The power by which, when administered in the intervals between the paroxysms of intermittent disorders, it interrupts the progress of the disease, is something more than what is usually understood by the tonic property; for no other substance belonging to the class, however powerful or permanent may be the excitement which it produces, exercises a control over intermittents at all comparable to that of the medicine under consideration. As it is probable that, in the intervals of these complaints, a train of morbid actions is going on out of our sight, within the recesses of the nervous system; so it is also probable that bark produces, in the same system, an action equally mysterious, which supersedes that of the malady, and thus accomplishes the restoration of the patient. When taken very largely, especially in the form of its active principles, in which its effects on the system can be obtained with less of the direct irritant influence on the stomach, cinchona has been found, while it produces the effects already adverted to upon the brain, at the same time to lessen considerably the force and frequency of the pulse. This sedative effect is probably secondary, and dependent on an influence upon the nervous centres in the encephalon, interfering with the due performance of their functions, and consequently of the in some degree dependent function of the heart. From the possession of tonic, *anti-intermittent*, and indirect sedative properties, bark is capable of being usefully employed in the treatment of numerous diseases.

It may usually be employed with benefit in all morbid conditions of the system, whatever may be the peculiar modifications, in which a permanent corroborant effect is desirable, provided the stomach be in a proper state for its reception. In low or typhoid forms of disease, in which either no inflammation exists, or that which does exist has been moderated by proper measures, or has passed into the suppurative or the gangrenous stage, this remedy is often of the greatest advantage in supporting the system till the morbid action ceases. Hence its use in the latter stages of typhus gravior; in malignant scarlatina, measles, and smallpox; in carbuncle and gangrenous erysipelas; and in all cases in which the system is exhausted under large purulent discharges, and the tendency of the affection is towards recovery. As a tonic, bark is also advantageously employed in chronic diseases connected with debility; as, for example, in scrofula, dropsy, passive hemorrhages, certain forms of dyspepsia, obstinate cutaneous affections, amenorrhœa, chorea, hysteria; in fact, whenever a corroborant influence is desired, and no contraindicating symptoms exist. But in all these cases it greatly behooves the physician to examine well the condition of the system, and, before resorting to the tonic, to ascertain the real existence of an enfeebled condition of the functions, and the absence of such local irritations or inflammations, especially of the stomach or bowels, as might be aggravated by its use. In doubtful cases, we have been in the habit of considering the occurrence of profuse sweating during sleep as an indication for its use, and, under these circumstances, have prescribed it very advantageously, in the form of sulphate of quinia, in acute rheumatism, and in the advanced stages of protracted fevers.

But it is in the cure of intermittent diseases that bark displays its most extraordinary powers. It was originally introduced into notice as a remedy in fever and ague, and the reputation which it acquired at an early period it has ever since retained. Very few cases of this disease will be found to resist the judicious use of bark, or some one of its preparations. This is not the place to speak of the precise circumstances under which it is best administered. It will be sufficient to say that physicians generally concur in recommending its early employment, in divided doses, to the extent of one or two ounces, during the intermission, and the repetition of this plan till the disease is subdued, or the remedy is found insufficient for its cure. Other intermittent diseases have been found to yield with almost equal certainty to the remedy, particularly those of a neuralgic character. Hemicrania and violent pains in the eyes, face, and other parts of the body, occurring periodically, are often almost immediately

relieved by the use of bark. Some cases of epilepsy, in which the convulsions recurred at regular intervals, have also been cured by it; and even the hectic intermittent is frequently arrested, though, as the cause still generally continues to operate, the relief is too often only temporary. Diarrhœa and dysentery sometimes put on the intermittent form, especially in miasmatic districts; and under these circumstances may often be cured by bark. Nor is it necessary that, in the various diseases which have been mentioned, the intermission should always be complete, in order to justify a resort to the remedy. Remittent fevers, in which the remission is very decided, not unfrequently yield to the use of bark, if preceded by proper depleting measures. But, as a general rule, the less of the diseased action there is in the interval, the better is the chance of success.

In reference to its indirect sedative effects, bark or its alkaloids have been of late considerably used, in large doses, in various febrile and inflammatory affections, as in the early stage of remittent and yellow fevers, typhoid and typhus fevers, and acute rheumatism; but, in this use of the medicine, caution is required lest, in suppressing the general arterial excitement, injurious congestion or inflammation of the brain may be induced. In the form of sulphate of quinia, it has of late been recommended, in large doses, in puerperal fever.

Some observations are requisite as to the choice of the bark, and the forms of administration. In the treatment of intermittents, either the best red or the yellow (Calisaya) bark is decidedly preferable to the pale. The pale bark may, in its finest forms, be superior for the purposes of a general tonic; as it is less liable to offend the stomach, and perhaps to irritate the bowels.

Where the object is to obtain the full influence of the bark, it may in some instances be advisable to administer it in substance. We are not absolutely certain that the alkaloids are the only active ingredients; and, even supposing them to be so, we are equally uncertain whether they may not be somewhat modified in their properties, even by the therapeutically inert principles with which they are associated. In fact, bark in substance has been repeatedly known to cure intermittents when sulphate of quinia has failed. It is best administered diffused in water or some aromatic infusion. Experience has proved that its efficacy in intermittents is often greatly promoted by admixture with other substances. A mixture of powdered bark, Virginia snakeroot, and carbonate of soda was at one time highly esteemed in this city; and another, consisting of bark, confection of opium, lemon-juice, and port wine, has proved highly efficacious in obstinate cases of fever and ague.*

But, notwithstanding the supposed superior efficacy of the bark in substance, in the same relative dose, it is in the great majority of instances sufficient to resort to some one of its preparations; and in many cases we are compelled to this resort by the inability of the stomach to support the powder, or the unwillingness of the patient to encounter its disagreeable taste. The best substitutes, in intermittent diseases, are the sulphates of its alkaloids. Sulphate of quinia has until recently been used almost to the exclusion of the others; but sulphate of cinchonia is now considerably employed, and with nearly equal effect; and there is every reason to believe that the sulphates of quinidia and cinchonidia will be found not less efficient. In fact any one, or any combination of the cinchona alkaloids, may be used with propriety for obtaining the therapeutic effects of bark. The advantage of these preparations is their facility of administration, and the possibility, by their employment, of introducing a large quantity of the active matter, with less risk of offending the stomach. (See *Quiniæ Sulphas.*)

Though the alkaloids possess the anti-intermittent power of bark, they have not been certainly ascertained to exert all the peculiar influence of that medicine as a tonic; but, as bark in powder can seldom be supported, by a delicate

* The following are the formulas for these mixtures.—1. ℞. Cinchon. Pulv. ℥ss; Serpentariæ pulv. ʒj; Sodæ Carbonat. ʒss. Misce et in pulveres quatuor divide, una tertiâ vel quartâ quâque horâ sumenda. 2. ℞. Cinchon. Rub. Pulv. ℥ss; Confect. Opii ʒj; Suc. Limon. recentis fʒij; Vin. Rub. f℥iv. Misce. Tertia pars tertiâ quâque horâ sumenda.

stomach, for a sufficient period to ensure the necessary influence of the medicine in chronic disease, it is customary to resort, in this case, to some one of its preparations in which the alkaloids are extracted in connection with the other principles; as the infusion, decoction, tincture, extract, and fluid extract. Each of these will be particularly treated of among the Preparations. It is here only necessary to say that their use is mostly confined to chronic cases, or those of a malignant character, as typhus gravior, &c., in which the whole virtues of the bark are desired, but the stomach is unable to bear the powder. Should bark or its preparations produce purging, as they occasionally do, they ought to be combined with a small portion of laudanum.

It is sometimes desirable to introduce bark into the system by other avenues than the stomach; as it exercises its peculiar influence to whatever part it is applied. Injected into the rectum, in connection with opium to prevent purging, it has been employed successfully in the cure of intermittents; and the use of bark jackets, made by quilting the powder between two pieces of flannel or muslin, and worn next the skin, and of bark baths made by infusing the medicine in water, has proved serviceable in cases of children. But the best preparation of bark for injection, or external use, is sulphate of quinia, which, thrown with a little laudanum into the rectum, or applied to a blistered surface denuded of the cuticle, produces on the system effects scarcely less decided than those which result from it when swallowed.

The medium dose of bark, as administered in intermittents, is a drachm, to be repeated more or less frequently according to circumstances. When given as a tonic in chronic complaints, the dose is usually smaller; from ten to thirty grains being sufficient to commence with.

CINNAMOMUM. *U. S.*

Cinnamon.

The bark of Cinnamomum Zeylanicum and of Cinnamomum aromaticum. *U. S.*

Off. Syn. CINNAMOMI CORTEX. *Cinnamon Bark.* The inner bark of shoots from the truncated stocks of Cinnamomum Zeylanicum. *Br.*

Cinnamon.—Canelle, *Fr.;* Brauner Canel, Zimmt, *Germ.;* Canella, *Ital.;* Canela, *Span.;* Kurundu, *Cingalese;* Karua puttay, *Tamul.*

Cassia.—Cassia lignea; Casse, *Fr.;* Cassienzimmt, *Germ.;* Cannellina, *Ital.;* Casia, *Span.*

The U. S. Pharmacopœia embraces, under the title of cinnamon, not only the bark of that name obtained from the island of Ceylon, which is the only variety recognised in the new British Pharmacopœia, but also the commercial cassia, which is imported from China; and, as the two products, though very different in price, and somewhat in flavour, possess identical medical properties, and are used for the same purposes, there seems to be no necessity for giving them distinct officinal designations. Indeed, the barks of all the species of the genus Cinnamomum, possessing analogous properties, are as much entitled to the common name of cinnamon, as the barks of the Cinchonas are to the name of cinchona, and the juice of different species of Aloe to that of aloes. Varieties may be sufficiently distinguished by an appropriate epithet. Both *cinnamomum* and *cassia* were terms employed by the ancients, but whether exactly as now understood, it is impossible to determine. The term *cassia*, or *cassia lignea*, has been generally used in modern times to designate the coarser barks analogous to cinnamon It was probably first applied to the barks from Malabar, and afterwards

extended to those of China and other parts of Eastern Asia. It has been customary to ascribe *cassia lignea* to the *Laurus Cassia* of Linnæus; but the specific character given by that botanist was so indefinite, and based on such imperfect information, that the species has been almost unanimously abandoned by botanists. The fact appears to be, that the barks sold as cinnamon and cassia in different parts of the world are derived from various species of Cinnamomum. Dr. Wight, who was commissioned by the British Indian Government to inquire into the botanical source of "the common cassia bark of the markets of the world," expresses his belief, that the list of plants yielding this product extends to nearly every species of the genus, including not less than six plants on the Malabar Coast and in Ceylon, and nearly twice as many more in the eastern part of Asia, and in the islands of the Eastern Archipelago. (*Madras Journ. of Literat. and Sci.*, 1839, no. 22.) We shall describe only the two species recognised in the U. S. Pharmacopœia.

Cinnamomum. *Sex. Syst.* Enneandria Monogynia. — *Nat. Ord.* Lauraceæ.

Gen. Ch. Flowers hermaphrodite or polygamous, panicled or fascicled, naked. *Calyx* six-cleft, with the limb deciduous. *Fertile stamens* nine, in three rows; the inner three with two sessile glands at the base; *anthers* four-celled, the three inner turned outwards. Three capitate *abortive stamens* next the centre. *Fruit* seated in a cup-like calyx. *Leaves* ribbed. *Leaf-buds* not scaly. *Lindley.*

1. *Cinnamomum Zeylanicum.* Nees, *Laurineæ*, 52; Lindley, *Flor. Med.* 329; Hayne, *Darstel. und Beschreib. &c.* xii. 263. — *Laurus Cinnamomum.* Linn. This is a tree about twenty or thirty feet high, with a trunk from twelve to eighteen inches in diameter, and covered with a thick, scabrous bark. The branches are numerous, strong, horizontal, and declining; and the young shoots are beautifully speckled with dark green and light orange colours. The leaves are opposite for the most part, coriaceous, entire, ovate, or ovate-oblong, obtusely pointed, and three-nerved, with the lateral nerves vanishing as they approach the point. There are also two less obvious nerves, one on each side, arising from the base, proceeding towards the border of the leaf, and then quickly vanishing. The footstalks are short and slightly channeled, and, together with the extreme twigs, are smooth and without the least appearance of down. In one variety, the leaves are very broad and somewhat cordate. When mature, they are of a shining green upon their upper surface, and lighter coloured beneath. The flowers are small, white, and arranged in axillary and terminal panicles. The fruit is an oval berry, which adheres like the acorn to the receptacle, is larger than the black currant, and when ripe has a bluish-brown surface, diversified with numerous white spots.

The tree emits no smell perceptible at any distance. The bark of the root has the odour of cinnamon with the pungency of camphor, and yields this principle upon distillation. The leaves have a spicy odour when rubbed, and a hot taste. A volatile oil distilled from them has been introduced into commerce.* The petiole has the flavour of cinnamon. It is a singular fact, that the odour of the flowers is to people in general disagreeable, being compared by some to the scent exhaled from newly sawn bones. The fruit has a terebinthinate odour when opened, and a taste in some degree like that of Juniper berries. A fatty substance, called *cinnamon-suet*, is obtained from it when ripe, by bruising and then boiling it in water, and removing the oleaginous matter which rises to the surface, and concretes upon cooling. It is the prepared bark that constitutes the genuine cinnamon.

This species is a native of Ceylon, where it has long been cultivated. It is said also to be a native of the Malabar Coast, and has at various periods been

* The *cinnamon leaf oil*, as imported into Great Britain, is of two kinds, one containing a considerable quantity of a fatty fixed oil, perhaps cinnamon suet from the fruit, the other a pure volatile oil. The oil is said to be obtained by distilling the leaves after maceration in sea-water. It resembles the oil of cloves and pimento in sensible properties, having a brownish colour, a penetrating, fragrant odour, and a very pungent taste. According to Stenhouse, it is of the sp. gr. 1·053, has an acid reaction, and consists essentially of eugenic acid and a neuter substance with the formula $C_{20}H_{16}$, but contains also a minute proportion of benzoic acid. (*Pharm. Journ.*, xiv. 319.)—*Note to the twelfth edition.*

introduced into Java, the Isle of France, Bourbon, the Cape de Verds, Brazil, Cayenne, several of the West India islands, and Egypt; and in some of these places is at this time highly productive, especially in Cayenne, where the plant was flourishing so early as 1755. It is exceedingly influenced, as regards the aromatic character of its bark, by the circumstances of soil, climate, and mode of culture. Thus we are told by Marshall that in Ceylon, beyond the limits of Negombo and Matura, in the western and southern aspect of the island, the bark is never of good quality, being greatly deficient in the aromatic flavour of the cinnamon; and that even within these limits it is of unequal value, from the various influence of exposure, soil, shade, and other circumstances.

2. *C. aromaticum*. Nees, *Laurineæ*, 52; Lindley, *Flor. Med.* 330. — *C. Cassia*. Blume, Ed. Ph.; Hayne, *Darstel. und Beschreib. &c.* xii. 23.— *Laurus Cassia*. Aiton, *Hort. Kew.* ii. 427. — Not *Laurus Cassia* of Linn. This is of about the same magnitude as the former species, and like it has nearly opposite, shortly petiolate, coriaceous, entire leaves, of a shining green upon the upper surface, lighter-coloured beneath, and furnished with three nerves of which the two lateral vanish towards the point. The leaves, however, differ in being oblong-lanceolate and pointed, and in exhibiting, under the microscope, a very fine down upon the under surface. The footstalks and extreme twigs are also downy. The flowers are in narrow, silky panicles. The plant grows in China, Sumatra, and other parts of Eastern Asia, and is said to be cultivated in Java. It is believed to be the species which furnishes, wholly or in part, the Chinese cinnamon or cassia brought from Canton, and is supposed to be the source of the *cassia buds*.

Besides the two species above described, others have been thought to contribute to the cinnamon and cassia of commerce. The opinion of Dr. Wight has been already stated. *C. Loureirii* of Nees, growing in the mountains of Cochin-China near Laos, and in Japan, affords, according to Loureiro, a cinnamon of which the finest kind is superior to that of Ceylon. *C. nitidum*, growing in Ceylon, Java, and on the continent of India, is said to have been the chief source of the drug known formerly by the name of *Folia Malabathri*, and consisting of the leaves of different species of Cinnamomum mixed together. The leaves of *C. Tamala* of Hindostan have been sold under the same name. *C. Culilawan* of the Moluccas yields the aromatic bark called culilawan, noticed in the *third part* of this work; and similar barks are obtained from another species of the same region, named *C. rubrum*, and from *C. Sintoc* of Java. *Massoy-bark*, from which an aromatic volatile oil is obtained called *oil of massoy*, is the product of *C. Kiamis*. (Gmelin, *Hand-book*, xiv. 380.)

Culture, Collection, Commerce, &c. Our remarks under this head will first be directed to the cinnamon of Ceylon, in relation to which we have more precise information than concerning the aromatic obtained from other sources. The bark was originally collected exclusively from the tree in a wild state; but the Dutch introduced the practice of cultivating it, which has been continued since the British came into possession of the island. The principal cinnamon gardens are in the vicinity of Columbo. The seeds are planted in a prepared soil at certain distances; and, as four or five are placed in a spot, the plants usually grow in clusters like the hazel bush. In favourable situations they attain the height of five or six feet in six or seven years; and a healthy bush will then afford two or three shoots fit for peeling, and every second year afterwards from four to seven shoots in a good soil. The cinnamon harvest commences in May, and continues till late in October. The first object is to select shoots proper for decortication, and those are seldom cut which are less than half an inch, or more than two or three inches in diameter. The bark is divided by longitudinal incisions, of which two are made in the smaller shoots, several in the larger, and is then removed in strips by means of a suitable instrument. The pieces are next collected in bundles, and allowed to remain in this state for a short time, so as to undergo a degree of fermentation, which facilitates the separation of the epidermis. This, with the green matter beneath it, is removed by placing the strip of bark upon a convex piece of wood, and

scraping its external surface with a curved knife. The bark now dries and contracts, assuming the appearance of a quill. The peeler introduces the smaller tubes into the larger, and connects them also endwise, thus forming a congeries of quills which is about forty inches long. When sufficiently dry, these cylinders are collected into bundles weighing about thirty pounds, and bound together by pieces of split bamboo. The commerce in Ceylon cinnamon was formerly monopolized by the East India Company; but the cultivation is now unrestricted, and the bark may be freely exported upon the payment of a fixed duty. It is assorted in the island into three qualities, distinguished by the designations of *first*, *second*, and *third*. The inferior kinds, which are of insufficient value to pay the duty, are used for the preparation of oil of cinnamon.

Immense quantities of cinnamon are exported from China, the finest of which is little inferior to that of Ceylon, though the mass of it is much coarser. It passes in commerce under the name of *cassia*, and is said by Mr. Reeves to be brought to Canton from the province of Kwangse, where the tree producing it grows very abundantly. (*Trans. Medico-bot. Soc.*, 1828, p. 26.) It has already been stated that this tree is supposed to be the *Cinnamomum aromaticum;* but we have no positive proof of the fact. Travellers inform us that cinnamon is also collected in Cochin-China; but that the best of it is monopolized by the sovereign of the country. It is supposed to be obtained from the *Cinnamomum Loureirii* of Nees, the *Laurus Cinnamomum* of Loureiro. According to Siebold, the bark of the large branches is of inferior quality and is rejected; that from the smallest branches resembles the Ceylon cinnamon in thickness, but has a very pungent taste and smell, and is little esteemed; while the intermediate branches yield an excellent bark, about a line in thickness, which is even more highly valued than the cinnamon of Ceylon, and yields a sweeter and less pungent oil. (*Annal. der Pharm.*, xx. 280.) Cinnamon of good quality is said to be collected in Java, and considerable quantities of inferior quality have been thrown into commerce, as *cassia lignea*, from the Malabar Coast. Manilla and the Isle of France are also mentioned as sources whence this drug is supplied. Little, however, reaches the United States from these places.

Cayenne, and several of the West India islands, yield to commerce considerable quantities of cinnamon of various qualities. That of Cayenne is of two kinds, one of which closely resembles, though it does not quite equal, the aromatic of Ceylon, the other resembles the Chinese. The former is supposed to be derived from plants propagated from a Ceylonese stock, the latter from those which have sprung from a tree introduced from Sumatra.*

By far the greater proportion of cinnamon brought to this country is imported from China. It is entered as *cassia* at the custom house, while the same article brought from other sources is almost uniformly entered as cinnamon. Much of it is afterwards exported.

From what source the ancients derived their cinnamon and cassia is not certainly known. Neither the plants nor their localities, as described by Dioscorides, Pliny, and Theophrastus, correspond precisely with our present knowledge; but in this respect much allowance must be made for the inaccurate geography of the ancients. It is not improbable that the Arabian navigators, at a very early period, conveyed this spice within the limits of Phœnician and Grecian, and subsequently of Roman commerce.

* While on a visit, Nov. 1860, to the *Palais d'Industrie*, in Paris, where is kept a noble collection of industrial and natural products from the various French colonies, we noticed specimens of the Ceylon cinnamon (C. Zeylanicum), from the W. India island of Martinique. It was apparently of fine quality, consisting of pieces, singly and doubly quilled, and bearing a close resemblance to the product of Ceylon, except that the quills were single, and not, like the Ceylonese, introduced one into the other, forming a sort of compact cylinder. There were, besides, large flat pieces of the bark from the same source, bearing, in their general aspect, some resemblance to the flat Calisaya bark. These were, no doubt, from the trunk or larger branches. How far they possessed the aromatic properties of the true cinnamon could not be determined; for they were enclosed in cases in such a manner that, though they could be seen, they could not be submitted to the test of taste and smell. (*Note to the twelfth edition.*)

Properties. *Ceylon cinnamon* is in long cylindrical fasciculi, composed of numerous quills, the larger enclosing the smaller. In the original sticks, which are somewhat more than three feet in length, two or three fasciculi are neatly joined at the end, so as to appear as if the whole were one continuous piece. The finest is of a light brownish-yellow colour, almost as thin as paper, smooth, often somewhat shining, pliable to a considerable extent, with a splintery fracture when broken. It has a pleasant fragrant odour, and a warm, aromatic, pungent, sweetish, slightly astringent, and highly agreeable taste. When distilled it affords but a small quantity of essential oil, which, however, has an exceedingly grateful flavour. It is brought to this country from England; but is very costly, and is not generally kept in the shops. The inferior sorts are browner, thicker, less splintery, and of a less agreeable flavour, and are little if at all superior to the best Chinese. The finer variety of *Cayenne cinnamon* approaches in character to that above described, but is paler and in thicker pieces, being usually collected from older branches. That which is gathered very young is scarcely distinguishable from the cinnamon of Ceylon.

Chinese cinnamon, or *cassia*, is in tubes from the eighth of an inch to an inch in diameter, usually single, sometimes double, but very rarely more than double. In some instances the bark is rolled very much upon itself, in others is not even completely quilled, forming segments more or less extensive of a hollow cylinder. It is of a redder or darker colour than the finest Ceylon cinnamon, thicker, rougher, denser, and breaks with a shorter fracture. It has a stronger, more pungent and astringent, but less sweet and grateful taste; and, though of a similar odour, is less agreeably fragrant. It is the kind almost universally kept in our shops. Of a similar character is the cinnamon imported directly from various parts of the East Indies. But under the name of cassia have also been brought to us very inferior kinds of cinnamon, collected from the trunks or large branches of the trees, or injured by want of care in keeping, or perhaps derived from inferior species. It is said that cinnamon from which the oil has been distilled, is sometimes fraudulently mixed with the genuine. These inferior kinds are detected, independently of their greater thickness, and coarseness of fracture, by their deficiency in the peculiar sensible properties of the spice.

According to the analysis of Vauquelin, cinnamon contains a peculiar volatile oil, tannin, mucilage, a colouring matter, an acid, and lignin. The tannin is of the variety which yields a greenish-black precipitate with the salts of iron. The oil obtained from the Cayenne cinnamon, he found to be more biting than that from the Ceylonese, and at the same time to be somewhat peppery. Bucholz found in 100 parts of *cassia lignea*, 0·8 of volatile oil, 4·0 of resin, 14·6 of gummy extractive (probably including tannin), 64·3 of lignin and bassorin, and 16·3 of water including loss. This aromatic yields its virtues wholly to alcohol, and less readily to water. At the temperature of boiling alcohol very little of the oil rises, and an extract prepared from the tincture retains, therefore, the aromatic properties. For an account of the volatile oil, see *Oleum Cinnamomi.*

Medical Properties and Uses. Cinnamon is among the most grateful and efficient of the aromatics. It is warm and cordial to the stomach, carminative, astringent, and, like most other substances of this class, more powerful as a local than general stimulant. It is seldom prescribed alone, though, when given in powder or infusion, it will sometimes allay nausea, check vomiting, and relieve flatulence. It is chiefly used as an adjuvant to other less pleasant medicines, and enters into a great number of officinal preparations. It is often employed in diarrhœa, in connection with chalk and astringents; and has recently been recommended as peculiarly efficacious in uterine hemorrhage. The dose of the powder is from ten grains to a scruple.

Cassia Buds. This spice consists of the calyx of one or more species of Cinnamomum, surrounding the young germ, and, as stated by Dr. Martius, on the authority of the elder Nees, about one-quarter of the normal size. It is produced in China; and Mr. Reeves states that great quantities of it are brought to Canton from the province which affords cassia. The species which yields it

is in all probability the same with that which yields the bark, though it has been ascribed by Nees to *Cinnamomum Loureirii*. In favour of the former opinion is the statement of Dr. Christison, that *C. aromaticum*, cultivated in the hot-houses of Europe, bears a flower-bud which closely resembles the cassia bud when at the same period of advancement. Cassia buds have some resemblance to cloves, and are compared to small nails with round heads. The enclosed germen is sometimes removed, and they are then cup-shaped at top. They have a brown colour, with the flavour of cinnamon, and yield an essential oil upon distillation. They may be used for the same purposes as the bark.

COCCUS. *U. S., Br.*

Cochineal.

Coccus Cacti. *U. S.* The dried female insect, Coccus Cacti. *Br.*
Cochenille, *Fr., Germ.;* Cocciniglia, *Ital.;* Cochinilla, *Span.*

The coccus is a genus of hemipterous insects, having the snout or rostrum in the breast, the antennæ filiform, and the posterior part of the abdomen furnished with bristles. The male has two erect wings, the female is wingless. The *C. Cacti* is characterized by its depressed, downy, transversely wrinkled body, its purplish abdomen, its short and black legs, and its subulate antennæ, which are about one-third of the length of the body. (*Rees's Cyclopædia.*) Another species, *C. Ilicis*, which inhabits a species of oak, is collected in the mountainous parts of the Morea, in Greece, and used as a dye-stuff in the East. (*Landerer.*) The Coccus Cacti is found wild in Mexico and Central America, inhabiting different species of Cactus and allied genera of plants; and is said to have been discovered also in some of the West India islands, and the southern parts of the United States. In Mexico, particularly in the provinces of Oaxaca and Guaxaca, it is an important object of culture. The Indians form plantations of the *nopal* (*Opuntia cochinillifera*), upon which the insect feeds and propagates. During the rainy season, a number of the females are preserved under cover upon the branches of the plant, and, after the cessation of the rains, are distributed upon the plants without. They perish quickly after having deposited their eggs. These, hatched by the heat of the sun, give origin to innumerable minute insects, which spread themselves over the plant. The males, of which, according to Mr. Ellis, the proportion is not greater than one to one hundred or two hundred females, being provided with wings and very active, approach and fecundate the latter. After this period, the females, which before moved about, attach themselves to the leaves, and increase rapidly in size; so that, in the end, their legs, antennæ, and proboscis are scarcely discoverable, and they appear more like excrescences on the plant than distinct animated beings. They are now gathered for use, by detaching them by means of a blunt knife, a quill, or a feather; a few being left to continue the race. They are destroyed either by dipping them enclosed in a bag into boiling water, or by the heat of a stove. In the former case they are subsequently dried in the sun. The males, which are much smaller than the full-grown females, are not collected. It is said that of the wild insect there are six generations every year, furnishing an equal number of crops; but the domestic is collected only three times annually, the propagation being suspended during the rainy season, in consequence of its inability to support the inclemency of the weather. The insect has been taken from Mexico to the Canary Islands; and very large quantities of cochineal have been delivered to commerce from the

Island of Teneriffe.* The culture has also been successfully introduced into Java; and attempts have been made to introduce it into Spain, Corsica, and Algiers.†

As kept in the shops, the finer cochineal, *grana fina* of Spanish commerce, is in irregularly circular or oval, somewhat angular grains, about one-eighth of an inch in diameter, convex on one side, concave or flat on the other, and marked with several transverse wrinkles. Two varieties of this kind of cochineal are known to the druggist, distinguished by their external appearance. One is of a reddish-gray colour, formed by an intermixture of the dark colour of the insect with the whiteness of a powder by which it is almost covered, and with patches of a rosy tinge irregularly interspersed. From its diversified appearance, it is called by the Spaniards *cochinilla jaspeada*. It is the variety commonly kept in our shops. The other, *cochinilla renegrida*, or *grana nigra*, is dark-coloured, almost black, with only a minute quantity of the whitish powder between the wrinkles. The two are distinguished in our markets by the names of *silver grains* and *black grains*. Some suppose the difference to arise from the mode of preparation; the gray cochineal consisting of the insects destroyed by a dry heat; the black, of those destroyed by hot water, which removes the external whitish powder. According to Mr. Faber, who derived his information from a merchant residing in the neighbourhood where the cochineal is collected, the silver grains consist of the impregnated female just before she has laid her eggs; the black, of the female after the eggs have been laid and hatched. (*Am. Journ. of Pharm.*, xviii. 47.) There is little or no difference in their quality.‡ Another and much inferior variety is the *grana sylvestra*, or wild cochineal, consisting partly of very small separate insects, partly of roundish or oval masses, which exhibit, under the microscope, minute and apparently new born insects, enclosed in a white or reddish cotton-like substance. It is scarcely known in our drug market.

Cochineal has a faint heavy odour, and a bitter slightly acidulous taste. Its powder is of a purplish-carmine colour, tinging the saliva intensely red. According to Pelletier and Caventou, it consists of a peculiar colouring principle, a peculiar animal matter constituting the skeleton of the insect, stearin, olein, an odorous fatty acid, and various salts. Tyrosin, a crystallizable animal principle, has been found by De la Rue. (*Gmelin*, xiii. 358.) It was also analyzed by John, who called the colouring principle *cochinilin*. This is of a brilliant purple-red colour, unalterable in dry air, fusible at 122° F., very soluble in water, soluble in cold, and more so in boiling alcohol, insoluble in ether, and without nitrogen. It is obtained by macerating cochineal in ether, and treating the residue with successive portions of boiling alcohol, which on cooling deposits a part of the cochinilin, and yields the remainder by spontaneous evaporation. It may be freed from a small proportion of adhering fatty matter, by dissolving it in alcohol of 40° Baumé, and then adding an equal quantity of sulphuric

* Various species of Opuntia are adapted to the support of the cochineal insect, especially those which are very juicy, with few thorns and a thick skin. It is the *O. Ficus Indica* which is chiefly cultivated in Teneriffe, the dry but hot climate of which is peculiarly adapted to the growth both of the plant and the insect. In the year 1856, the product of the Canaries is stated to have amounted to more than one and a half millions of pounds, having increased to that amount from eight pounds in 1831. (*Neues Repertorium für Pharm.*, viii. 195.)—*Note to the twelfth edition.*

† At the Palais d'Industrie, in Paris, in Nov. 1860, the author noticed considerable quantities of apparently good cochineal, said to be the product of Algiers. In Spain, the cultivation seems to have proved unprofitable. The author observed a small field near Malaga, in 1861, still appropriated to the culture; but was informed that it was now neglected. In Asia Minor, in the vicinity of *Oushak*, are great quantities of an insect, closely resembling the Coccus Cacti, which feed on a species of cistus; but it is unknown whether any portion has been introduced into general commerce. (*Am. Journ. of Pharm.*, xxxv. 455.)—*Note to the twelfth edition.*

‡ *Cake cochineal* is the name given to a variety of this drug, produced in the Argentine Republic, in South America, a specimen of which was sent by Mr. Black from Cordova, in that country, to London, and was examined by Dr. Stark. It was in flat cakes about a quarter of an inch thick, and, under the microscope, was seen to consist chiefly of the cochineal insect, mixed with small portions of the thorns and epidermis of the cactus, in consequence of careless gathering. It is inferior for dyeing purposes to the ordinary variety. (*Pharm. Journ.*, xiv. 346.)

ether. The pure cochinilin is deposited in the course of a few days. The watery infusion of cochineal is of a violet-crimson colour, which is brightened by the acids, and deepened by the alkalies. The colouring matter is readily precipitated. The salts of zinc, bismuth, and nickel produce a lilac precipitate, and those of iron a dark-purple approaching to black. The salts of tin, especially the nitrate and chloride, precipitate the colouring matter of a brilliant scarlet, and form the basis of those splendid scarlet and crimson dyes, which have rendered cochineal so valuable in the arts. With alumina the colouring matter forms the pigment called *lake*. The finest *lakes* are obtained by mixing the decoction of cochineal with freshly prepared gelatinous alumina. The pigment called *carmine* is the colouring matter of cochineal precipitated from the decoction by acids, the salts of tin, &c., or by animal gelatin, and when properly made is of the most intense and brilliant scarlet. The colouring principle has been named *carminic acid*, in consequence of its possession of acid properties.

Cochineal has been adulterated by causing certain heavy substances, such as powdered talc and carbonate of lead, by shaking in a bag or otherwise, to adhere to the surface of the insects, and thus increase their weight. The fraud may be detected by the absence, under the microscope, of a woolly appearance, which characterizes the white powder upon the surface of the unadulterated insect. Metallic lead, which is said frequently to exist in fine particles in the artificial coating, may be discovered by powdering the cochineal, and suspending it in water, when the metal will remain behind. Grains of a substance artificially prepared to imitate the dried insect have been mixed with the genuine in France. A close inspection will serve to detect the difference. (*Journ. de Pharm.*, 3e sér., ix. 110.) Vermilion and chromic-red (dichromate of lead) are said also to have been largely used in the adulteration of carmine, to the extent sometimes of 60 or even 70 per cent. (*Pharm. Journ.*, May, 1860, p. 547.) There can be no difficulty in detecting them by the appropriate tests. Starch has been used, according to Prof. Maisch, for the same purpose in the U. States, and in one specimen he found 57·14 per cent. (*Am. Journ. of Pharm.*, xxxiii. 18.)

Medical Properties, &c. Cochineal is supposed by some to possess anodyne properties, and has been highly recommended in hooping-cough and neuralgic affections. It is frequently associated, in prescription, with carbonate of potassa, especially in the treatment of hooping-cough. In pharmacy it is employed to colour tinctures and ointments. To infants with hooping-cough, cochineal in substance is given in the dose of about one-third of a grain three times a day. The dose of a tincture, prepared by macerating one part of the medicine in eight parts of diluted alcohol, is for an adult from twenty to thirty drops twice a day. In neuralgic paroxysms, Sauter gave half a tablespoonful, with the asserted effect of curing the disease.

Colchicum autumnale. Willd. *Sp. Plant.* ii. 272; Woodv. *Med. Bot.* p. 759, t. 258. This species of Colchicum, often called *meadow-saffron*, is a perennial bulbous plant, the leaves of which appear in spring, and the flowers in autumn. Its manner of growth is peculiar, and deserves notice as connected in some measure with its medicinal efficacy. In the latter part of summer, a new bulb, or *cormus* as the part is now called, begins to form at the lateral inferior portion of the old one, which receives the young offshoot in its bosom, and embraces it half round. The new plant sends out fibres from its base, and is furnished with a radical spathe, which is cylindrical, tubular, cloven at top on one side, and half under ground. In September, from two to six flowers, of a lilac or pale-purple colour, emerge from the spathe, unaccompanied with leaves. The corolla consists of a tube five inches long, concealed for two-thirds of its length in the ground, and of a limb divided into six segments. The flowers perish by the end of October, and the rudiments of the fruit remain under ground till the following spring, when they rise upon a stem above the surface, in the form of a three-lobed, three-celled capsule. The leaves of the new plant appear at the same time; so that in fact they follow the flower instead of preceding it, as might be inferred from the order of the seasons in which they respectively show themselves. The leaves are radical, spear-shaped, erect, numerous, about five inches long, and one inch broad at the base. In the mean time, the new bulb has been increasing at the expense of the old one, which, having performed its appointed office, perishes; while the former, after attaining its full growth, sends forth shoots, and in its turn decays. The old bulb, in its second spring, and a little before it perishes, sometimes puts forth one or more small bulbs, which separate from the parent, and are supposed to be sources of new plants.

C. autumnale is a native of the temperate parts of Europe, where it grows wild in moist meadows. Attempts have been made to introduce its culture into this country, but with no great success; though small quantities of the bulb, of apparently good quality, have been brought into the market. The officinal portions are the bulb or cormus, and the seeds. The root, botanically speaking, consists of the fibres attached to the base of the bulb. The flowers possess similar virtues with the bulb and seeds.

1. Colchici Radix.

The medicinal virtue of the bulb depends much upon the season at which it is collected. Early in the spring, it is too young to have fully developed its peculiar properties; and, late in the fall, it has become exhausted by the nourishment afforded to the new plant. The proper period for its collection is from the early part of June, when it has usually attained perfection, to the middle of August, when the offset appears.* It may be owing, in part, to this inequality at different seasons, that entirely opposite reports have been given of its powers. Krapf ate whole bulbs without inconvenience; Haller found the bulbs entirely void of taste and acrimony; and we are told that in Carniola the peasants use it as food with impunity in the autumn. On the other hand, there can be no doubt of its highly irritating and poisonous nature, when fully developed, under ordinary circumstances. Perhaps soil and climate may have some influence in modifying its character.

The bulb is often used in the fresh state in the countries where it grows; as it is apt to be injured in drying, unless the process is carefully conducted. The usual plan is to cut the bulb, as soon after it has been dug up as possible, into thin transverse slices, which are spread out separately upon paper or perforated

* Dr. Christison, however, has found the roots collected in April, though shrivelled and less abundant in starch than those gathered in July, to be even more bitter; and conjectures, therefore, that the common opinion of their superior efficacy at the latter season may not be well founded. Prof. Schroff states, as the result of his observation, that the autumn root is much stronger than that dug in summer. (See *Am. Journ. of Pharm.*, xxix. 324.)

trays, and dried with a moderate heat. The reason for drying it quickly, after removal from the ground, is that it otherwise begins to vegetate, and a change in its chemical nature takes place; and such is its retentiveness of life, that, if not cut in slices, it is liable to undergo a partial vegetation even during the drying process. Dr. Houlton recommends that the bulb should be stripped of its dry coating, carefully deprived of the bud or young bulb, and then dried whole. It is owing to the high vitality of the bud that the bulb is so apt to vegetate. Much loss of weight is sustained by exsiccation. Mr. Bainbridge obtained only two pounds fifteen ounces of dried bulb from eight pounds of the fresh.

Properties. The recent bulb or cormus of *C. autumnale* resembles that of the tulip in shape and size, and is covered with a brown membranous coat. Internally it is solid, white, and fleshy; and, when cut transversely, yields, if mature, an acrid milky juice. There is often a small lateral projection from its base, particularly noticed by Dr. J. R. Coxe, which appears to be merely a connecting process between it and the new plant, and is not always present. When dried, and deprived of its external membranous covering, the bulb is of an ash-brown colour, convex on one side, and somewhat flattened on the other, where it is marked by a deep groove, extending from the base to the summit. As found in our shops it is always in the dried state, sometimes in segments made by vertical sections of the bulb, but generally in transverse circular slices, about the eighth or tenth of an inch in thickness, with a notch at one part of their circumference. The cut surface is white, and of an amylaceous aspect. The odour of the recent bulb is said to be *hircine*. It is diminished but not lost by drying. The taste is bitter, hot, and acrid. Its constituents, according to Pelletier and Caventou, are a vegetable alkali combined with an excess of gallic acid; a fatty matter composed of olein, stearin, and a peculiar volatile acid analogous to the cevadic; a yellow colouring matter; gum; starch; inulin in large quantity; and lignin. The active properties are ascribed to the alkaline principle, which was believed by its discoverers to be identical with *veratria*, but has been subsequently found to be peculiar, and has received the appropriate name of *colchicine*, or *colchicia*.* Wine and vinegar extract all the virtues of the bulb. Dr. A. T.

* *Colchicia* or *Colchicine*, and *Colchiceine*. The alkaloid of colchicum has been a subject of some controversy. According to Geiger and Hesse, to whom has been ascribed the credit of determining its precise nature, *colchicine* (*colchicia*) is crystallizable, and has a very bitter and sharp taste, but is destitute of the extreme acrimony of veratria, and does not, like that principle, excite violent sneezing when applied to the nostrils. It differs also in being more soluble in water, and less poisonous. To a kitten eight weeks old, one-tenth of a grain was given dissolved in dilute alcohol. Violent purging and vomiting were produced, with apparently severe pain and convulsions, and the animal died at the end of twelve hours. The stomach and bowels were found violently inflamed, with effusion of blood through their whole extent. A kitten somewhat younger was destroyed in ten minutes by only the twentieth of a grain of veratria; and, on examination after death, marks of inflammation were found only in the upper part of the œsophagus. The alkaloid was obtained from the seeds by a process similar to that employed in the preparation of hyoscyamia from hyoscyamus. (See *Hyoscyamus.*) A simpler process is to digest the seeds of meadow-saffron in boiling alcohol, precipitate with magnesia, treat the precipitated matter with boiling alcohol, and finally filter and evaporate.

The nature of the active principle of colchicum subsequently engaged the attention of L. Oberlin. Upon repeating the process of Geiger and Hesse, he was unable to obtain a crystallizable product, and came to the conclusion that the substance obtained by them was complex. By acidifying its watery solution by sulphuric or muriatic acid, and concentrating until the liquid became intensely yellow, he obtained, upon the addition of water, a yellowish-white precipitate, which, when well washed and freed from colouring matter, dissolved readily in alcohol or ether, and crystallized with facility. The crystalline product thus obtained he proposed to call *colchiceine*. It is a neuter substance, contains no acid, and is therefore not a salt, crystallizes in pearly lamellæ, is almost insoluble in cold water, to which, however, it imparts a slight bitterness, is more soluble in boiling water, and readily dissolves in alcohol, ether, methylic alcohol, and chloroform. It is dissolved by concentrated sulphuric, muriatic, and nitric acids, becoming yellow, by acetic acid without change of colour, and by ammonia and potassa. It is not altered nor precipitated by acetate or subacetate of lead, nitrate of silver, bichloride of mercury, or infusion of galls, but is rendered green by sesquichloride of iron. It consists of carbon, hydrogen, nitrogen, and oxygen. It was found to be very poisonous to

Thomson states that the milky juice of fresh colchicum produces a fine blue colour, if rubbed with the tincture of guaiac; and that the same effect is obtained

rabbits, killing an animal in 12 hours in the dose of about one-seventh of a grain, and in a few minutes by five times that quantity. (*Comptes Rendus*, Dec. 1856, p. 1199. See also *Am. Journ. of Pharm.*, xxix. 235.)

More recently, Mr. J. E. Carter, of Philadelphia, has made some experiments which appear to invalidate the conclusions of Oberlin as to the nature of colchicia, and to confirm the previous opinion of its alkaloid character. Mr. Carter used the bulb, instead of the seeds, which had previously in general been made the subject of experiment. He employed two processes for the extraction of the alkaloid, but found the following most productive. The dried and powdered bulb was exhausted by alcohol of 0·835 by means of percolation; the tincture thus obtained was evaporated to the consistence of syrup; water acidulated with acetic acid was added, and the liquor, after filtration, was nearly neutralized with ammonia, and then precipitated by solution of tannic acid; the precipitated tannate, after being well washed, was rubbed with five times its weight of freshly prepared hydrated oxide of lead, small quantities of alcohol being added from time to time during the trituration; the whole was then filtered, and the filtered liquid evaporated at a gentle heat. Twenty grains were thus obtained from three pounds of the dried root. Thus obtained *colchicia* was yellowish in mass, nearly white in powder, inodorous, bitter without being acrid, not sternutatory, soluble in water hot or cold, still more so in dilute acids and alkaline solutions, very soluble in alcohol and chloroform, sparingly so in pure ether, and insoluble in benzole. Mr. Carter did not succeed in crystallizing it. It was alkaline to test-paper, neutralized the acids, and with sulphuric acid formed a crystallizable salt. The most delicate test appeared to be that of sulphuric acid and nitre. A piece of nitre, added to its solution in sulphuric acid, produced a beautiful blue colour, changing to green, dark-brown or purple, and finally reddish-yellow. (For a further account of Mr. Carter's experiments, see *Am. Journ. of Pharm.*, May, 1858, p. 209.)—*Note to the eleventh and twelfth editions.*

Since Mr. Carter's experiments, others have engaged in the same inquiry. Ludwig confirms the statements of Oberlin. Hubler, operating on the unbruised seeds by a process similar to that of Mr. Carter with the cormus, for the details of which we refer to the *Am. Journ. of Pharm.* (March, 1866, p. 105), obtained an amorphous substance, soluble without residue in water and in alcohol, of an odour like that of hay, and very bitter. It had no effect on test-paper; its solution was precipitated yellow by chloride of gold, and white by corrosive sublimate; mineral acids and alkalies turned it yellow; at 284° F. it melted, with no other observable change except in colour, which became brown; and its composition was represented by the formula $C_{34}H_{19}NO_{10}$. When treated with acids it yielded crystallizable bodies, but these, instead of salts, were a new product, isomeric with colchicia, but in character resembling if not identical with the colchiceine of Oberlin, which is therefore a result of change in the colchicia. Both these substances are poisonous. Between the substance obtained by Hubler and the one by Carter, there is this apparently irreconcilable difference, that the latter is decidedly though feebly alkaline, while the former is entirely neuter. Either there is some error on the part of one of these experimenters, or the alkaloid obtained from the cormus is different from the active principle of the seeds.

That Mr. Carter's statement was correct has been fully confirmed by Prof. J. M. Maisch, who made a very careful examination of a portion of the colchicia obtained by Mr. Carter, and kept as a specimen, with the following results. It was an amorphous powder; of a light-yellow colour, a faint odour, and intense bitterness; sparingly soluble in ether, and readily in water and alcohol. The aqueous solution was slightly turbid, probably from the decomposition by time and exposure of a portion of the colchicia into resin and col chicceine. Heated on platinum foil, it melted, and at a higher temperature took fire, and burned without residue. It restored the blue colour of reddened litmus, and even neutralized sulphuric acid in very minute proportion. It answered to the best tests of colchicia, namely, 1. the effect on its solution of both acids and alkalies, which cause it to assume a yellow colour, and 2. the violet and blue colour produced by oxidizing agents on the dry colchicia. When treated first with concentrated sulphuric acid, and then with nitric acid or a fragment of a nitrate, it went through a series of changes of colour, ending in yellow. The same effect resulted from sulphuric acid with a trace of chromate or bichromate of potassa, sesquichloride of iron, or binoxide of lead; the first two causing a green colour with the solution, through the intermixture of their yellowness with the blue developed. The colchicia also answered to the following tests of the alkaloids, giving precipitates with iodohydrargyrate of potassium, phosphomolybdic acid, and tannic acid.

Colchiceine was produced by treating colchicia with diluted sulphuric and muriatic acids, evaporating the solution to dryness, repeating this operation once and again, then dissolving the residue in water, filtering the solution to separate the resin formed, evaporating with an excess of carbonate of lead to remove acid, treating with strong alcohol, and slowly evaporating. Colchiceine was deposited in yellow crystals, the solution of which precipitated, like colchicia, tannic and phosphomolybdic acids, and iodohydrargyrate of mercury, but exercised no reaction on litmus paper whether red or blue.

from an acetic solution of the dried bulb. He considers the appearance of this colour, when the slices are rubbed with a little distilled vinegar and tincture of guaiac, as a proof that the drug is good and has been well dried. Dr. J. M. Maclagan has shown that this change of colour is produced with the albumen, which is not affected if previously coagulated; so that the value of the test consists simply in proving that the drying has not been effected at a heat above 180°, or the temperature at which albumen coagulates. A very deep or large notch in the circumference of the slices is considered an unfavourable sign; as it indicates that the bulb has been somewhat exhausted in the nourishment of the offset. The decoction yields a deep-blue precipitate with solution of iodine, white precipitates with acetate and subacetate of lead, nitrate of protoxide of mercury, and nitrate of silver, and a slight precipitate with tincture of galls. The value of colchicum is best tested by its bitterness.

Medical Properties and Uses. Colchicum root is believed to act upon the nervous system, allaying pain and producing other sedative effects, even when it exerts no obvious influence over the secretions. Generally speaking, when taken in doses sufficiently large to affect the system, it gives rise to more or less disorder of the stomach or bowels, and sometimes occasions active vomiting and purging, with the most distressing nausea. When not carried off by the bowels, it often produces copious diaphoresis, and occasionally acts as a diuretic and expectorant; and a case is on record of violent salivation, supposed to have resulted from its use. It appears in fact to have the property of stimulating all the secretions, while it somewhat diminishes the action of the heart. In an overdose, it may produce dangerous and even fatal effects. Excessive nausea and vomiting, abdominal pains, purging and tenesmus, great thirst, sinking of the pulse, coldness of the extremities, and general prostration, with occasional symptoms of nervous derangement, such as headache, delirium, and stupor, are among the results of its poisonous action. It was well known to the ancients as a poison, and is said to have been employed by them as a remedy in gout and other diseases. Störck revived its use among the moderns. He gave it as a diuretic and expectorant in dropsy and humoral asthma; and on the continent of Europe it acquired considerable reputation in these complaints; but the uncertainty of its operation led to its general abandonment, and it had fallen into almost entire neglect, when Dr. Want, of London, again brought it into notice by attempting to prove its identity with the active ingredient of the *eau medicinale d'Husson*, so highly celebrated as a cure for gout. In James's Dispensatory, printed in 1747, it is said to be used in gout as an external application. The chief employment of the meadow-saffron is at present in the treatment of gout and rheumatism, in which experience has abundantly proved it to be a highly valuable remedy. We have, within our own observation, found it especially useful in these affections, when of a shifting or neuralgic character. It sometimes produces relief without obviously affecting the system; but is more efficient when it evinces its influence upon the skin or alimentary canal. Professor Chelius states that it changes the chemical constitution of the urine in arthritic patients, producing an evident increase of the uric acid. Dr. Maclagan has found it greatly to increase the proportion both of urea and uric acid in the urine, and, where

The inference from these experiments is that the active principle of colchicum, known by the name of colchicia, is an alkaloid, but that its salts in solution, on being kept, or evaporated, especially if heat is used, are decomposed, and converted into resin and colchiceine, the latter of which crystallizes; and, as this is isomeric with colchicia, the probability is that the resin has the same composition. In preparing colchicum pharmaceutically, if it be desired to retain the colchicia unchanged, both acids and alkalies should be avoided, especially when heat is employed. Of the officinal preparations, the two fluid extracts contain the colchicia as in nature; the acetic extract has a portion at least of colchiceine in its composition. In the wines, when kept, the colchicia probably passes gradually into colchiceine. (*Am. Journ. of Pharm.*, March, 1867, p. 97.) But it has not been proved that these latter preparations are in any degree less efficacious remedially; and, in the absence of all experience to the contrary, the inference is that colchiceine may have all the powers of colchicia; for the acetic extract, and the wines after being long kept, have often been used in practice, without having been found less effectual than other preparations of colchicum. (*Note to the thirteenth edition.*)

these previously existed in the blood, to separate them from it. (*Ed. Monthly Journ. of Med. Sci.*, N. S., v. 23.) Dr. Elliotson successfully treated a case of prurigo with the wine of colchicum, given in the dose of half a drachm three times a day, and continued for three weeks; and it has been found useful in urticaria and other cutaneous affections. Dr. Smith, of Port au Prince, employed it advantageously in tetanus both traumatic and idiopathic. He gave it in full doses, repeated every half hour till it produced an emetic or cathartic effect. (*Am. Journ. of the Med. Sci.*, xvii. 66.) Mr. Ritton found the powdered bulb an effectual remedy in numerous cases of leucorrhœa. (*Ibid.*, vi. 527.) Colchicum has also been recommended in inflammatory and febrile diseases as an adjuvant to the lancet, in diseases of the heart with excessive action, in various nervous complaints, as chorea, hysteria, and hypochondriasis, and in chronic bronchial affections. It is generally given in the state of vinous tincture (see *Vinum Colchici Radicis*); but there are various other officinal preparations, any one of which may be used efficiently. The wine has been employed externally in rheumatism. The dose of the dried bulb is from two to eight grains, which may be repeated every four or six hours till its effects are obtained.

2. Colchici Semen.

The seeds of the meadow-saffron ripen in summer, and should be collected about the end of July or beginning of August. They never arrive at maturity in plants cultivated in a dry soil, or in confined gardens. (*Williams.*) They are nearly spherical, about the eighth of an inch in diameter, of a reddish-brown colour externally, white within, and of a bitter acrid taste. Dr. Williams, of Ipswich, England, who first brought them into notice, recommends them in the warmest terms in chronic rheumatism, and considers them superior to the bulb, both in the certainty of their effects, and the mildness of their operation. Prof. Schroff, however, has found that their activity is inferior to that of the dried bulb, dug in autumn. (*Am. Journ. of Pharm.*, xxix. 324.) There is no doubt that they possess virtues analogous to those of the bulb, and have this advantage, that they are not liable to become injured by drying; an advantage of peculiar value in a country where the plant is not cultivated, and a fresh bulb cannot be readily procured. A wine, fluid extract, and tincture of the seeds are directed in the U. S. Pharmacopœia. Their dose is about the same with that of the bulb.*

COLOCYNTHIS. *U. S.*

Colocynth.

The fruit, deprived of its rind, of Citrullus Colocynthis. *U. S.*

Off. Syn. COLOCYNTHIDIS PULPA. *Colocynth Pulp.* The dried decorticated fruit, freed from seeds, of Citrullus Colocynthis. *Br.*

* The following description of the seeds is given by Mr. Gray in the *Lond. Med. Repository* for April, 1821. "*Seeds*, ovate, globose, about one-eighth of an inch in diameter. *Integuments*, simple, soft, spongy, membranaceous, thin, reddish-brown, closely adherent to the perisperm. *Perisperm* or *albumen*, hard, rather cartilaginous, pellucid, pale, not in the least divided, of the same shape as the seed. *Corculum* or *embryo*, very small, ovate-globose, not in the least divided, whitish, placed nearly opposite to the *hylum*, or that part where the seed is affixed to the parent plant, but out of the axis of the seed. Base pointing to the hylum, slender. Apex very obtuse." An acquaintance with the characters of these seeds is the more necessary, as the seeds of other plants have been sold for them.

The *flowers* have been repeatedly employed as a substitute for the root or seeds, and by some have been thought more uniform in their effects, and at the same time less irritating. M. Luskind, of Geneva, Switzerland, prepares them in the following manner. The flowers having been gathered when in full perfection, on a sunny day, are submitted to expression in a silk bag. A dark-brown juice is obtained, which is to be mingled with an equal measure of strong alcohol, allowed to stand for a month, and then filtered. (See *Va. Med. and Surg. Journ.*, March, 1854, p. 486.)

Cucumis Colocynthis. Willd. *Sp. Plant.* iv. 611; Woodv. *Med. Bot.* p. 189. t 71. — *Citrullus Colocynthis*, Royle's Mat. Med. The *bitter cucumber* is an annual plant, bearing considerable resemblance to the common watermelon. The stems, which are herbaceous and beset with rough hairs, trail upon the ground, or rise upon neighbouring bodies, to which they attach themselves by their numerous tendrils. The leaves, which stand alternately on long petioles, are triangular, many-cleft, variously sinuated, obtuse, hairy, of a fine green colour on the upper surface, rough and pale on the under. The flowers are yellow, and appear singly at the axils of the leaves. The fruit is a globular pepo, of the size of a small orange, yellow and smooth when ripe; and contains, within a hard, coriaceous rind, a white spongy medullary matter, enclosing numerous ovate, compressed, white or brownish seeds.

The plant is a native of Turkey, and abounds in the islands of the Archipelago. It grows also in various parts of Africa and Asia. Burkhardt, in his travels across Nubia, found the country covered with it; Thunberg met with it at the Cape of Good Hope; and Ainslie says that it grows in many parts of Lower India, particularly in sandy places near the sea. It is said to be cultivated in Spain. The fruit is gathered in autumn, when it begins to become yellow, and, having been peeled, is dried quickly in a stove or by the sun. Thus prepared, it is imported from the Levant. Small quantities are said to be imported into England from Mogador unpeeled.*

Properties. As kept in the shops, colocynth is in the shape of whitish balls about the size of an orange, very light and spongy, and abounding in seeds which constitute three-fourths of their weight. The seeds are somewhat bitter; but possess little activity, and, according to Captain Lyon, are even used as food in the north of Africa. When the medicine is prepared for use, they are separated and rejected, the pulpy or medullary matter only being employed. This has a very feeble odour, but a nauseous and intensely bitter taste. Water and alcohol extract its virtues. Vauquelin obtained the bitter principle in a separate state, and called it *colocynthin*. According to Meissner, 100 parts of the dry pulp of colocynth contain 14·4 parts of colocynthin, 10·0 of extractive, 4·2 of fixed oil, 13·2 of a resinous substance insoluble in ether, 9·5 of gum, 3·0 of pectic acid (pectin), 17·6 of gummy extract derived from the lignin by means of potassa, 2·7 of phosphate of lime, 3·0 of phosphate of magnesia, and 19·0 of lignin, besides water.† Colocynthin is obtained by boiling the pulp in water, evaporating the decoction, treating the extract thus procured with alcohol, evaporating the alcoholic solution, and submitting the residue, which consists of the bitter principle and acetate of potassa, to the action of a little cold water, which dissolves the

* In a letter from Mr. R. W. Pelham, of the Shakers' Village, near New Lebanon, Ohio, the author was informed that a hybrid plant between the colocynth and watermelon had been successfully cultivated in that place, and yielded a bitter fruit having the medical virtues of colocynth. With the letter came also some seeds of the plant, and a portion of extract prepared from the pulp of the fruit. This was found, upon trial, to be actively cathartic. The seeds, planted in the garden of the author, produced vigorous plants, which perfected their fruit. The plant appeared intermediate between the colocynth and watermelon. The fruit was globular, about four inches in diameter, green like the watermelon externally, having the same odour when cut, but of an extremely bitter taste. A portion of the pulp was dried; and an extract prepared from it was found to have the cathartic properties of the extract of colocynth.

† Dr. Waltz supposes that he has found another peculiar principle in colocynth, to which he gives the name of *colocynthitin*. It was obtained by treating with ether the alcoholic extract previously exhausted by water, decolorizing the ethereal solution with animal charcoal, evaporating to dryness, and dissolving the residue in anhydrous alcohol, which deposited it in crystals on spontaneous evaporation. It is white and tasteless, and is probably a resin. (*N. Jahrbuch der Pharm.*, xvi. 10.)—*Note to the twelfth edition.*

latter, and leaves the greater part of the former untouched. Mr. Bastick obtained it by exhausting the pulp with cold water, heating the solution to ebullition, adding subacetate of lead so long as a precipitate was produced, filtering the liquor when cold, adding dilute sulphuric acid gradually until it no longer occasioned a precipitate, boiling to expel free acetic acid, filtering to separate sulphate of lead, evaporating cautiously nearly to dryness, extracting the colocynthin from the residuum by strong alcohol, which left the salts, and finally evaporating the alcoholic solution. The following process, employed by Dr. Waltz, probably yields it in a purer state. Colocynth is exhausted by alcohol of 0·84, the tincture evaporated to dryness, the residue treated with water, and the solution precipitated first with acetate and afterwards with subacetate of lead. The yellow filtered liquor is then treated with sulphuretted hydrogen to separate the lead, and, after filtration, with solution of tannic acid, which throws down a compound of tannic acid and colocynthin. This is dissolved in alcohol, the tannin thrown down by subacetate of lead, the excess of lead separated, and the liquid digested with animal charcoal, filtered, and evaporated. The residue, washed with anhydrous ether, is pure colocynthin. This is yellowish, somewhat translucent, brittle and friable, fusible by a heat below 212°, inflammable, more soluble in alcohol than in water, but capable of rendering the latter intensely bitter. M. Mouchon states that it is insoluble in ether. It is neither acid nor alkaline; but its aqueous solution gives with infusion of galls a copious white precipitate. It consists of carbon, hydrogen, and oxygen, and its formula, according to Dr. Waltz, is $C_{56}H_{42}O_{23}$. Upon the same authority it is a glucoside, being resolved, by the action of sulphuric acid, into sugar and a peculiar resinous substance. An infusion of colocynth, made with boiling water, gelatinizes upon cooling. Neumann obtained from 768 parts of the pulp, treated first with alcohol and then with water, 168 parts of alcoholic and 216 of aqueous extract.

Medical Properties and Uses. The pulp of colocynth is a powerful drastic, hydragogue cathartic, producing, when given in large doses, violent griping, and sometimes bloody discharges, with dangerous inflammation of the bowels. Death has resulted from a teaspoonful and a half of the powder. (*Christison.*) Even in moderate doses, it sometimes acts with much harshness, and is, therefore, seldom prescribed alone. By some writers it is said to be diuretic. It was frequently employed by the ancient Greeks and the Arabians, though its drastic nature was not unknown to them. Among the moderns it is occasionally used in obstinate dropsy, and in various affections depending on disordered action of the brain. In combination with other cathartics it loses much of its violence, but retains its purgative energy; and in this state is extensively employed. The compound extract of colocynth is a favourite preparation with many practitioners; and, combined with calomel, extract of jalap, and gamboge, it forms a highly efficient and safe cathartic, especially useful in congestion of the portal circle and torpidity of the liver. (See *Pilulæ Catharticæ Compositæ.*) The dose of colocynth is from five to ten grains. It is best administered in minute division, effected by trituration with gum or farinaceous matter. The active principle has sometimes been employed; and, in the impure state in which it is prepared by the process of M. Émile Mouchon, may be given in the dose of a grain.*

Thunberg states that the fruit of C. Colocynthis, at the Cape of Good Hope, is rendered so mild by being properly pickled, that it is eaten both by the na-

* The following is the simple process of M. Mouchon. Take 125 parts of colocynth in very fine powder, and 60 parts of purified animal charcoal. Mix the colocynth intimately with half the charcoal; introduce the mixture into a percolator containing the other half of the charcoal; and percolate first with strong alcohol, then with dilute alcohol, and finally with water so as to displace the previous liquid, until 250 parts of concentrated alcoholic tincture are obtained. Allow this to evaporate spontaneously on flat dishes to dryness. A garnet-coloured pulverizable product is thus obtained, of insupportable bitterness, and powerfully cathartic in the dose of a grain and a half. In this state it is sufficiently pure for use. It may be further purified by dissolving in strong alcohol, and treating with a little animal charcoal. One part of colocynthin is obtained from 32 of the entire fruit. (*Am. Journ. of Pharm.*, xxviii. 166; from *Repert. der Pharm.*, Nov. 1855.) For a process by Prof. Procter, see *Ibid.*, March, 1863, p. 116.)—*Note to the twelfth edition.*

tives and colonists; but, as it is thus employed before attaining perfect maturity, it is possible that the drastic principle may not have been developed.

Gen. Ch. Partial involucre halved, usually three-leaved. *Fruit* nearly globular, five-streaked, notched on both sides. *Willd.*

Conium maculatum. Willd. *Sp. Plant.* i. 1395; Bigelow, *Am. Med. Bot.* i. 113; Woodv. *Med. Bot.* p. 104, t. 42. This is an umbelliferous plant, having a biennial spindle-shaped whitish root, and an herbaceous branching stem, from three to six feet high, round, hollow, smooth, shining, slightly striated, and marked with brownish-purple spots. The lower leaves are tripinnate, more than a foot in length, shining, and attached to the joints of the stem by sheathing petioles; the upper are smaller, bipinnate, and inserted at the division of the branches; both have channeled footstalks, and incised leaflets, which are deep-green on their upper surface and paler beneath. The flowers are very small, white, and disposed in compound terminal umbels. The general involucre consists of from three to seven lanceolate, reflected leaflets, whitish at their edges; the partial involucre, of three or four, oval, pointed, spreading, and on one side only. There are five petals, cordate, with their points inflected, and nearly equal. The stamens are spreading, and about as long as the corolla; the styles diverging. The fruit, commonly called seeds, is roundish-ovate, a line and a half or rather less in length by a line in breadth, striated, and composed of two plano-convex, easily separable parts, which have on their outer surface five crenated ribs.

Hemlock is a native of Europe, and has become naturalized in the United States, where it is also cultivated for medicinal purposes. It grows usually in clusters along the road-sides, or in waste grounds, and is found most abundantly near old settlements. It flowers in June and July. The whole plant, especially at this period, exhales a fetid odour, compared by some to that of mice, by others to that of the urine of cats; and narcotic effects result from breathing for a long time air loaded with the effluvia. The plant varies in narcotic power according to the weather and climate, being most active in hot and dry seasons, and in warm countries. The hemlock of Greece, Italy, and Spain is said to be much more energetic than that of the north of Europe. As a general rule, those plants are most active which grow in a sunny exposure. The term *cicuta*, which has often been applied to this plant, belongs to a different genus. The leaves and fruit are officinal.

The proper season for gathering the leaves is when the plant is in flower; and Dr. Fothergill asserts, from experiment, that they are most active about the time when the flowers begin to fade. The footstalks should be rejected, and the leaflets quickly dried, either in the hot sun, on tin plates before a fire, or by a stove-

heat not exceeding 120° F. They should be kept in boxes or tin cases, excluded from the air and light, by exposure to which they lose their fine green colour, and become deteriorated. The same end is answered by pulverizing them, and preserving the powder in opaque and well-stopped bottles. But little reliance can be placed on the dried leaves; as, even when possessed of a strong odour and a fine green colour, they may be destitute of the narcotic principle. When rubbed with caustic potassa they should exhale the odour of conia. The fruit retains its activity much longer than the leaves. Dr. Christison found it to have sustained no diminution of power, after having been kept eight years. Hirtz inferred from experiment that the relative strength of extracts of the seeds and the leaves was as ten to one in favour of the former.

Properties. The dried leaves of the hemlock have a strong, heavy, narcotic odour, less disagreeable than that of the recent plant. Their taste is bitterish and nauseous; their colour a dark green, which is retained in the powder. A slight degree of acrimony possessed by the fresh leaves is said to be dissipated by drying. The seeds have a yellowish-gray colour, a feeble odour, and a bitterish taste. Their form has already been described. Water distilled from the fresh leaves has the odour of hemlock, and a nauseous taste, but does not produce narcotic effects. The decoction has little taste, and the extract resulting from its evaporation is nearly inert. From these facts it is inferrible that the active principle, as it exists in the plant, is not volatile at 212°, and, if soluble in water, is injured by a boiling heat. Alcohol and ether take up the narcotic properties of the leaves; and the ethereal extract, which is of a rich dark-green colour, is stated by Dr. A. T. Thomson to have the smell and taste of the plant in perfection, and in the dose of half a grain to produce headache and vertigo. Upon destructive distillation, the leaves yield a very poisonous empyreumatic oil. We have no satisfactory analysis of hemlock. Schrader found in the juice of the leaves, resin, extractive, gum, albumen, a green fecula, and various saline substances. Brandes obtained from the plant a very odorous oil, albumen, resin, colouring matter, and salts.

So long ago as 1827, Giseke obtained an alkaline liquid by distilling hemlock leaves with water and caustic lime; but he did not succeed in isolating the substance in which the alkalinity resided. Geiger was the first who obtained the active principle in a separate state, and proved it to be alkaline. It appears that there are two volatile substances in hemlock; one of them an *oil*, which comes over by simple distillation, and upon which the odour of the plant depends, and the other an *alkaline principle*, which, as it exists in the plant, is so combined as not to be volatilizable, but which, when separated by one of the mineral alkalies from its native combination, rises readily in distillation, and may thus be procured separate. The latter substance is the active principle, and has received the name of *conia* or *coniine*. It probably exists in the plant united with an acid, as it is separated by the alkalies. This acid Peschier believed to be peculiar, and named *coniic acid*. Geiger obtained conia by the following process. He distilled fresh hemlock with caustic potassa and water, neutralized with sulphuric acid the alkaline liquid which came over, evaporated this liquid to the consistence of syrup, added anhydrous alcohol so long as a precipitate of sulphate of ammonia was afforded, separated this salt by filtration, distilled off the alcohol, mixed the residue with a strong solution of caustic potassa, and distilled anew. The conia passed over with the water, from which it separated, floating on the surface in the form of a yellowish oil. According to Dr. Christison, an easier process is to distil cautiously a mixture of a strong solution of potassa and the alcoholic extract of the unripe fruit. As obtained by the above process, conia is in the state of a hydrate, containing one-fourth of its weight of water and a little ammonia. From the former, it may be freed by chloride of calcium; from the latter, by exposing it under an exhausted receiver till it ceases to emit bubbles of gas.

The fresh leaves or seeds should be employed in the preparation of conia; as the alkali undergoes decomposition by time and exposure. The seeds contain

most of this principle; but even in these it exists in very small proportion From 6 pounds of the fresh and 9 of the dried seeds, Geiger obtained about an ounce of conia; while from 100 pounds of the fresh herb he got only a drachm, and from the dried leaves none. Christison recommends the full-grown fruit while yet green, and states that 8 pounds will yield half an ounce of hydrate of conia, and contains much more.*

Conia is in the form of a yellowish oily liquid, lighter than water, of a very acrid taste, and a strong penetrating odour, compared to that of the urine of mice, and recalling the smell of fresh hemlock, though not identical with it. In volatility it resembles the essential oils, readily rising with the vapour of boiling water, but, when unmixed, requiring for ebullition, according to Christison, a temperature of 370°. It is freely soluble in alcohol, ether, the fixed and volatile oils, and slightly so in water. It unites with about one-fourth of its weight of water to form a hydrate. It reddens turmeric, and neutralizes the acids, forming with them soluble salts, some of which are crystallizable. With tannic acid it forms an insoluble compound Like ammonia it occasions a white cloud, when approached by a rod moistened with muriatic acid; and the resulting muriate, contrary to previous statements, is asserted by Prof. Wertheim to be crystallizable, and not in the least deliquescent. It coagulates albumen, and precipitates the salts of aluminium, copper, zinc, manganese, and iron. It also precipitates nitrate of silver, but in excess redissolves the precipitate. Most of its salts are decomposed by evaporation. When exposed to the air, it speedily assumes a deep-brown colour, and is ultimately converted into a resinous matter, and into ammonia which escapes. Under the influence of heat this change takes place with much greater rapidity. The presence of conia may be detected in an extract, or other preparation of hemlock, by rubbing it with potassa, which instantly developes its peculiar odour. It consists of nitrogen, carbon, and hydrogen; its admitted formula being $C_{16}H_{15}N$.† In its effects on the system it closely resembles hemlock itself. Dr. Christison found it, contrary to the experience of Geiger, more active in the saline state than when uncombined. It is a most energetic poison; one drop of it injected into the eye of a rabbit killing the animal in nine minutes, and three drops killing a stout cat in a minute and a half when similarly applied. Dr. Christison (*Trans. Roy. Soc. Ed.*, 1836) thinks that it acts upon the spinal marrow, directly prostrating the nervous power,

* *Methylconia. Ethylconia.* From a communication by Drs. A. von Planta and Aug. Kekulé to the *Annal. der Chem. und Pharm.* (lxxxix., s. 129–156), it would appear that commercial conia consists most commonly of at least two homologous bases; one being the proper *conia* ($C_{16}H_{15}N$), which contains one eq. of hydrogen capable of being replaced by radicals, and the other, named *methylconia* ($C_{18}H_{17}N$), having no hydrogen which can be replaced by radicals. A third, *ethylconia* ($C_{20}H_{19}N$), was obtained from a specimen of commercial conia containing no methylconia. In relation to the modes of separating these alkaloids and their distinctive properties, we must content ourselves with referring to the original paper; as no practical advantage has yet accrued from the investigation, and it may be doubted whether the new alkaloids may not be products of the operation, as they are obtained by the action respectively of iodide of methyl, and iodide of ethyl on conia.

Conhydria. Prof. T. Wertheim has also found a new alkaloid mixed with the conia obtained by distillation from fresh hemlock flowers. It is crystallizable, fusible at a temperature below 212° F., and volatilizable at a higher temperature, diffusing the peculiar odour of conia, or one very much like it. Water dissolves it considerably, ether and alcohol freely; and the solution has a strong alkaline reaction. Its formula is given as $C_{16}H_{15}N,H_2O_2$, or conia with two eqs. of water. Hence it has been named *conhydrine* (*conhydria*). (*Am. Journ. of Pharm.*, xxix. 321.) It may be separated from conia by exposing the mixed alkaloids to a freezing mixture, expressing, and then repeatedly crystallizing from ether. (*Gmelin*, xiii. 169.)—*Note to the eleventh and twelfth editions.*

† Orfila gives the following additional chemical characters of conia. Heated in a capsule, it forms white vapours, *having a strong smell of celery and of the urine of mice.* Weak tincture of iodine gives a white precipitate, becoming olive with excess of the tincture. *Pure concentrated sulphuric acid does not alter it;* but when the mixture is heated, it becomes first brown, then blood-red, and finally black. *Nitric acid imparts a topaz colour*, not changed by heat. The chlorides of platinum and of gold give yellow precipitates, and corrosive sublimate a white one. Red permanganate of potassa is immediately decolorized. *Neutral acetate of lead gives no precipitate*, nor does the subacetate. The parts of this note in Italics indicate the means of distinguishing this alkaloid from nicotia. (See *Pharm. Journ.*, xi. 89.)

producing paralysis of the voluntary muscles, and destroying life by arresting respiration. The brain does not seem to be especially attacked; as the animal, when it dies slowly, preserves its senses unimpaired so long as it breathes. In cases of sudden death from the poison, the heart does not cease to act till after apparent death; and its action may be sustained after the animal has ceased to breathe, by keeping up artificial respiration. A recently prepared extract of hemlock acted precisely as conia. Locally the alkali appears to act as an irritant.

Medical Properties and Uses. Hemlock is narcotic, and somewhat sedative to the circulation. Mr. Judd inferred from his experiments that it directly diminishes the action of the heart; and when it produces death, contrary to the results obtained by Christison, exhausts the contractility of that organ. (*Medico-bot. Trans.*, vol. i pt. 4.) When given so as fully to affect the system, it produces more or less vertigo, dimness of vision, nausea, faintness, sensations of numbness, and general muscular debility. In larger doses it occasions dilated pupils, difficulty of speech, delirium or stupor, tremors and paralysis, and ultimately convulsions and death. Sometimes it produces fatal effects through paralysis alone, without coma or convulsions. Its operation usually commences in less than half an hour, and if moderate, seldom continues longer than twenty-four hours. It is supposed to be the narcotic used by the Athenians to destroy the life of condemned individuals, and by which Socrates and Phocion died. It was also used by the ancients as a medicine, but fell into entire neglect, and did not again come into notice till the time of Störck, by whom it was much employed and extravagantly praised. Since that time it has been submitted to ample trial, and, though its original reputation has not been fully sustained, it still retains a place in the catalogue of useful medicines. Anodyne, soporific, antispasmodic, antaphrodisiac, deobstruent, and diuretic properties have been ascribed to it. It was highly recommended by Störck as a remedy in scirrhus and cancerous ulcers, but at present is considered only a useful palliative in those affections. In mammary tumours and chronic enlargements of the liver and other abdominal viscera; in painful scrofulous tumours and ulcers; in various diseases of the skin, as lichen, prurigo, acne, eczema, psoriasis, leprosy, and elephantiasis; in the complicated derangements of health attendant upon secondary syphilis; in chronic rheumatism and neuralgic affections; in excessive secretion of milk; in pertussis, asthma, chronic catarrh, and consumption; and in various other disorders connected with nervous derangement, or a general depraved state of the health, it is occasionally employed with the effect of relieving or palliating the symptoms, or favourably modifying the action of other remedies. The late Prof. Gibson considered it efficacious in the cure of goitre.

The powdered leaves, and the inspissated juice (the extract of the Pharmacopœias) are the forms in which conium has been usually administered; but the juice of the fresh leaves, prepared by the addition of one-third of its measure of alcohol, has been adopted in the British Pharmacopœia, and is one of the most efficient of the preparations. Either the leaves or extract may be given in the dose of three or four grains twice a day, gradually increased till the occurrence of slight vertigo or nausea indicates that it has taken effect. To maintain a given impression, it is necessary to increase the dose even more rapidly than is customary with most other narcotics; as the system becomes very speedily habituated to its influence. In some instances, the quantity administered in one day has been augmented to more than two ounces. The strength of the preparations of hemlock is exceedingly unequal; and caution is therefore necessary, when the medicine is given in very large quantities, to employ the same parcel, or, if a change be made, to commence with the new parcel in small doses, so as to obviate any danger which might result from its greater power. Unpleasant consequences have followed a neglect of this precaution. There are also an officinal tincture and alcoholic extract, both of which, when properly made, have been considered as efficient preparations. But some doubt has been thrown upon this point, particularly in reference to the tincture, by Dr. John Harley of London, whose experiments seem to show that this preparation is

medically inert. (See *Tinctura* and *Extractum Conii.*) The fresh juice of the plant has been recommended by Hufeland in the dose of from twelve to forty drops. The powdered seeds should be given in a dose considerably smaller than that of the leaves * The fresh leaves are sometimes used externally as an anodyne cataplasm; and the extract, and an ointment prepared from the leaves, are applied to the same purpose. A plaster made from the extract has also been employed.†

Conia has been occasionally employed, both internally and externally, with asserted advantage, for the same purposes as hemlock itself, or the extract. It has been particularly recommended in hooping-cough. Dr. Spengler, of Herborn, gave it to an infant a year old in the dose of one-sixteenth of a grain every six hours, with the effect of curing the disease in ten days. (*Ann. de Thérap.*, 1853, p. 73.) According to the formula of Fronmüller, two drops are dissolved in twenty-four drops of alcohol, and three drops of the solution are given, each on a piece of sugar. (*Arch. Gén.*, 4e sér., xxiii. 226.) From one-quarter of a drop to a drop may be given to an adult, and one or two drops by enema in emulsion of starch A solution of one part in one hundred of very dilute alcohol has been used with advantage in certain cases of scrofulous ophthalmia with photophobia, applied several times daily by friction about the eyelids (*Journ. de Pharm.*, 3e sér., xix. 219.) Prof. Mauthner, of Vienna, recommends it especially in the spasmodic contraction of the orbicularis in scrofulous children, using a solution containing half a grain of conia in a drachm of almond oil, which he applies by a pencil to the eyelids twice or thrice daily. As a collyrium, from one to three drops may be added to six drachms of pure water, and two drachms of mucilage of quince seeds. Introduced into the cavity of a carious tooth, it is said to be very effectual in toothache. For this purpose it should be diluted with ten parts of tincture of cinnamon, and applied by means of a camel's-hair pencil. In diseases of the skin it may be used as an ointment, made with three drops to a drachm of simple ointment. In neuralgia, three or four drops may be applied on linen to the skin, and confined by oiled silk.

Though fatal to some animals, hemlock is eaten with impunity by others, as horses, goats, and sheep. The best method of relieving its poisonous effects is the speedy evacuation of the stomach.

Copaiba.

The juice of Copaifera multijuga and of other species of Copaifera. *U. S.*

The oleo-resin obtained from incisions made in the trunk of Copaifera multijuga and other species of Copaifera. *Br.*

* From their greater strength, permanency, and uniformity, the seeds might well supersede the leaves for internal use. They should be pulverized, made into pills with syrup, and given in the commencing dose of half a grain, to be gradually increased till their effects are experienced. MM. Devay and Guillermond prepare a *syrup* from the seeds made by exhausting 10 parts of them with 60 parts of alcohol of 28°, and adding the tincture to 3000 parts of syrup "aromatised *ad libitum.*" One or two fluidrachms may be taken at first. (*Ann. de Thérap.*, 1853, p. 54.)—*Note to the tenth edition.*

The root, while containing a small proportion of conia, is too feeble, according to the experiments of Dr. John Harley of London, to be used practically with advantage. Dr. Harley has found in the root three new proximate principles, one a very bitter resin which he names *conamarine*, and the two others crystallizable bodies, named, respectively *rhizoconin* and *rhizoconolein.* They are all neuter, and so far as known medicinally inert For further particulars, the reader is referred to the *Pharm. Journ. and Trans.* (Aug. 1867, p. 53).—*Note to the thirteenth edition.*

† The following formula of Planche has been approved by the Society of Pharmacy, of Paris. Take of extract of hemlock 90 parts, of purified elemi 20 parts, of white wax 10 parts. Melt the resin and wax with a gentle heat, and incorporate the extract with the mixture. (*Journ. de Pharm.*, Juillet, 1862, p. 46.)—*Note to the twelfth edition.*

Gen. Ch. Calyx none. *Petals* four. *Legume* ovate. *Seed* one, with an ovate arillus. *Willd.*

The first notice to be found of the copaiba plant is by Marcgrav and Piso in the year 1648 Jacquin in 1763 described a species of Copaifera, growing in Martinique, which he named *C. officinalis.* As this was believed to be the same plant with the one observed by Marcgrav in Brazil, it was adopted in the Pharmacopœias; but their identity is now denied; and Desfontaines has proposed for Jacquin's species the title of *C. Jacquini,* in honour of that botanist. It is now known that many species of Copaifera exist in Brazil and other parts of South America; and all of them, according to Martius, yield copaiba. Besides C. officinalis or C. Jacquini, the following are described by Hayne;—*C. Guianensis, C. Langsdorffii, C. coriacea, C. Beyrichii, C. Martii, C. bijuga, C. nitida, C. laxa, C. cordifolia, C. Jussieui, C. Sellowii, C. oblongifolia,* and *C. multijuga.* Hayne believed that C. bijuga was the plant seen by Marcgrav and Piso.

Copaifera officinalis. Willd. *Sp. Plant.* ii. 630; Woodv. *Med. Bot.* p. 609. t. 216.—*C. Jacquini.* Desfont. *Mem. du Mus.* vii. 376; Hayne, *Darstel. und Beschreib. &c.* x. 14. This is an elegant tree, with a lofty stem, much branched at the top, and crowned by a thick canopy of foliage. The leaves are alternate, large, and pinnate, composed of from two to five pairs of ovate, entire, obtusely acuminate leaflets, two or three inches in length, rather narrower on one side than the other, smooth, pellucidly punctate, somewhat shining, and on short footstalks. The flowers are whitish, and in terminal branched spikes. The fruit is an oval, two-valved pod, containing a single seed.

This species of Copaifera is a native of Venezuela, and grows in the province of Carthagena, mingled with the trees which afford the balsam of Tolu. It grows also in some of the West India islands, particularly Trinidad and Martinique. Though recognised in former editions of the U. S. Pharmacopœia as a source of copaiba, it probably yields little of that now in use. According to Hayne, the species from which most of the copaiba of commerce is derived is *C. multijuga,* growing in the province of Para; and this is now the one specially recognised by our national standard. Like many other species it was discovered by Martius; and a leaf of it is figured by Hayne (x. t. 17 f. c.). It is specifically characterized by its pinnate leaves, with from six to ten pairs of leaflets, which are somewhat incurved, with unequal sides, acuminate, with pellucid spots, the lower ovate-oblong, the upper lanceolate, and all supported by slightly pubescent petioles. It is probable that *C. Guianensis,* which inhabits the neighbouring province of Guiana, especially in the vicinity of the Rio Negro, affords also considerable quantities; and *C. Langsdorffii* and *C. coriacea,* which are natives of Santo Paulo, are thought to yield most of the juice collected in the latter province. *C. nitida,* inhabiting the province of Minas-Geraes, probably also contributes to the commercial supplies, through Rio Janeiro.

The juice is obtained by making deep incisions into the stems of the trees; and the operation is said to be repeated several times in the same season. As it flows from the wound, it is clear, colourless, and very thin, but soon acquires a thicker consistence, and a yellowish tinge. It is most largely collected in the provinces of Para and Maranham, in Brazil, and is brought to this country from the port of Para, in small casks or barrels. Large quantities of it come from Maracaybo, in Venezuela, and from other ports on the Caribbean sea, whence it is brought in casks, demijohns, cans, jugs, &c. The drug is also exported from Angustura, Cayenne, Rio Janeiro, and some of the West India islands.

Properties. Copaiba is a clear, transparent liquid, usually of the consistence of olive oil, of a pale-yellow colour, a peculiar not unpleasant odour, and a bitterish, hot, nauseous taste. Its sp. gr. varies ordinarily from 0·950 to 1·000; but

has been known to be as low as 0·916. (Procter, *Am. J. of Pharm.*, xxii. 292)* It is insoluble in water, but entirely soluble in absolute alcohol, ether, and the fixed and volatile oils. Strong alkaline solutions dissolve it perfectly; but the resulting solution becomes turbid when largely diluted with water. With the alkalies and alkaline earths it forms saponaceous compounds, in which the resin of the copaiba acts the part of an acid. It dissolves magnesia, especially with the aid of heat, and even disengages carbonic acid from the carbonate of that earth. If triturated with a sixteenth of its weight of magnesia and set aside, it gradually assumes a solid consistence; and a similar change is produced with hydrate of lime. (See *Pilulæ Copaibæ*.) Its essential constituents are volatile oil and resin, with a minute proportion of an acid which appears to be the acetic. (*Durand.*) As it contains no benzoic acid, it cannot with propriety retain its old title of *balsam of copaiva*. The substances which it most closely resembles, both in composition and properties, are the turpentines. The *volatile oil* will be treated of among the preparations. (See *Oleum Copaibæ*.)

The *resinous* mass which remains after the distillation of the oil is hard, brittle, translucent, greenish-brown, and nearly destitute of smell and taste. By mixing it with the oil in proper proportion, we may obtain a liquid identical or nearly so with the original juice. When treated with the oil of petroleum, it is separated into two distinct resins, one of which is dissolved, and may be obtained separate by evaporation, the other is left behind. The first is yellowish, hard, and brittle, and constitutes by far the largest proportion of the residuum of the distillation. It forms definite compounds with the alkalies; and its alcoholic solution reddens litmus. It is therefore an acid, and has been named *copaivic acid*. The second resin is yellowish-brown, soft, unctuous, and without acid reaction; and is believed to result from the resinification of the volatile oil. Recent copaiba, examined by Gerber, yielded 41 per cent. of volatile oil, 51·38 of the hard and brittle resin, 2·18 of the soft resin, and 5·44 of water; while an older specimen gave 31·07 per cent. of oil, 53·68 of hard resin, 11·15 of soft resin, and 4·10 of water.

Copaiba, upon exposure to the air, acquires a deeper colour, a thicker consistence, and greater density, and, if spread out upon an extended surface, ultimately becomes dry and brittle. This change is owing partly to the volatilization, partly to the oxidation of the essential oil. As it is the soft resin that results from the oxidation of the oil, it follows that the proportion of this resin increases with age. Considerable diversity must, therefore, exist in the drug, both in physical properties and the proportion of its ingredients, according to its age and degree of exposure. Similar differences also exist in the copaiba procured from different sources. Thus, that of the *West Indies*, when compared with the *Brazilian*, which is the variety above described, and in common use, is of a thicker consistence, of a deeper or darker yellow colour, less transparent, and of a less agreeable, more terebinthinate odour; and specimens obtained from the ports of Venezuela or new Granada were found, upon examination by M. Vigne, to differ from each other not only in physical properties, but also in their chemical relations. (*Journ. de Pharm.*, N. S., i. 52.) The same is true, as observed by M. Buignet, in their action on polarized light, in which they differ not only in degree, but sometimes also even in direction. (*Journ. de Pharm.*, Oct. 1861, p. 266–7.) It is not impossible that differences may exist in the juice according to the circumstances of its collection. The species of Copaifera from which the juice is collected, as well as the age of the tree, its position, and the season of collection must also have influence over the product. It is highly probable that the resin-

* The variety of copaiba found by Prof. Procter to have this low sp. gr. was of uncertain origin, but supposed to be from Para. It was of a light straw colour, very fluid, and possessed of the pure copaiba odour. It contained 80 per cent. of volatile oil and 20 of resin, and was not affected by recently calcined magnesia. It appears to be the same with a variety described by Dr. L. Posselt, of which an account is contained in the Chemical Gazette for May 1st, 1849. The view of Prof. Procter that it is the product of young trees, in which the juice has not become fully elaborated, is highly probable As the virtues of copaiba depend mainly on the oil, this variety should be more efficacious than the copaiba in common use. (*Note to the ninth edition.*)

ous matter results from oxidation of the oil in the cells of the plant, and that the less elaborated the juice may be, the larger proportion it will contain of the oil. It is said that a volatile oil flows abundantly from a tree near Bogota, which is employed to adulterate the copaiba collected in that vicinity, and shipped from Maracaybo and other neighbouring ports.

Adulterations. Copaiba is said to be frequently adulterated; but the remark is applicable rather to the markets of Europe than to those of the United States.* The fixed oils are the most frequent addition, especially castor oil, which, in consequence of its solubility in alcohol, cannot, like the others, be detected by the agency of that fluid. Various plans have been proposed for detecting the presence of castor oil. The simplest is to boil a drachm of the copaiba in a pint of water, till the liquid is wholly evaporated. If the copaiba contain a fixed oil, the residue will be more or less soft, according to the quantity present; otherwise it will be hard. Another mode, proposed by M. Planche, consists in shaking together in a bottle one part of solution of ammonia of the sp. gr. 0·9212 (22° Baumé) with two and a half parts of copaiba, at a temperature of from 50° to 60° F. The mixture, at first cloudy, quickly becomes transparent if the copaiba is pure, but remains more or less opaque if it is adulterated with castor oil. According to J. E. Simon, however, a variety of genuine copaiba occurs in commerce, in which this test fails (*Am. Journ. of Pharm.*, xvi. 236); and it does not apply to the variety containing 80 per cent. of volatile oil, described by Prof. Procter. (See *note*, p. 333.) Carbonate of magnesia, caustic potassa, and sulphuric acid have also been proposed as tests. In the late Edinburgh Pharmacopœia, it was stated that copaiba "dissolves a fourth part of its weight of carbonate of magnesia, with the aid of a gentle heat, and continues translucent." The presence of a small proportion of any fixed oil renders the mixture opaque. One part of potassa dissolved in two of water forms a clear solution with nine parts of pure copaiba, and the liquid continues clear when moderately diluted with water or alcohol; but the presence of one-sixth of fixed oil in the copaiba occasions more or less opacity in the liquid, and half the quantity causes the precipitation of white flakes in a few hours. (*Stolze.*) Turpentine, which is said to be sometimes added to copaiba, may be detected by its smell, especially if the copaiba be heated. According to Mr. Redwood, most of the proposed tests of the purity of copaiba are liable to fallacy; and the best measure of its activity is the quantity of volatile oil it affords by distillation.†

* We have a specimen of a substance imported into New York, under the name of *red copaiba*, which has not a single character of the genuine drug. It is of a thick, semifluid consistence, not unlike that of balsam of Tolu, as it often reaches us, a brown colour similar to that of the same balsam, though darker, and an unpleasant yet somewhat aromatic odour, recalling that of liquidamber, but less agreeable. Its origin is unknown. (*Note to the ninth edition.*)

† *Wood Oil. Gurjun Balsam.* In the *Pharm. Journ. and Trans.* for August, 1854 (p. 65), appeared an account, by Mr. Charles Lowe, of Manchester, of a "*new variety of balsam of copaiba*," derived from the East Indies. In a subsequent communication to the same journal (Jan. 1856, p. 321) from Mr. Daniel Hanbury, it appears that this product, though offered for sale in the London market as *balsam of copaiba*, is known in India under the names of *wood oil* and *Gurjun balsam*. Considerable quantities had been imported from Moulmein, in Burmah; and specimens of a similar drug had been received from Canara and Tenasserim: and it appears to be widely diffused in the Indian markets.

According to Roxburgh, this liquid is obtained from *Dipterocarpus turbinatus*, a very large tree, growing in Pegu, and other parts of further India. A large notch is cut in the trunk of the tree, between two and three feet from the ground, and a fire made so as to char the wound. The juice then begins to flow, and is received in suitable vessels. Every 3 or 4 weeks, the charred surface is cut off and burned anew. A single tree sometimes yields 40 gallons during the season. Other species of Dipterocarpus afford a similar product; and hence probably the difference which has been observed in the specimens examined. It is at first turbid, but may be clarified either by filtration or deposition. After filtration, wood oil is a clear, dark-brown liquid, of the sp. gr. 0·964 (*Hanbury*), and, in consistence, smell, and taste, bears a close resemblance to copaiba. It is soluble in two parts of alcohol of the sp. gr. 0·796, with the exception of a very small proportion of darkish flocculent matter, which subsides on standing. According to Lowe, it contains 65 per cent. of volatile oil, 34 of resin, and 1 of acetic acid and water. A characteristic property

Medical Properties and Uses. Copaiba is gently stimulant, diuretic, laxative, and in very large doses often actively purgative. It produces, when swallowed, a sense of heat in the throat and stomach, and extends an irritant action, not only throughout the alimentary canal, but also to the urinary passages, and in fact, in a greater or less degree, to all the mucous membranes, for which it appears to have a strong affinity. The urine acquires a peculiar odour during its use, and its smell may be detected in the breath. It sometimes occasions an eruption upon the skin, resembling that of measles, and attended with disagreeable itching and tingling. Nausea and vomiting, painful purgation, strangury and bloody urine, and a general state of fever are among the morbid results of its excessive action. As a remedy it has been found most efficient in diseases of the mucous membranes, particularly those of a chronic character. Thus, it is given with occasional advantage in leucorrhœa, gleet, chronic dysentery and diarrhœa, painful hemorrhoidal affections, and chronic bronchitis, and has recently been used, with great asserted success, in diphtheria and pseudomembranous croup. By Dr. La Roche, of Philadelphia, it is highly recommended in catarrh of the bladder, and in chronic irritation of the same organ. (*Am. Journ. of Med. Sci.*, xiv. 13.) It has been given in psoriasis and dropsy, and is said to be used as a vermifuge in Brazil. The complaint, however, in which it is most employed is gonorrhœa. It is given in all stages of the disorder; but caution is requisite when the inflammatory symptoms are high. Even in health, if taken largely, it sometimes produces very unpleasant irritation of the urinary passages, and, by sympathy, of the testicles. It was formerly much esteemed as a vulnerary, and as an application to ulcers; but it is now seldom used externally. Dr. Ruschenberger recommends it locally in chilblains. (*Med. Examiner*, i. 77.) Prof. Marchal, of Strasburg, has employed it with great success in gonorrhœa and leucorrhœa, injecting it in the form of an emulsion made with 5 parts of copaiba, 8 of gum arabic, and 100 of water, and applying it also by means of catheters or tampons smeared with the emulsion.

The dose of copaiba is from twenty drops to a fluidrachm three times a day, or a smaller quantity repeated more frequently. It may be given dropped on sugar; but in this form is often so exceedingly offensive as to render some concealment of its nauseous qualities necessary. It is sometimes given floating on the surface of an aromatic water, or mixed with an equal measure of spirit of nitrous ether. A less disagreeable form is that of emulsion, prepared by rubbing the copaiba first with mucilage or the yolk of an egg, and sugar, and afterwards with some aromatic water, as that of mint or cinnamon. The *volatile oil*, which is the active ingredient of copaiba, may be given in the dose of ten or fifteen drops, either upon sugar, or in emulsion. The resin, which has been pro-

noticed first by Mr. Lowe, by which it may be distinguished from copaiba, is that, when heated in a closed vial to 266° (230°, Lowe), it becomes slightly turbid and coagulates, so that the vial may be inverted without changing the position of its contents; and this consistence is retained when the liquid cools. By a gentle heat with agitation the fluidity returns; but the liquid again coagulates if heated to 266°. Guibourt states that it does not solidify, like copaiba, with one-sixteenth of magnesia; and the two separate on standing. (*Journ. de Pharm.*, xxx. 192.) De Vry, of Rotterdam, proposes the reaction of benzole with wood oil and copaiba respectively as a test to distinguish them. With an equal volume of the wood oil, benzole forms a turbid mixture, from which, after a long time, a resinous matter is deposited in flocculi; with copaiba it forms a transparent solution. (*Pharm. Journ.*, Jan. 1857, p. 374.) According to De Vry, the volatile oil obtained by distillation has the sp. gr. 0·928, and boils at 255°. (*Ibid.*)

Roxburgh states that this liquid is much employed in India for painting ships, houses, &c. According to Dr. O'Shaughnessy, it is little inferior to copaiba in the diseases for which that medicine is employed. Dr. T. B. Henderson has found it very successful in gonorrhœa, given in the dose of a teaspoonful two or three times a day, uncombined. He has used it only in cases where copaiba had failed; and in every case it was successful within a week, and no inconvenience occurred in any instance. (*Med. T. & Gaz.*, June, 1865, p. 571.) It probably has a similar remedial influence on diseased mucous membranes with the different turpentines, which it appears to resemble in composition. The juice may be given in emulsion, in doses of from fifteen to forty drops; the volatile oil, from ten to thirty drops. (*Note to the eleventh and thirteenth editions.*)

posed as a substitute, is nearly inert. The pills made with magnesia may sometimes be resorted to with advantage; and it is customary to administer copaiba, enclosed in capsules of gelatin, which cover the taste, while they readily dissolve in the stomach. (See *Glue*, in *Part* III.) Velpeau has found the best effects from copaiba in the form of enema. He gives two drachms made into an emulsion with the yolk of an egg, twenty or thirty drops of laudanum, and eight fluidounces of water. A distilled water of copaiba has recently been recommended by Dr. E. Langlebert both for internal use, in the dose of one or two fluidounces three or four times a day, and as a vehicle in urethral injections.

COPTIS. *U. S.*

Goldthread.

The root of Coptis trifolia. *U. S.*

Coptis. *Sex. Syst.* Polyandria Polygynia. — *Nat. Ord.* Ranunculaceæ.

Gen. Ch. Calyx none. *Petals* five or six, caducous. *Nectaries* five or six, cucullate. *Capsules* five to eight, stipitate, stellately diverging, and rostrate, many-seeded. *Nuttall.*

Coptis trifolia. Bigelow, *Am. Med. Bot.* i. 60; Barton, *Med. Bot.* ii. 97. This little evergreen has a perennial creeping root, the slenderness and bright-yellow colour of which have given rise to the common name of *goldthread*. The caudex, from which the petioles and flower-stems proceed, is invested with ovate, acuminate, yellowish, imbricated scales. The leaves, which stand on long slender footstalks, are ternate, with firm, rounded or obovate, sessile leaflets, having an acute base, a lobed and acuminately crenate margin, and a smooth veined surface. The flower-stem is slender, round, rather longer than the leaves, and surmounted by one small white flower, with a minute mucronate bracte beneath it. The petals are oblong, concave, and white; the nectaries inversely conical, hollow, and yellow at the top. The stamens have capillary filaments and globose anthers. The germs are from five to eight, stipitate, oblong, compressed, and support short recurved styles, with acute stigmas. The capsules, which diverge in a star-like form, are pedicelled, compressed, beaked, and contain numerous black seeds attached to the inner side.

The goldthread inhabits the northern regions of this continent and of Asia, and is found in Greenland and Iceland. It delights in the dark shady swamps and cold morasses of northern latitudes and Alpine regions, and abounds in Canada, and in the hilly districts of New England. We have seen it growing abundantly in the forests of N. Western Pennsylvania. Its blossoms appear in May. All parts of the plant possess more or less bitterness; but this property is most intense in the root, which is the only officinal portion.

Dried goldthread, as brought into the market, is in loosely matted masses, consisting of the long, thread-like, orange-yellow roots, frequently interlaced, and mingled with the leaves and stems of the plant. It is without smell and has a purely bitter taste, unattended with aroma or astringency. It imparts a bitterness and yellow colour to water and alcohol, but most perfectly to the latter, with which it forms a bright-yellow tincture. The infusion is precipitated by nitrate of silver and acetate of lead. (*Bigelow.*) It affords no evidence of containing either resin, gum, or tannin.

The fact of the presence of the alkaloid *berberina* in several plants, characterized by bitterness and a yellow colour, naturally suggested its existence in this root; and Professors Maisch and Procter have satisfied themselves of the truth of this conjecture. According to Prof. F. F. Mayer, the berberina is here, as in Hydrastis, associated with a colourless alkaloid, which is not precipitated by muriatic or nitric acid, but the precise nature of which does not yet appear to have been demonstrated. (*Am. Journ. of Pharm.*, March, 1863, p. 97.)

Medical Properties and Uses. Goldthread is a simple tonic bitter, bearing a

close resemblance to quassia in its mode of action, and applicable to all cases in which that medicine is prescribed, though from its higher price, not likely to come into general use as a substitute. In New England it is employed as a local application in aphthous ulcerations of the mouth; but it probably has no other virtues in this complaint than such as are common to the simple bitters. It may be given in substance, infusion, or tincture. The dose of the powder is from ten to thirty grains, of a tincture made with an ounce of the root to a pint of diluted alcohol, one fluidrachm.

Another species of Coptis has been described by Dr. Wallich, under the name of *Coptis Teeta*, which grows in the mountainous regions bordering on Assam, and is much used as a tonic by the natives, and by the Chinese. It appears to be closely analogous in properties to C. trifolia, and like it contains berberina.

W.

CORIANDRUM. *U.S.*

Coriander.

The fruit of Coriandrum sativum. *U.S.*

Off. Syn. CORIANDRI FRUCTUS. *Coriander Fruit.* The dried ripe fruit of Coriandrum sativum, cultivated in Britain. *Br.*

Coriandre, *Fr.;* Koriander, *Germ.;* Coriandro, *Ital.;* Cilantro, *Span.*

CORIANDRUM. *Sex. Syst.* Pentandria Digynia. — *Nat. Ord.* Apiaceæ or Umbelliferæ.

Gen. Ch. Corolla radiate. *Petals* inflex-emarginate. *Universal involucre* one-leafed. *Partial involucres* halved. *Fruit* spherical. *Willd.*

Coriandrum sativum. Willd. *Sp. Plant.* i. 1448; Woodv. *Med. Bot.* p. 137, t. 53. This is an annual plant, with an erect, round, smooth, branching stem, rising about two feet, and furnished with compound leaves, of which the upper are thrice ternate, with linear pointed leaflets, the lower pinnate, with the pinnæ cut into irregular serrated lobes like those of parsley. The flowers are white or rose-coloured, and in compound terminal umbels; the fruit globular, and composed of two concave hemispherical portions.

C. sativum is a native of Italy, but at present grows wild in most parts of Europe, having become naturalized in consequence of its extended cultivation. The flowers appear in June, and the fruit ripens in August. It is a singular fact, that all parts of the fresh plant are extremely fetid when bruised, while the fruit becomes fragrant by drying. This is the officinal portion. It is brought to us from Europe.

The fruit of the coriander is globular, about the eighth of an inch in diameter, obscurely ribbed, of a grayish or brownish-yellow colour, and separable into the two portions (half-fruits) of which it consists. It has the persistent calyx at its base, and is sometimes surmounted by the adhering style. The smell and taste are gratefully aromatic, and depend on a *volatile oil*, which may be obtained separate by distillation, and is said to belong to the camphene family. One pound of the seeds yields forty-two grains of the oil. (*Zeller.*) It is colourless or pale-yellow, with an agreeable odour of coriander, a mild aromatic taste, and a sp. gr. varying from 0·859 to 0·871. It is recognised among the officinals in the Br. Pharmacopœia, which employs it in the Syrup of Senna. The virtues of the fruit are imparted to alcohol by maceration, and less readily to water.

Medical Properties and Uses. Coriander has, in a moderate degree, the ordinary medicinal virtues of the aromatics. It is almost exclusively employed in combination with other medicines, either to cover their taste, to render them acceptable to the stomach, or to correct their griping qualities. It was well known to the ancients. The dose is from a scruple to a drachm.

CORNUS CIRCINATA. *U. S. Secondary.*

Round-Leaved Dogwood.

The bark of Cornus circinata. *U. S.*

Cornus. *Sex. Syst.* Tetrandria Monogynia. — *Nat. Ord.* Cornaceæ.

Gen. Ch. Involucre usually four-leaved. *Petals* superior, four. *Drupe* with a two-celled nut. *Willd.*

We have ten indigenous species of Cornus, all supposed to possess similar medical properties; and three — *C. Florida*, *C. circinata*, and *C. sericea* — are noticed in the Pharmacopœia of the United States. The last two are placed in the secondary list, not because they are esteemed less efficient than the first, but because they have hitherto attracted less attention.

Cornus circinata. Willd. *Sp. Plant.* i. 663. This is a shrub from six to ten feet high, with warty branches, large, roundish, pointed leaves, waved on their edges and downy beneath, and white flowers disposed in depressed cymes. The fruit is blue. The plant is a native of the United States, extending from Canada to Virginia, and growing on hill-sides and the banks of rivers. It flowers in June and July.

The bark, when dried, is in quills of a whitish or ash colour, and affords a powder resembling that of ipecacuanha. Its taste is bitter, astringent, and aromatic. In chemical composition, so far as this has been ascertained, it is analogous to Cornus Florida. It possesses also similar medical virtues, and may be employed in the same doses. It has been much used as a tonic and astringent in Connecticut, and was highly extolled by the late Dr. Ives, of New York, who recommended, as the most eligible preparation, an infusion made by pouring a pint of boiling water on an ounce of the coarsely powdered bark. The dose of this is from one to two fluidounces. W.

CORNUS FLORIDA. *U. S.*

Dogwood.

The bark of Cornus Florida. *U. S.*

Cornus. See CORNUS CIRCINATA.

Cornus Florida. Willd. *Sp. Plant.* i. 661; Bigelow, *Am. Med. Bot.* ii. 73; Barton, *Med. Bot.* i. 44. This is a small indigenous tree, usually about fifteen or twenty feet in height, though sometimes not less than thirty or thirty-five feet. It is of slow growth; and the stem, which generally attains a diameter of four or five inches, is compact, and covered with a brownish bark, the epidermis of which is minutely divided by numerous superficial cracks or fissures. The branches are spreading, and regularly disposed, sometimes opposite, sometimes in fours nearly in the form of crosses. The leaves are opposite, oval, about three inches long, pointed, dark-green and sulcated on the upper surface, glaucous or whitish beneath, and marked with strong parallel veins. Towards the close of summer they are speckled with black spots, and on the approach of cold weather become red. The proper flowers are small, yellowish, and collected in heads, which are surrounded by a large conspicuous involucre, consisting of four white obcordate leaves, having the notch at their summit tinged with red or purple. This involucre constitutes the chief beauty of the tree when in flower. The calyx is four-toothed, and the corolla composed of four obtuse reflexed petals. The fruit is an oval drupe, of a vivid glossy redness, containing a two-celled and two-seeded nucleus. The drupes are usually associated together to the number of three or four, and remain on the tree till after the early frosts. They ripen in September.

The dogwood is found in all parts of the United States, from Massachusetts to the Mississippi and the Gulf of Mexico; but is most abundant in the Middle States. In the month of May, it is clothed with a profusion of large white blos-

soms, which render it one of the most conspicuous ornaments of the American forests. The bark is the officinal portion, and is derived for use both from the stem and branches, and from the root. That from the root is preferred.

As brought into market, the bark is in pieces of various size, usually more or less rolled, sometimes invested with a fawn-coloured epidermis, sometimes partially or wholly deprived of it, of a reddish-gray colour, very brittle, and affording, when pulverized, a grayish powder tinged with red. The odour of dogwood is feeble, its taste bitter, astringent, and slightly aromatic. Water and alcohol extract its virtues. It has not been accurately analyzed; but, from the experiments of Dr. Walker and Mr. James Cockburn (*Am. Journ. of Pharm.*, vii. 109), appears to contain bitter extractive, gum, resin, tannin, gallic acid, fixed oil, wax, red colouring matter, lignin, and salts of potassa and iron. Mr. Cockburn also obtained a crystallized substance, without taste, the characters of which, however, were not sufficiently investigated to authorize an opinion as to its nature. A peculiar bitter principle, for which the name of *cornine* was proposed, was announced as an ingredient by Mr. Carpenter; but his results have not been confirmed. More recently, an examination of the bark, with a view to the isolation of its active principle, has been made by Prof. John M. Maisch, who appears to have obtained the bitter principle pure in solution, but, in consequence of its extreme facility of decomposition, could not succeed in isolating it in the solid state. He inferred, however, that it is a neuter, colourless substance, very soluble in water and alcohol, insoluble in ether, not capable of precipitation by chemical reagents, but very easily destroyed on exposure to the air. (*Proceed. of Am. Pharm. Assoc.*, 1859, p. 315.) The flowers of *C. Florida* have the same bitter taste as the bark, and, though not officinal, are sometimes employed for the same purposes.

Medical Properties and Uses. Cornus Florida is tonic and astringent. By Dr. Walker it was found, when taken internally, to increase the force and frequency of the pulse, and the heat of the body. It is thought to possess remedial properties analogous to those of Peruvian bark, for which it has occasionally been successfully substituted in the treatment of intermittent fevers; but the introduction of sulphate of quinia into use has nearly banished this, as well as many other substitutes for cinchona, from regular practice. The dogwood has also been employed in low fevers, and other complaints for which Peruvian bark is usually prescribed.

It may be given in powder, decoction, or extract. The dose of the powder is from a scruple to a drachm, repeated, in cases of intermittent fever, so that from one to two ounces may be taken in the interval between the paroxysms. The decoction is officinal. (See *Decoctum Cornûs Floridæ.*) The dried bark is said to be preferable to the fresh; as it possesses all the activity of the latter, without being equally liable to offend the stomach and bowels. An extract might probably be used with advantage in intermittents in large doses.

Off. Prep. Decoctum Cornûs Floridæ, *U. S.* W.

CORNUS SERICEA. *U. S. Secondary.*

Swamp Dogwood.

The bark of Cornus sericea. *U. S.*

Cornus. See CORNUS CIRCINATA.

Cornus sericea. Willd. *Sp. Plant.* i. 663; Barton, *Med. Bot.* i. 115. This species of Cornus is usually six or eight feet in height, with numerous erect stems, which are covered with a shining reddish bark, and send out opposite spreading branches. The young shoots are more or less pubescent. The leaves are opposite, petiolate, ovate, pointed, entire, and on the under surface covered with soft brownish hairs. The flowers are small, white, and disposed in terminal cymes, which are depressed and woolly. The fruit consists of globular, berry-formed drupes, of a cerulean blue colour, and collected in bunches.

The swamp dogwood inhabits the United States from Canada to Carolina, and is found in moist woods, in swamps, and on the borders of streams. It flowers in June and July. The bark was ascertained by Dr. Walker to have the same medical properties as that of Cornus Florida. It may be given in the same doses, and administered in a similar manner. W.

COTULA. *U. S. Secondary.*

Mayweed.

The herb of Anthemis Cotula, Maruta Cotula (*De Candolle*). *U. S.*

Camomille puante, Maroute, *Fr.;* Hunds-Kamille, Stinkende-Kamille, *Germ.;* Camomilla fetida, Cotula, *Ital.;* Manzanilla loca, *Span.*

ANTHEMIS. See ANTHEMIS.

Anthemis Cotula. Willd. *Sp. Plant.* iii. 2181; Barton, *Med. Bot.* i. 161.—*Maruta Cotula.* De Cand. *Prodrom.* vi. 13. The mayweed is an annual plant, with a fibrous root, and an erect, striated stem, very much branched even to the bottom, from one to two feet in height, and supporting alternate, sessile, flat, doubly pinnated, somewhat hairy leaves, with pointed linear leaflets. The flowers stand singly upon the summits of the branches, and consist of a central, convex, golden-yellow disk, with white radial florets, which spread horizontally during the day, but are reflexed, or bent towards the stem at night. The calyx, which is common to all the florets, is hemispherical, and composed of imbricated hairy scales. The receptacle is conical or nearly cylindrical, and surmounted by rigid, bristle-shaped paleæ, shorter than the florets. The seeds are naked.

This plant grows abundantly both in the United States and Europe. In this country it is found in the vicinity of inhabited places, growing among rubbish, along the sides of roads, and in waste grounds. Notwithstanding its extensive diffusion, it is generally believed to be a naturalized and not an indigenous plant. It is frequently called *wild chamomile.* It flowers from the middle of summer till late in autumn.

Mr. W. H. Warner, from a chemical examination of the flowers, concluded that they contain volatile oil, oxalic, valerianic, and tannic acids, colouring matter, acrid fatty matter, bitter extractive, and salts of potassa, lime, magnesia, and iron. (*Am. Journ. of Pharm.*, Sept. 1858, p. 390.)

The whole plant has a strong, disagreeable smell, and a warm, bitter taste, and imparts these properties to water.

The medical properties of this species of Anthemis are essentially the same as those of chamomile, for which it may be substituted; but its disagreeable odour is an obstacle to its general use. On the continent of Europe, it has been given in nervous diseases, especially in hysteria, under the impression, probably derived from its peculiar smell, that it possesses antispasmodic powers. It has also been thought to be emmenagogue. It is said to have the property of vesicating, if applied to the surface fresh and bruised. In this country it is scarcely employed, except as a domestic remedy. The whole plant is active; but the flowers, being less disagreeable than the leaves, are preferred for internal use. The remedy is best administered in the state of infusion. W.

CREASOTUM. *U. S., Br.*

Creasote.

A peculiar substance obtained from wood-tar. *U. S.* A product of the distillation of wood-tar. *Br.*

This is a substance of the nature of the volatile oils, discovered in 1830 by Reichenbach in the products of the distillation of wood. M. Deville conceives that it is a volatile oil, derived by heat from the resin of wood, and isomeric with the original volatile oil, from which the resin is supposed to have been formed by a slow alteration occurring in the vegetable. It may, therefore, be classed with the volatile oils which are regenerated by distillation.

In the products of the distillation of organic substances generally, whether vegetable or animal, Reichenbach also discovered five other principles, called paraffin, eupion, picamar, capnomor, and pittacal, which, as being associated with creasote, will be here described. *Paraffin* is a solid carbohydrogen, most abundantly obtained by distilling cannel-coal, when it comes over with certain isomeric oils, several of the least volatile of which, appearing towards the close of the distillation, form a mixture called *paraffin oil*. Mr. Young, an English manufacturing chemist, has succeeded in obtaining paraffin from this coal in the proportion of thirteen pounds to the ton. Crude paraffin, as first obtained, is recommended to be purified by R. Reichenbach, the son of the discoverer, by distillation from fuming sulphuric acid, which destroys an empyreumatic substance by which it is contaminated. Paraffin is a white crystalline solid, resembling white wax, for which it has been proposed as a substitute in the composition of cerates. It is devoid of taste and smell, and is characterized by its feeble affinity for other bodies, as indicated by its name, from *parum affinis*. It resists the action of concentrated acids and alkalies. It burns with a bright, white flame, without smoke. At present it is much used in England as a lubricating substance for machinery, and to a considerable extent as a material for candles. It is also prepared in this country for practical purposes. A rich bituminous coal, rivaling the Boghead cannel-coal of England, has been discovered in Western Virginia, and is the source of the American paraffin. (*Proceedings of the Am. Pharm. Assoc.*, Sept. 1856.) The product of paraffin oil from a ton of English cannel-coal, as manufactured by Mr. Young, is about thirty gallons. This also is a good lubricating substance. The empirical formula of paraffin is CH in equal equivalents, but how many of each element is not known. *Eupion* is an inodorous, insipid, limpid, and colourless liquid, of the sp. gr. 0·740, obtained most abundantly from animal tar and Dippel's animal oil. It likewise consists exclusively of carbon and hydrogen. *Picamar* is a colourless, oily liquid, heavier than water, of a peculiar odour and very bitter taste. It is present in the heaviest portion of the rectified oil of tar, and constitutes the bitter principle of that substance. *Capnomor*, so called from being an ingredient of smoke, is a colourless liquid, lighter than water, having a pleasant odour and pungent taste, and occurring in the heavy oil of tar, and in coal naphtha. It has the property of dissolving caoutchouc. *Pittacal*, also obtained from the heavy oil of tar, is a solid of a beautiful blue colour, differing from the substances above noticed in containing nitrogen as one of its elements.

Preparation. Creasote is obtained either from wood tar or from crude pyroligneous acid. When wood tar is used, it is distilled until it has attained the consistence of pitch. The distilled liquid divides itself into three layers, an aqueous between two oily layers. The inferior oily layer, which alone contains the creasote, is separated, and saturated with carbonate of potassa to remove acetic acid. The liquid is allowed to rest, and the new oil which separates is decanted from it. This oil is distilled, and yields products lighter than water, and a liquid heavier. The latter alone is preserved, and, after having been agitated repeatedly with weak phosphoric acid to neutralize ammonia, is allowed to remain at rest for some time. It is next washed as long as acidity is removed, and then distilled with a fresh portion of weak phosphoric acid; care being taken to cohobate from time to time. The oily liquid thus rectified is colourless, and contains much creasote, but also a portion of eupion. To separate the latter, the liquid is mixed with a solution of caustic potassa of the density 1·12, which dissolves the creasote, but not the eupion. The eupion, which swims above from its levity, is then separated; and the alkaline solution of the creasote is exposed to the air, until it becomes brown in consequence of the decomposition of a foreign matter, and is then saturated with sulphuric acid. This sets free the creasote, which is decanted and again distilled. The treatment by solution of potassa, sulphuric acid, &c. is to be repeated until the creasote no longer becomes brown by exposure to the air, but only slightly reddish. It is then dissolved in a stronger solution of potassa and distilled again, and finally redistilled for the

last time, rejecting the first portion which comes over on account of its containing much water, collecting the next portion, and avoiding to push the distillation too far. The product collected in this distillation is creasote.

When creasote is extracted from pyroligneous acid, the first step is to dissolve sulphate of soda in it to saturation. The oil which separates and swims above is decanted, and, having been allowed to remain at rest for a few days, is saturated by carbonate of potassa with the assistance of heat, and distilled with water. The oleaginous liquid obtained is of a pale-yellow colour, and is to be treated with phosphoric acid, &c., as above detailed, in relation to the treatment of the corresponding oil obtained from wood tar.

According to M. Koene, the tar of the pine furnishes but little pure creasote; while coal tar yields nearly five drachms to the pint. This, however, is not properly creasote, but a liquid having analogous properties, consisting chiefly of carbolic or phenylic and of cresylic acid.

At present there is very little genuine creasote in our market, the impure mixture of carbolic and cresylic acids just referred to, as being obtained from coal tar, having been substituted for it, and often sold under its name.

Properties. Creasote, when pure, is a colourless oleaginous liquid, of the consistence of oil of almonds, slightly greasy to the touch, volatilizable by heat, and having a caustic, burning taste, and a penetrating, disagreeable odour, like that of smoked meat, and analogous to, yet different from that of phenylic acid. As met with in the shops, it has frequently a brownish tinge. It burns with a sooty flame. Applied in a concentrated state to the skin, it corrugates and then destroys the cuticle, causing a white spot. On paper it leaves a greasy stain, which disappears in a few hours, or in ten minutes when heated to about 212°. Its sp. gr. is 1·057 at 55° (*Gorup-Besanez*), 1·046 (*U. S.*), 1·071 (*Br.*). It boils at 397°, and remains fluid at 17° below zero. It is a non-conductor of electricity, and a powerful refractor of light. It is devoid of acid or alkaline reaction. Mixed with water, it forms two solutions; one consisting of one part of creasote and about 80 of water, the other, of 1 part of water and 10 of creasote. (*Berzelius.*) It unites in all proportions with alcohol, ether, naphtha, and bisulphuret of carbon, and is dissolved freely by acetic acid. It dissolves a large proportion of iodine and phosphorus, and a considerable amount of sulphur, especially when assisted by heat.

Creasote forms two combinations with potassa; one anhydrous, of an oleaginous consistence, the other hydrated, and in the form of small, white, pearly scales. It forms similar compounds with soda. Its formula is $C_{28}H_{16}O_4$ (*Regnault*), or $C_{14}H_8O_2$ (*Fownes*); but it is differently given by other authorities; and the probability is that creasote, as ordinarily obtained at least, is not a definite principle. Creasote instantly dissolves ammonia, and retains it with great force. Strong nitric and sulphuric acids decompose it; the former giving rise to reddish vapours, the latter to a red colour, which becomes black on the addition of more of the acid. Dilute nitric acid converts it into a brown resin, which, treated with ammonia, and then dissolved in boiling alcohol, gives, by evaporation, certain salts of ammonia, two of which contain new acids, discovered by Laurent. Muriatic acid produces no change in it. The following tests will distinguish it from carbolic or phenylic acid from coal tar, which in some respects strongly resembles it. A splinter of pine wood, dipped first into an alkaline solution of carbolic acid and allowed to dry, and subsequently into muriatic acid, will after a time assume a deep blue colour. Creasote does not produce the same effect. The British Pharmacopœia gives, as one of the characters of its creasote, that a "slip of deal dipped into it, and afterwards into hydrochloric acid, and then allowed to dry in the air, acquires a greenish-blue colour;" and consequently does not consider the presence of phenylic acid as a contamination. The probability is that the creasote upon which the description in the British Pharmacopœia was prepared was not really derived from wood, but from coal tar. The true creasote differs from carbolic acid in not coagulating collodion. M. Gorup states that with a neutral solution of

perchloride of iron, beech-wood creasote, dissolved in alcohol, gives a green colour, whilst a similar solution of the product of coal tar causes a brown colour; but, dissolved in water, the true creasote produces no change, while coal tar creasote produces a blue. (*Am. Journ. of Pharm.*, May, 1868, p. 257.) Creasote dissolves a large number of metallic salts, and reduces a few to the metallic state; as, for example, nitrate and acetate of silver. It powerfully coagulates albumen, and in this way is supposed to act as a hemostatic.

Of all the properties of creasote, the most remarkable is its power of preserving meat. It is this property which has suggested its name, derived from *κρεὰς flesh*, and *σώζω I preserve.*

Impurities and Adulterations Creasote is apt to contain eupion, picamar, and capnomor, and is sometimes adulterated with rectified oil of tar, and the fixed and volatile oils. All these substances are detected by strong acetic acid, which dissolves the creasote, and leaves them behind, floating above the creasote solution. Creasote, however, from beech-wood tar, is only partially dissolved by hot acetic acid of ordinary strength. Fixed oils are also discovered by a stain on paper, not discharged by heat. Any trace of the matter which produces the brownish tinge (see *page* 341) is detected by the liquid becoming discoloured by exposure to sunshine.

Commercial creasote almost always contains carbolic and cresylic acids, from coal tar; and, indeed, there is reason to believe that what is now sold for creasote, is generally nothing more than impure carbolic or phenylic acid. (See *Acidum Carbolicum.*) It has been already stated that this acid strongly resembles creasote; and this resemblance probably extends also to their therapeutical effects; so that the substitution is less to be regretted than might otherwise be the case. But as the effects of the two on the system may not be identical, and those from creasote have been verified by a long experience, it is highly desirable to be able to distinguish between them. Tests for this purpose have been given above; and the following observations are to the same effect. The substitution of phenylic acid may be discovered by its lower boiling point (368° F.). Its presence in creasote is detected by the addition of sesquichloride of iron, which causes a violet-blue colour, and afterwards a whitish turbidness, if this impurity is present. According to Mr. E. N. Kent, of New York, phenylic acid from the oil of coal tar, and creasote from wood tar are essentially the same; the former being a purer state of the latter. (*N. Y. Journ. of Pharm.*, Oct. 1853.) This view is contradicted by the results of Gorup-Besanez, who obtained creasote which did not respond to the tests of phenylic acid. Still he admits that creasote, as pure as he could get it with a boiling point between 398° and 406°, is not a chemically definite compound. Gmelin considers the creasote from wood tar, and the carbolic acid from coal tar, as differing from each other only in the degree of purity; but this opinion is irreconcilable with facts at present known.

Medical Properties, &c. Creasote is irritant, narcotic, styptic, antiseptic, and moderately escharotic. Internally, it has been employed in a number of diseases; externally, for the most part, as an application to eruptions, wounds, and ulcers, and as an injection and gargle. Dr. R. Dick, of Glasgow, recommends it as an internal remedy in chronic gonorrhœa and gleet. Dr. Elliotson, of London, considers it an efficacious remedy in arresting nausea and vomiting, when not dependent on inflammation or structural disease of the stomach, as in hysteria, pregnancy, and sea-sickness. Mr. Kesteven, of England, found it a very useful remedy in diarrhœa; and others have confirmed this statement. Dr. D. J. Cain, of Charleston, used it with advantage in cholera morbus and cholera infantum, either alone, or conjoined with charcoal, chalk, or bicarbonate of soda. It has also been used with benefit in dysentery and malignant cholera; and has been recommended in pectoral affections with purulent expectoration.

The eruptions, to the treatment of which creasote has been supposed to be best suited, are those of a scaly character. In burns its efficacy has been insisted on, especially in those attended with excessive suppuration and fungous granu-

lations. In chilblains also it is stated to be a useful application. Mixed with four parts of lard, it is said to have proved very serviceable in erysipelas. When applied to wounds it acts as a hemostatic, stopping the capillary hemorrhage, but possesses no power to arrest the bleeding from large vessels. Accordingly, creasote water has been applied locally in menorrhagia, and to arrest uterine hemorrhage and the bleeding from leech-bites. The ulcers, in the treatment of which it has been found most useful, are those of an indolent and gangrenous character, in which its several properties of escharotic, stimulant, and antiseptic are usefully brought into play. It is also praised as an application to syphilitic, scrofulous, and cancerous ulcers, and to malignant pustule. In all these cases, should the remedy cause irritation, it must be suspended, or alternated with emollient and soothing applications. Injected into fistulous ulcers, it proves a useful resource, by exciting the callous surfaces, and disposing them to unite. Dr. Hildreth, of Zanesville, Ohio, found it efficacious, mixed with mercurial ointment, in the proportion of from ten to thirty drops to the ounce, in scrofulous ophthalmia, and scrofulous ulceration of the cornea. A small portion of the ointment is introduced under the upper eyelid, morning and evening, and rubbed over the whole globe. The application should be strong enough to produce a smarting pain for about five minutes. The local must of course be combined with constitutional treatment. In chronic varicose ophthalmia it is a valuable remedy, in the form of collyrium, of the strength of from one to three drops to the fluidounce of water. In putrid sorethroat, requiring the use of a stimulant and antiseptic, a gargle of creasote acts beneficially; and in chronic suppuration of the external meatus of the ear, it is valuable as an injection. It has been much used topically in diphtheria, in which it corrects the fetor, and is said to cure the local affection. In deafness from deficient cerumen, Mr. Curtis has found it useful. The meatus is first well cleansed, and afterwards brushed over, night and morning, by means of a camel's-hair brush, with a mixture formed of a drachm of creasote and four drachms of oil of almonds. The meatus may be cleansed by dropping into the ear at night a few drops of olive oil, and syringing it out the next morning with a weak and warm solution of castile soap, to which a sixth of Cologne water has been added. This may be repeated for five or six days, if required. In leucorrhœa M. Arendt has found creasote very useful in the form of injection, made with two drops to the fluidounce of water, used several times a day. Dr. Mackenzie has derived advantage from it as a vaginal injection in puerperal fever, arising from the absorption of vitiated secretions. It is also efficacious in the destruction of warts, applied freely every day or two, and kept on by adhesive plaster. In toothache, depending on caries of the tooth and exposure of the nerve, creasote often acts promptly and radically in the removal of the pain. One or two drops of the pure substance must be carefully introduced into the hollow of the tooth, on a little cotton, avoiding contact with the tongue or cheek. To render it effectual, the hollow of the tooth must be well cleansed before it is applied. A mixture of 15 parts of creasote and ten of collodion is said to have a jelly-like consistence, and to be usefully applied to carious teeth, which it protects from the air; but as proper creasote does not coagulate collodion, this remark applies to the impure carbolic acid, before stated to be commonly sold under the same name.

Creasote is employed in the pure state, in mixture or solution, and in the form of ointment. (See *Mistura Creasoti* and *Unguentum Creasoti.*) In the pure state, it may be brushed over indolent or ill-conditioned ulcers, or applied to them by means of lint. Internally it is given in the dose of from one to two drops or more, repeated several times a day, diluted with weak mucilage in the proportion of half a fluidounce to the drop. When used as a lotion for eruptions, ulcers, or burns, or as a gargle or injection, it is employed in solution, containing two, four, or six drops to the fluidounce of water; the strength being determined by the circumstances of each particular case. In some cases the solution of creasote is used externally, mixed with poultices.

Under the name of VAPOR CREASOTI (*Inhalation of Creasote*), the British Pharmacopœia directs a preparation consisting of 12 minims of crea-

sote and 8 fluidounces of boiling water, which are to be mixed in an inhaling apparatus, so arranged that the air shall be made to pass through the solution and then inhaled. It may be used in chronic inflammation of the air-passages.

Creasote, in an overdose, acts as a poison. It produces giddiness, obscurity of vision, depressed action of the heart, convulsions, and coma. No antidote is known. The medical treatment consists in the evacuation of the poison, and the administration of ammonia and other stimulants.

The addition of three or four drops of creasote to a pint of ink effectually prevents it from becoming mouldy. Dr. Christison finds that creasote water is as good a preservative of some anatomical preparations as spirit, with the advantage of not hardening the parts. It is probably to creasote that the antiseptic properties of wood-smoke and of pyroligneous acid are owing.

CRETA. *U. S., Br.*

Chalk.

Native friable carbonate of lime. *U. S., Br.*

Craie, *Fr.;* Kreide, *Germ.;* Creta, *Ital.;* Greda, *Span., Port.*

Carbonate of lime, in the extended meaning of the term, is the most abundant of simple minerals, constituting, according to its state of aggregation and other peculiarities, the different varieties of calcareous spar, common and shell limestone, marble, marl, and chalk. It occurs also in the animal kingdom, forming the principal part of shells, and a small proportion of the bones of the higher orders of animals. It is present in small quantity in most natural waters, being held in solution by the carbonic acid which they contain. In the waters of limestone districts it is a very common impregnation, and causes purging in those not accustomed to their use. In all such cases, boiling the water by expelling the carbonic acid, causes the carbonate to be deposited. It has been shown, however, that carbonate of lime is itself in a slight degree soluble in water; so that a small proportion remains in limestone water, which has been long exposed to boiling. Hofmann estimated the quantity remaining in solution at 34 thousandths of a gramme in a litre. That the carbonate is not held in solution by free carbonic acid is shown by the fact that lime-water causes no precipitation. (*Journ. de Pharm. et de Chim.*, 4e sér., iii. 147.) Besides being officinal in the state of chalk, carbonate of lime is also ordered as it exists in marble and oyster-shell, and as obtained by precipitation. (See *Marmor*, *Testa*, and *Calcis Carbonas Præcipitata.*) In the present article we shall confine our observations to chalk. This occurs abundantly in the south of England and north of France. It exists massive in beds, and very frequently contains nodules of flint, and fossil remains of land and marine animals. Until recently it was not known to exist in the United States; but Prof. F. V. Hayden states that he observed it in great abundance in Dakota Territory, constituting beds which extend for 400 miles along the Missouri river. He considers this deposit as identical in character with the chalk beds of Europe, and applicable to the same useful purposes. (*Am. Journ. of Sci. and Arts*, xliii. 16, A.D. 1867.)

Properties. Chalk is an insipid, inodorous, insoluble, opaque, soft solid, generally white, but grayish-white when impure. It is rough to the touch, easily pulverized, and breaks with an earthy fracture. It soils the fingers, yields a white trace when drawn across an unyielding surface, and when applied to the tongue adheres slightly. Its sp. gr. varies from 2·3 to 2·6. It is never a perfectly pure carbonate of lime; but contains, besides gritty silicious particles, small portions of alumina and of oxidized iron. If pure it is entirely soluble in muriatic acid; but usually a little silica is left. If the muriatic solution is not precipitated by ammonia, it is free from alumina and iron. Like all carbonates, it effervesces with acids. Though insoluble in water, it dissolves in an excess of carbonic acid. It consists, like the other varieties of carbonate of lime, of one eq. of carbonic acid 22, and one of lime 28 = 50.

Chalk, on account of the gritty particles which it contains, is unfit for medicinal use, until it has undergone levigation, when it is called *prepared chalk.* (See *Creta Præparata.*)*

Crocus sativus. Willd. *Sp. Plant.* i. 194; Woodv. *Med. Bot.* p. 763, t. 259. The common cultivated saffron is a perennial plant, with a rounded and depressed bulb or cormus, from which the flower rises a little above the ground, upon a long, slender, white, and succulent tube. The flower is large, of a beautiful lilac or bluish-purple colour, and appears in September or October. The leaves are radical, linear, slightly revolute, dark-green upon their upper surface with a white longitudinal furrow in the centre, paler underneath with a prominent flattened midrib, and enclosed at their base, together with the tube of the corolla, in a membranous sheath, from which they emerge soon after the appearance of the flower. The style bangs out on one side between the two segments of the corolla, and terminates in three long convoluted stigmas, which are of a rich orange colour, highly odorous, rolled in at the edges, and notched at the summit. These stigmas are the officinal part of the plant.

* *Chalk as a ferment.* That chalk consists mainly of the mineral remains of extremely minute organized beings has been for years a recognised fact. M. A. Bechamp states that these were so minute that the remains of more than two millions of them are contained in 100 grammes of chalk. Another important fact in relation to chalk, familiar to chemists, is that it has the power, under certain circumstances, of promoting fermentation. In relation to this point, M. Bechamp has recently made some highly interesting statements in a communication to the Academy of Sciences of Paris, reported in the *Journal de Pharmacie et de Chimie* (4e sér., iv. 279, A.D. 1866), from which the following abstract has been made.

According to M. Bechamp, there are in chalk, besides the remains of former organized beings, innumerable organisms, smaller than any hitherto known, smaller than any of the infusoria or microphytes now studied in connection with fermentation. These are still living, though doubtless very old. They act powerfully as fermenting agents, the most powerful that M. Bechamp has ever met with, and capable of nourishing themselves on the most diversified organic substances. Powdered chalk, taken from the centre of masses immediately from the quarry far beneath the surface, so that it could have derived nothing from the air, and rubbed with distilled water, exhibits, under a powerful microscope, numerous shining points, agitated with a lively movement of trepidation. M. Bechamp considers them as living organisms, the smallest yet known; and in support of this opinion advances these two proofs; first, that chalk acts as a ferment without the presence of albuminoid matter, and, secondly, that these bodies can be isolated, and shown by analysis to consist of carbon, hydrogen, oxygen, and nitrogen. If chalk is mixed with starch and a little creasote, and another mixture of a similar kind be made with pure carbonate of lime, on the second day no change will have occurred in the latter mixture, while the former will show evident signs of fermentation, notwithstanding the repressive force of the creasote, which checks other fermentations. The results of the fermentation thus produced are alcohol, butyric acid, acetic acid largely, and signs of lactic acid; and sugar, under similar circumstances, undergoes similar changes. To prevent the chalk from thus acting, its temperature must be raised to 300° Cent. With due precaution, assurance may be had that no other ferment is present; while that of the chalk is increased in quantity. To prove by analysis the organic nature of these bodies, if chalk be treated with dilute muriatic acid, 1·15 per cent. will be left undissolved, of which 7·17 per cent. may be shown to be organic, by yielding on decomposition, carbon, hydrogen, and nitrogen. M. Bechamp proposes for these newly discovered beings the name of *Microzyma cretæ.* The Microzyma is found everywhere, accompanying several other ferments, in certain mineral waters, and in cultivated earth. (*Note to the thirteenth edition.*)

C. sativus, or *autumnal crocus*, is a native of Greece and Asia Minor, where it has been cultivated from the earliest ages. It is also cultivated for medicinal use in Sicily, Spain, France, England, and other temperate countries of Europe. Large quantities of saffron are raised in Egypt, Persia, and Cashmere, whence it is sent to India. Much of the drug reaches the market of Constantinople from the neighbourhood of Tifflis and the Caucasus. We cultivate the plant in this country chiefly, if not solely, as a garden flower. It is liable to two diseases, which interfere with its culture; one dependent on a parasitic fungus which attaches itself to the bulb, the other called by the cultivators in France *tacon*, by which the bulb is converted into a blackish powder. (*Journ. de Pharm.*, xviii. 41.)

In England the flowers appear in October, and the leaves continue green through the winter; but the plant does not ripen its seed, and is propagated by offsets from the bulb. These are planted in grounds prepared for the purpose, and are arranged either in rows, or in small patches at certain distances. The flowers are gathered soon after they show themselves, as the period of flowering is very short. The stigmas, or summits of the pistils, together with a portion of the style, are separated from the remainder of the flower, and carefully dried by artificial heat, or in the sun. During this process, they are sometimes made to assume the form of a cake by pressure; but the finest saffron is that which has been dried loosely. The two forms are distinguished by the names of *cake-saffron* and *hay-saffron*. Five pounds of the fresh stigmas are said to yield one pound of the dried.

The English saffron, formerly most highly esteemed in this country, has disappeared from our market. What may be sold under the name is probably derived from other sources. Much of the drug is imported from Gibraltar, packed in canisters. Parcels of it are also brought from Trieste, and other ports of the Mediterranean. The Spanish saffron is generally considered the best. Genuine *cake-saffron* is at present seldom found in commerce. According to Landerer, the stigmas of several other species besides those of C. sativus are gathered and sold as saffron in Greece and Turkey.*

Properties. Saffron has a peculiar, sweetish, aromatic odour, a warm, pungent, bitter taste, and a rich deep-orange colour, which it imparts to the saliva when chewed. The stigmas of which it consists are an inch or more in length, expanded and notched at the upper extremity, and narrowing towards the lower, where they terminate in a slender, capillary, yellowish portion, forming a part of the style. Analyzed by Vogel and Bouillon-Lagrange, it afforded 65·0 per

* At the International Exhibition, in London, in the year 1862, the author noticed a specimen of saffron, from the island of Ceylon, closely resembling that of the Crocus sativus. It consisted of the stigmas of the *Crocus orientalis*. (*Note to the twelfth edition.*)

In a communication by Mr. Charles A. Heinitsh, to the American Pharmaceutical Association, A.D. 1866, it is stated that until within a few years, saffron was cultivated to a considerable extent in Lancaster Co., Pennsylvania. The plant requires a rich soil, which should be deeply dug and heavily manured. The bulbs are planted in August, eight inches apart, and the growing plant should be kept free from weeds. The flowering period begins about the middle of September, and continues till the beginning of October. The flowers are picked early in the morning, and the stigmas separated and dried in the shade. This is done every day during the period of flowering. He thinks the cultivation can be profitably conducted. A plot of 72 square feet will produce 9000 stigmas, weighing 420 grains, or from 33 to 36 lbs. to the acre; and at present prices this would be remunerative to the grower. (*Am. Journ. of Pharm.*, Jan. 1867, p. 38.)

M. Monthus, an experienced cultivator in France, prefers a dry calcareous soil; plants the bulbs 3 or 4 inches deep; after the harvest in October manures the ground, and renews the planting every three years. He thus prevents the diseases peculiar to the plant.

M. Monthus recommends the *petals* of the flower as applicable to the same purposes as the stigmas, having found them to be possessed of aromatic properties. They demand no peculiar caution in drying; but to preserve them it is necessary to exclude light and moisture. Acids redden them with extreme facility, and alkalies turn them green. He, therefore, recommends a tincture to be made from them, as a substitute for syrup of violets. He prepares the tincture by macerating 10 parts of the dried flowers in 100 parts of alcohol of 40°, for 48 hours. A longer maceration would destroy the colour. Paper may be stained with the tincture, and kept green or red, the former for acids, the latter for alkalies. (*Journ. de Pharm.*, Juillet, 1867, p. 54.)—*Note to the thirteenth edition.*

cent. of a peculiar extractive matter, and 7·5 of an odorous volatile oil, together with wax, gum, albumen, saline matter, water, and lignin. The extractive was named *polychroïte*, from the changes of colour which it undergoes by the action of reagents. They prepared it by evaporating the watery infusion to the consistence of honey, digesting the residue in alcohol, filtering the tincture, and evaporating it to dryness. Thus obtained, it is in the form of a reddish-yellow mass, of an agreeable smell, slightly bitter, soluble in water and alcohol, and somewhat deliquescent. Its solution becomes grass-green by the action of nitric acid, blue and then violet by that of sulphuric acid, and loses its colour altogether on exposure to light, and by chlorine. M. Henry, sen., found it to contain about 20 per cent. of volatile oil, which could be separated only by an alkali. M. Quadrat obtained it pure by exhausting saffron with ether, then treating it with boiling water, precipitating with subacetate of lead, decomposing the compound of oxide of lead and colouring matter thus obtained with sulphuretted hydrogen, treating the precipitate with boiling alcohol, evaporating the solution, dissolving the residue in water, and lastly evaporating by means of a water-bath. Thus procured, it is of a brilliant red colour, inodorous, slightly soluble in water which it renders yellow, much more soluble by the least addition of an alkali, readily soluble in alcohol, but sparingly in ether. Its formula is $C_{20}H_{13}O_{11}$. M. Quadrat found also, in saffron, a fatty matter, glucose, and a peculiar acid. (*Ann. der Chem. und Pharm.*, lxxx. 340.) According to M. Henry, the colouring principle constitutes 42 per cent. of saffron, and the essential oil 10 per cent. It is to the latter that the medicine owes its activity. It may be partially separated by distillation. It is yellow, of a hot, acrid, bitterish taste, and heavier than water, in which it is slightly soluble. According to B. Huss, polychroïte appears to be a glucoside, splitting, when treated with sulphuric acid, into sugar, a volatile oil, and a secondary colouring matter, which he calls *crocin*. (*Chem. News*, Jan. 3, 1868, p. 9.)

Adulterations. The high price of this medicine gives rise to frequent adulterations. Water is said to be very often added in order to increase its weight. Oil is also added for the same purpose, or to improve the appearance. Sometimes the flowers of other plants, particularly *Carthamus tinctorius* or safflower, *Calendula officinalis* or officinal marygold, and *arnica*, are fraudulently mixed with the genuine stigmas. They may be known by their shape, which is rendered obvious by throwing a portion of the suspected mass into hot water, which causes them to expand. (See *Carthamus*.) Other adulterations are the fibres of dried beef, the stamens of the Crocus distinguishable by their yellow colour, the stigmas previously exhausted in the preparation of the infusion or tincture, and various mineral substances easily detected upon close examination. The flowers of a Brazilian plant, named *Fuminella*, have, according to M. J. L. Soubeiran, been recently employed for the adulteration of saffron. They may be detected by shaking gently but repeatedly a large pinch of the suspected saffron over a piece of paper. The flowers of Fuminella being smaller and heavier, separate and fall, and may be seen to consist of very short fragments, with a colour like that of saffron, but a rusty tint which the latter does not possess. (*Journ. de Pharm.*, Avril, 1855, p. 267.) J. Müller recommends concentrated sulphuric acid as the most certain test of saffron. It instantly changes the colour of pure saffron to indigo blue. (*Chem. Gaz.*, May, 1845, p. 197.)

Attention has been called to a product of the Cape of Good Hope, named *Cape saffron*, which has a remarkable resemblance to genuine saffron, having a similar odour, and yielding a similar colour to water, though the flowers themselves are differently coloured. It is the flower of a small plant very abundant at the Cape, belonging to the family of *Scrophulariaceæ*, and is said by Dr. Pappé, of Cape Town, to possess medical virtues closely resembling those of the proper saffron. The flowers have been used successfully in the convulsions of children (*Pharm. Journ. and Trans.*, N. S., vi. 462, A.D. 1865.)

Choice of Saffron. Saffron should not be very moist, nor very dry, nor easily pulverized; nor should it emit an offensive smell when thrown upon live coals.

The freshest is the best, and that which is less than a year old should, if possible, be selected. It should possess in a high degree the characteristic properties of colour, taste, and smell. If it do not colour the fingers when rubbed between them, or if it have an oily feel, or a musty flavour, or a black, yellow, or whitish colour, it should be rejected. In the purchase of this medicine in cakes, those should be selected which are close, tough, and firm in tearing; and care should be taken to avoid *cakes of safflower.*

As its activity depends, partly at least, on a volatile ingredient, saffron should be kept in well-stopped vessels. Some recommend that it should be enclosed in a bladder, and introduced into a tin case.

Medical Properties and Uses. Saffron was formerly considered highly stimulant and antispasmodic. It has been alleged that, in small doses, it moderately excites the different functions, exhilarates the spirits, relieves pain, and produces sleep; in large doses, gives rise to headache, intoxication, delirium, stupor, and other alarming symptoms; and Shröder asserts that, in the quantity of two or three drachms, it proves fatal. It was thought also to act powerfully on the uterine system, promoting menstruation. The ancients employed it extensively, both as a medicine and condiment, under the name of *crocus.* It was also highly esteemed by the Arabians, and enjoyed considerable reputation among the physicians of modern Europe till within a comparatively recent period. On the continent it is still much used as a stimulant and emmenagogue. But the experiments of Dr. Alexander have proved it to possess little activity; and in Great Britain and the United States it is seldom prescribed. In domestic practice saffron tea is occasionally used in exanthematous diseases, to promote the eruption. At present the chief use of the drug is to impart colour and flavour to officinal tinctures. The dose is from ten to thirty grains.

Piper Cubeba. Willd. *Sp. Plant.* i. 159; Woodv. *Med. Bot.*, 3d ed., v. 95.— *Cubeba officinalis. Miquel.* This is a climbing perennial plant, with a smooth, flexuous, jointed stem, and entire, petiolate, oblong or ovate-oblong, acuminate leaves, rounded or obliquely cordate at the base, strongly nerved, coriaceous, and very smooth. The flowers are diœcious and in spikes, with peduncles about as long as the petioles. The fruit is a globose, pedicelled berry.

This species of Piper is a native of Java, Penang, and probably other parts of the East Indies. It grows wild in the woods, and does not appear to be cultivated. The dried unripe fruit is the officinal portion. Dr. Blume thinks it probable that the drug is derived chiefly from another species, the *P. caninum,* inhabiting the same countries; but Dr. Lindley could discover no difference between the fruit of *P. Cubeba* and ordinary cubebs.*

* Cubebs were exhibited, at the great London Exhibition of 1862, among the products of Ceylon. It was at one time supposed that cubebs were also produced in Western Africa; but this was a mistake, originating probably in the fact, that a peculiar pepper growing in that region has, like cubebs, the stalk attached. It is, however, a different product, being, as shown by Dr. W. F. Daniell, the fruit of a distinct species, the *Piper Afzelii* of Lindley, *Cubeba Clusii* of Miquel, figured in the *Pharm. Journ.* (xiv. 201). This *Guinea pepper*, or *African black pepper*, was formerly taken to Europe in considerable quantities

Properties. Cubebs are round, about the size of a small pea, of a blackish or grayish-brown colour, and furnished with a short stalk, which is continuous with raised veins that run over the surface of the berry, and embrace it like a net-work. The shell is hard, almost ligneous, and contains within it a single loose seed, covered with a blackish coat, and internally white and oleaginous. The odour of the berry is agreeably aromatic; the taste warm, bitterish, and camphorous, leaving in the mouth a peculiar sensation of coolness, like that produced by oil of peppermint. The powder is dark-coloured and of an oily aspect. From 1000 parts of cubebs M. Monheim obtained 30 parts of a cerumінous substance, 25 of a green volatile oil, 10 of a yellow volatile oil, 45 of cubebin, 15 of a balsamic resin, 10 of chloride of sodium, 60 of extractive, and 650 of lignin, with 155 parts lost. Vauquelin found two resins, the *hard* and the *soft*, the former of which is left behind when cubebs are treated with ether, the latter is dissolved by that liquid, and yielded upon the separation of the volatile oil. It is green, liquid, acrid, and analogous in smell and taste to copaiba. From the experiments of Bernatzike, made in 1863, it appears that this soft resin is possessed of acid properties; and it is therefore called by him *cubebic acid.* Like copaivic acid, though itself amorphous, it forms crystallizable salts with baryta. (*Lehrb. der Pharmak. des Pflanzenreiches.*) By practical trial Bernatzike has satisfied himself that the peculiar virtues of cubebs, as a remedy in gonorrhœa, depend not on the cubebin or the volatile oil, but on the cubebic acid. (See *Am. Journ. of Med. Sci.*, Oct. 1867, p. 534.) According to MM. Capitaine and Soubeiran, *cubebin* is best obtained by expressing cubebs from which the oil has been distilled, preparing with them an alcoholic extract, treating this with a solution of potassa, washing the residue with water, and purifying it by repeated crystallizations in alcohol. Thus prepared, it is white, inodorous, and insipid, not volatilizable by heat, almost insoluble in water, slightly soluble in cold alcohol, freely so in that liquid when hot, and soluble also in ether, acetic acid, and the fixed and volatile oils. It bears a close resemblance to piperin, but materially differs from it in composition, as it contains no nitrogen. (*Journ. de Pharm.*, xxv. 355.) In the officinal oleoresin of cubebs a deposit takes place consisting chiefly of cubebin, which may be obtained by washing the deposit with a small quantity of cold alcohol to remove adhering resin and oil, and then dissolving repeatedly in boiling alcohol, and crystallizing until the product is white. The volatile oil is officinal. (See *Oleum Cubebæ.*) When the ethereal extract of cubebs is deprived of its volatile oil by evaporation on a water-bath, and of cubebin and wax by deposition, a soft resin is left, the cubebic acid of Bernatzike, in which, according to Mr. F. V. Heydenreich, who experimented with it as a physiological agent, the

by the Portuguese, but has been superseded by the more agreeable products of the E. Indies. The fruit is one-third smaller than the officinal cubebs, is more compact, and has a taste more analogous to that of ordinary black pepper. Dr. Stenhouse has also shown that it is chemically more analogous to black pepper than to cubebs, as it contains piperin and not cubebin. (*Ibid.*, xiv. 364.)

Under the name of cubebs, a product has been introduced into commerce from the Dutch E. Indies, which is probably the fruit of a different species of Piper, as it differs essentially from genuine cubebs, being somewhat larger, with less distinct veins and somewhat flattened footstalks, of a less agreeable odour, and a less hot and pungent taste. It has been ascribed to *Piper anisatum.* (See *Am. Journ. of Pharm.*, xxxv. 511; from *Journ. de Chim. Med.*)—*Note to the eleventh and twelfth editions.*

African Cubebs. From French Africa, a variety of cubebs is said to have been received in France, which it is thought might replace the Indian, as it has similar properties. It is only about half as large as the common, and has long footstalks attached. Its composition is said to be nearly the same. (*Ann. de Thérap.*, 1866, p. 88.) It is possibly the same as that described in the preceding note as the product of P. Afzelii. A product with the name of African cubebs has recently been sent to London, from Cape Coast Castle, in Africa, which, however, has no botanical relation to Cubeba, nor to the fruit of any other Piperacea; the plant producing it belonging to the *Xanthoxylaceæ*, and is probably either a *Toddalia* or *Vepris.* According to Prof. Archer, it is simply aromatic and stimulant, without any of the special virtues of cubebs. (*Pharm. Journ. & Trans.*, March, 1865, p. 463.)—*Note to the thirteenth edition.*

diuretic properties reside, the cubebin being without apparent effect, and the volatile oil, though stimulant and carminative, having no diuretic action. The soft resin, which was of the consistence of honey, of a dark olive-green colour, and some remaining odour of cubebs, when taken in the dose of 10 grains every two hours, for six hours, acted as a laxative, and gave the urine a peculiar odour, without increasing its quantity; but in the dose of a drachm, once repeated at an interval of three hours, while it produced the same effects as the smaller dose, considerably augmented the urine. In still larger doses it produced decided irritation of the urinary passages. (*Am. Journ. of Pharm.*, Jan. 1868.) Mr. Heydenreich's experiments are confirmatory of Bernatzike's conclusion as to the peculiar active principles of cubebs. Cubebs gradually deteriorate by age, and in powder become rapidly weaker, in consequence of the escape of their volatile oil. They should be kept whole, and pulverized when dispensed. The powder is said to be sometimes adulterated with that of pimento.

Medical Properties and Uses. Cubebs are gently stimulant, with a special direction to the urinary organs. In considerable quantities they excite the circulation, increase the heat of the body, and sometimes occasion headache and giddiness. At the same time they frequently produce an augmented flow of the urine, to which they impart a peculiar odour. Among their effects are also occasionally nausea and moderate purging; and they are said to cause a sense of coolness in the rectum during the passage of the feces. We have no evidence that they were known to the ancients. They were probably first brought into Europe by the Arabians, and were formerly employed for similar purposes with black pepper; but they were found much less powerful and fell into disuse. Some years since they were again brought into notice in England as a remedy in gonorrhœa. This application of cubebs was derived from India, where they have long been used in gonorrhœa and gleet, and as a grateful stomachic and carminative in disorders of the digestive organs. They are said to have sometimes produced swelled testicles, when given in gonorrhœa; and, though recommended in all its stages, will probably be found most safe and effectual in cases where the inflammation is confined to the mucous membrane of the urethra. If not speedily useful, they should be discontinued. They have been given also in leucorrhœa, cystirrhœa, the urethritis of women and female children, abscess of the prostate gland, piles, chronic bronchial inflammation, and, with great asserted advantage, in connection with copaiba, in pseudomembranous croup, and diphtheric affections of the fauces. In connection with copaiba they have been especially recommended in affections of the neck of the bladder and the prostatic portion of the urethra. They have also been found very effectual in tympanites. They are best administered in powder, of which the dose in gonorrhœa is from one to three drachms three or four times a day. For other affections, the dose is sometimes reduced to ten grains. The volatile oil may be substituted, in the dose of ten or twelve drops, suspended in water by means of sugar; though, if the experiments of Bernatzike and Heydenreich are to be relied on, the oil is much less efficient than the soft resin as a remedy in gonorrhœa, and diseases of the urinary passages generally. An ethereal extract is directed by the U. S. Pharmacopœia, and considerably used; and, as it contains the soft resin or cubebic acid, it is no doubt a very efficient preparation. (See *Oleoresina Cubebæ.*) An infusion, made in the proportion of an ounce of cubebs to a pint of water, has been employed as an injection in discharges from the vagina, with asserted advantage.

CUPRUM. *Br.*

Copper.

Fine Copper wire, about No. 25. *Br.*

Cuivre, *Fr.;* Kupfer, *Germ.;* Rame, *Ital.;* Cobre, *Span.*

This metal is very generally diffused in nature, and exists principally in four

states; as native copper, as an oxide, as a sulphuret, and as a salt. Its principal native salts are the sulphate, carbonate, arseniate, and phosphate. In the United States it occurs in various localities, but especially in the neighbourhood of Lake Superior. The principal copper mines of Europe are those of the Pyrenees in France, Cornwall in England, and Fahlun in Sweden.

Properties. Copper is a brilliant, sonorous metal, of a reddish colour, and very ductile, malleable, and tenacious. It has a slightly nauseous taste, and emits a disagreeable smell when rubbed. Its texture is granular, and its fracture hackly. Its sp. gr. is 8·89, and its fusing point 1996°, according to Daniell, being intermediate between the fusing points of silver and gold. Its equivalent number is 31·75. Exposed to the air it undergoes a slight tarnish. Its combinations are numerous and important. With oxygen it forms two well characterized oxides, a red suboxide or dioxide, consisting of two eqs. of copper and one of oxygen, and a black protoxide formed of one eq. of metal and one of oxygen. The latter oxide, which alone is salifiable, forms with acids several salts, important in medicine and the arts. With metals, copper forms numerous alloys, of which that with zinc, called brass, is the most useful.

Characteristics. Copper is recognised by its colour, and the effects of tests on its nitric solution. This solution, with potassa, soda, and ammonia, yields a blue precipitate, soluble in excess of the latter alkali, with which it forms a deep-blue liquid. Ferrocyanide of potassium occasions a brown precipitate of ferrocyanide of copper; and a bright plate of iron, immersed in the solution, immediately becomes covered with a film of metallic copper. The ferrocyanide of potassium is a very delicate test for minute portions of copper in solution. Another test, proposed by M. Verguin, is to precipitate the copper in the metallic state on platinum by electro-chemical action. For this purpose a drop of the liquid to be examined is placed on a slip of platinum foil, and a slip of bright iron is brought in contact with the platinum and the liquid. If copper be present it will be instantly precipitated on the surface of the platinum.

Action on the Animal Economy. Copper, in its pure state, is perfectly inert, but in combination is highly deleterious. Nevertheless a minute portion of the metal has been found in the human body. According to Millon, copper, when it exists in the blood, is, like the iron, attached to the red corpuscles. To bring the copper into a state favourable for ready detection, he advises that the blood, as it escapes from a vein, be received in about three times its bulk of water, and the mixture poured into a bottle of chlorine and agitated. The whole, upon being rapidly filtered, furnishes a liquid in which copper is readily detected. Wackenroder found copper in the blood of man, but does not consider it a constant and normal constituent. He also detected this metal in the blood of domestic animals living on a mixed diet, but not in their blood when nourished on vegetable food only. (*Chem. Gaz.*, May 1, 1854.) The combinations of copper, when taken in poisonous doses, produce a coppery taste in the mouth; nausea and vomiting; violent pain in the stomach and bowels; frequent black and bloody stools; small, irregular, sharp, and frequent pulse; faintings; burning thirst; difficulty of breathing; cold sweats; paucity of urine, and burning pain in voiding it; violent headache; cramps, convulsions, and finally death. The best antidote, according to Dr. Schrader, of Göttingen, is the ferrocyanide of potassium, given freely, which forms, with the poison, the very insoluble ferrocyanide of copper. Before the antidote can be procured, large quantities should be given of milk, and white of eggs mixed with water, which act favourably by forming the caseate and albuminate of copper; but these compounds should be evacuated as soon as possible by vomiting and purging. Should vomiting not take place, the stomach-pump may be employed. Magnesia was proposed as an antidote by M. Roucher; but Dr. Schrader says it is not to be depended on. (*Med. Times and Gaz.*, May, 1855.) The symptoms of slow poisoning by copper are, according to Dr. Corrigan, of Dublin, a cachectic appearance, emaciation, loss of muscular strength, colicky pains, cough without physical signs, and retraction of the gum, with a persistent purple edge, quite distinct from the blue edge produced by lead. (*Braithwaite's Retrospect*, Am. ed., xxx. 303.)

Dr. Horsley has detected sulphate of copper in bread and flour used in London, and presumes that it was added with the view of improving the appearance of the flour. (*Chem. News*, no. 63, p. 111, and no. 65, p. 142.)

In medico-legal examinations, where cupreous poisoning is suspected, Orfila recommends that the viscera be boiled in distilled water for an hour, and that the matter obtained by evaporating the filtered decoction to dryness be carbonized by nitric acid. The carbonized product will contain the copper. By proceeding in this way, there is no risk of obtaining the copper which may happen to pre-exist in the animal tissues. This method of search is preferable to that of examining the contents of the stomach and intestines, from which copper may be absent; while it may have penetrated the different organs by absorption, especially the abdominal viscera.

Vessels of copper should be discontinued in all operations connected with pharmacy and domestic economy; for, although the metal uncombined is inert, yet the risk is great that the vessels may be acted on; in which event, whatever may be contained in them would be rendered deleterious.

The Br. Pharmacopœia uses copper in preparing Spiritus Ætheris Nitrosi.

The following is a list of the preparations containing copper in the U. S. and Br. Pharmacopœias.

Cupri Subacetas, *U. S.* — *Subacetate of Copper.*
Cupri Sulphas, *U. S., Br.* — *Sulphate of Copper. Blue Vitriol.*
Cuprum Ammoniatum, *U. S.* — *Ammoniated Copper.* B.

CUPRI SUBACETAS. *U. S.*

Subacetate of Copper.

Impure subacetate of copper. *U. S.*

Verdigris; Ærugo, *Lat.;* Acetate de cuivre brut, Vert-de-gris, *Fr.;* Grünspan, *Germ.;* Verde rame, *Ital.;* Cardenillo, *Span.*

Preparation. Verdigris is prepared in large quantities in the south of France, more particularly in the neighbourhood of Montpellier. It is also manufactured in Great Britain and Sweden. In France the process is conducted in the following manner. Sheets of copper are stratified with the residue of the grape after the expression of the juice in making wine, and are allowed to remain in this state for a month or six weeks. At the end of this time, the plates are found coated with a considerable quantity of verdigris. This is scraped off, and the plates are then replaced as at first, to be further acted on. The scrapings thus obtained form a paste, which is afterwards well beaten with wooden mallets, and packed in oblong leathern sacks, about ten inches in length by eight in breadth, in which it is dried in the sun, until the loaf of verdigris, as it is called, attains the proper degree of hardness. The rationale of the process is easily understood. The grape-refuse contains a considerable quantity of juice, which, by contact with the air, undergoes the acetous fermentation. The copper becomes oxidized, and the resulting oxide, by combination with the acetic acid generated during the fermentation, forms the subacetate of copper, or verdigris. In England a purer verdigris is prepared by alternating copper plates with pieces of woollen cloth, steeped in pyroligneous acid.

Verdigris comes to this country exclusively from France, being imported principally from Bordeaux and Marseilles. The leathern packages in which it is put up, called sacks of verdigris, weigh generally from twenty-five to thirty pounds, and arrive in casks, each containing from thirty to forty sacks.

Properties. Verdigris is in masses of a pale-green colour, and composed of a multitude of minute silky crystals. Sometimes, however, it occurs of a bright-blue colour. Its taste is coppery. It is insoluble in alcohol, and, by the action of water, a portion of it is resolved into the neutral acetate which dissolves, and the trisacetate which remains behind in the form of a dark-green powder, gradually becoming black. It is hence evident that, when verdigris is prepared by levigation with water, it is altered in its nature. The neutral acetate is the

crystallized acetate of copper, or *Crystals of Venus.* (See *Part Third.*) When verdigris is acted on by sulphuric acid, it is decomposed, vapours of acetic acid being evolved, easily recognised by their vinegar odour. It is soluble almost entirely in ammonia, and dissolves in muriatic and dilute sulphuric acid with the exception of impurities, which should not exceed 5 per cent. When of good quality, it has a lively green colour, is free from black or white spots, and is dry and difficult to break. The green rust, called in popular language verdigris, which copper vessels are apt to contract when not kept clean, is a carbonate of copper, and should not be confounded with true verdigris.

Composition. Verdigris, apart from its impurities, is a variable mixture of the subacetates of copper; the basic sesquiacetate predominating in the green variety, the diacetate in the blue. When acted on by water, two eqs. of the portion consisting of diacetate are converted into one eq. of soluble neutral acetate, and one of insoluble trisacetate.

Medical Properties. Verdigris is used externally as a detergent and escharotic, and is occasionally applied to chronic eruptions, foul and indolent ulcers, and venereal warts. For its effects as a poison, see *Cuprum.** B.

CUPRI SULPHAS. *U.S., Br.*

Sulphate of Copper.

"CuO,SO_3+5HO. May be obtained by heating sulphuric acid and copper together, dissolving the soluble product in hot water, and evaporating the solution until crystallization takes place on cooling." *Br.*

Blue vitriol, Roman vitriol, Blue stone; Sulfate de cuivre, Vitriol bleu, Couperose blue, *Fr.;* Schwefelsaures Kupfer, Kupfervitriol, Blauervitriol, Blauer Galitzenstein, *Germ.;* Rame solfato, Vitriolo di rame, *Ital.;* Sulfato de cobre, Vitriolo azul, *Span.*

Preparation, &c. Sulphate of copper occasionally exists in nature, in solution in the water which flows through copper mines. In this case the salt is procured by merely evaporating the waters which naturally contain it. Another method for obtaining it is to roast the native sulphuret in a reverberatory furnace, whereby it is made to pass, by absorbing oxygen, into the state of sulphate. The roasted mass is lixiviated, and the solution obtained evaporated that crystals may form. The salt, procured by either of these methods, contains a little tersulphate of the sesquioxide of iron, from which it may be freed by adding either an excess of protoxide of copper, which precipitates the sesquioxide of iron, or recently precipitated subcarbonate of copper, which causes the deposition of the iron as a carbonate. (*Am. Journ. of Pharm.*, xxxiv. 507.) A third method consists in wetting, and then sprinkling with sulphur, sheets of copper, which are next heated to redness, and while hot plunged into water. The same

* *Linimentum Æruginis.* This is a very old preparation, formerly recognised as officinal in Great Britain, though abandoned in the British Pharmacopœia. The following is the process for it given in the late *London* Pharmacopœia. "Take of Verdigris (Subacetate of Copper), in powder, *an ounce;* Vinegar *seven fluidounces;* Honey *fourteen ounces.* Dissolve the Verdigris in the Vinegar, and strain through linen; then gradually add the Honey, and boil down to a proper consistence." The ounces used here are Troy-ounces. It sometimes happens during the boiling of the acetic solution of the verdigris, that a red deposit rapidly forms, consisting of the red or suboxide of copper; and that, at the end of the process, little or none of the metallic salt remains in the preparation. This happens especially when granular honey is employed. (Harley, *Pharm. Journ. and Trans.*, xi. 357.) The change is owing to the decomposition of the protoxide of copper by the grape sugar of the honey, converting it into the suboxide. The inference is that, in making the preparation, so as to fulfil the objects of the original prescription, fresh liquid honey should be used, which contains comparatively little glucose.

This is an external stimulant and escharotic, and was formerly called *Mel Ægyptiacum.* It is employed, either undiluted, or mixed with some mild ointment, to destroy fungous granulations, or to repress their growth. In the latter state, it is a useful stimulant to flabby, indolent, and ill-conditioned ulcers; and, largely diluted with water, it has been used as a gargle in venereal ulcerations of the mouth and throat. It is sometimes also applied undiluted to such ulcers in the fauces, by means of a camel's-hair brush. (*Note to the thirteenth edition.*)

operation is repeated until the sheets are entirely corroded. At first a sulphuret of the metal is formed, which, by the action of heat and air, gradually passes into the state of sulphate of the oxide. This is dissolved by the water, and obtained in crystals by evaporation. A fourth method is to dissolve copper scales to saturation in sulphuric acid, contained in a wooden vessel, lined with sheet lead. The scales consist of metallic copper, mixed with oxide, and are produced in the process for annealing sheet copper.

Sometimes sulphate of copper is obtained in pursuing one of the methods for separating silver from gold. The silver is dissolved by boiling the alloy in sulphuric acid. The sulphate of silver formed is then decomposed by the immersion of copper plates in its solution, with the effect of forming sulphate of copper and precipitating the silver.

In the *U. S. Pharmacopœia*, sulphate of copper is presumed to be obtained pure from the manufacturer; the *British* suggests the method in which it may be prepared, without entering into the details of the process.

Properties. Sulphate of copper has a rich deep-blue colour, and strong metallic styptic taste. It reddens vegetable blues, and crystallizes in large, transparent, rhomboidal prisms, which effloresce slightly in the air, and are soluble in four parts of cold, and two of boiling water, but insoluble in alcohol. When heated it first melts in its water of crystallization, and then dries and becomes white. If the heat is increased, it next undergoes the igneous fusion, and finally, at a high temperature, loses its acid, protoxide of copper being left. Potassa, soda, and ammonia throw down from it a bluish-white precipitate of hydrated protoxide of copper, which is immediately dissolved by an excess of the last-mentioned alkali, forming a rich deep-blue solution, called *aqua sapphirina*. It is decomposed by the alkaline carbonates, and by borax, acetate and subacetate of lead, acetate of iron, nitrate of silver, corrosive chloride of mercury, tartrate of potassa, and chloride of calcium; and it is precipitated by all astringent vegetable infusions. If it becomes very green on the surface by the action of the air, it contains sesquioxide of iron. This oxide may also be detected by ammonia, which will throw it down along with the oxide of copper, without taking it up when added in excess. When sulphate of copper is obtained from the dipping liquid of manufacturers of brass or German silver ware, it is always contaminated with sulphate of zinc, as pointed out by Mr. S. Piesse. This liquid is at first a mixture of sulphuric and nitric acids, but becomes, at last, nearly saturated with copper. When zinc is present in sulphate of copper, it will be taken up by solution of potassa, added in excess, from which it may be thrown down, in white flocks, by a solution of bicarbonated alkali.

Sulphate of copper consists of one eq. of sulphuric acid 40, one of protoxide of copper 39·75, and five of water 45 = 124·75.

Medical Properties. Sulphate of copper, in small doses, is astringent and tonic; in large ones a prompt emetic. With a view to its tonic effect, it has been given in intermittent fever, as well as in epilepsy and other spasmodic diseases; and as an emetic, for discharging poisons from the stomach, especially opium. In croup it has been employed as an emetic with encouraging success. M. Hönerkopf, a German practitioner, speaks warmly of his success with it in this disease. He uses the salt freely, especially in severe cases, in which great insensibility of the stomach is usually manifested. Out of ninety cases, half of which he estimates to have been pseudomembranous croup, he reports the cure of seventy-seven. (*Journ. de Pharm.*, Oct. 1855.) Sulphate of copper has also been highly recommended in chronic diarrhœa, and is said to have been very successfully used in cholera.* Externally it is employed in solu-

* M. Lisle, of Marseilles, having been induced by representations from M. Burq as to the extraordinary efficiency of *acetate of copper* in cholera, gave the *sulphate* a trial in that disease, with very satisfactory results. Of a solution of 5 parts of sulphate of copper in 100 parts of water, he added 1·5 grammes to 10 drops of Sydenham's laudanum and 150 grammes of sweetened water, and of this potion gave, as near the commencement of the attack as possible, a teaspoonful every 15 minutes in the severest cases, a

tion as a stimulant to ill-conditioned ulcers, as an escharotic for destroying warts, fungous granulations, and callous edges, and as a styptic to bleeding surfaces. It is found, in not a few instances, to promote the cicatrization of ulcers, and is not unfrequently employed, with that view, as a wash for chancres. In weak solution, either alone or associated with other substances, it forms a useful collyrium in the chronic stages of some forms of ophthalmia. Eight grains of it with an equal weight of Armenian bole, and two grains of camphor, added to half a pint of boiling water, form, after becoming limpid by rest, a collyrium strongly recommended by Mr. Ware in the purulent ophthalmia of infants. The preparation called *cuprum aluminatum* (*lapis divinus—pierre divine*) is made, according to the French Codex, by mixing, in powder, three ounces, each, of sulphate of copper, nitrate of potassa, and alum, heating the mixture in a crucible, so as to produce watery fusion, then mixing in a drachm of powdered camphor, and, finally, pouring out the whole on an oiled stone to congeal. The mass, when cold, is broken into pieces, and kept in a well-stopped bottle. When this preparation is used as a collyrium, a filtered solution is made of the average strength of thirty grains to the pint of water. It is employed in various affections of the eyes, in which astringent applications are admissible. It is often desirable to employ sulphate of copper, as a caustic, in the form of pencil. Its tendency to effloresce interferes with its use in this way in the pure state. M. Llovet recommends for the purpose a mixture of one part of potassa-alum and two of sulphate of copper, which are to be first powdered, and then gradually melted together in a porcelain vessel, and poured into moulds made of bronze. (*Gaz. des Hôp.*, Juillet 28, 1863.) Another mode of preparing pencils of sulphate of copper is to rub briskly together four parts of that salt and one of borax, and to mould the plastic mass which results into the desired form. (*Am. Journ. of Pharm.*, March, 1864, p. 106.)

The dose of sulphate of copper, as an astringent or tonic, is a quarter of a grain, gradually increased; as an emetic, from two to five grains. As a stimulant wash, the solution may be made of the strength of two, four, or eight grains to the fluidounce of water. Orfila cautions against giving large doses of this salt as an emetic in cases of poisoning; as it is apt, from its poisonous effects, to increase the mischief when not expelled by vomiting. Upon the whole, such is the activity of sulphate of copper, that it should always be exhibited with caution. For its effects as a poison, see *Cuprum*.

Curcuma longa. Willd. *Sp. Plant.* i. 14; Woodv. *Med. Bot.* p. 737, t. 252. The root of this plant is perennial, tuberous, palmate, and internally of a deep-yellow or orange colour. The leaves are radical, large, lanceolate, obliquely nerved, sheathing at their base, and closely embrace each other. The scape or flower-stem, which rises from the midst of the leaves, is short, thick, smooth,

dessertspoonful every half hour in the cases of mean severity, and the same quantity every hour in the lighter cases. With these doses he continued till the skin and tongue began to become warm, and the pulse a little raised, when he repeated the dose only every 3 or 5 hours, ceasing altogether when the algid period had passed. Of 68 cases under his notice, 36 were treated in the ordinary mode, and of these 28 proved fatal; while of 31 treated with sulphate of copper only 7 died. (*Ann. de Thérap.*, 1866, p. 271.) —*Note to the thirteenth edition.*

and constitutes a spike of numerous imbricated bracteal scales, between which the flowers successively make their appearance. The plant is a native of the East Indies and Cochin-China, and is cultivated in various parts of southern Asia, particularly in China, Bengal, and Java, whence the root is exported. The best is said to come from China.

The dried root is in cylindrical or oblong pieces, about as thick but not as long as the finger, tuberculated, somewhat contorted, externally yellowish-brown or greenish-yellow, internally deep orange-yellow, hard, compact, breaking with a fracture like that of wax, and yielding a yellow or orange-yellow powder. Another variety, comparatively rare, is round or oval, about the size of a pigeon's egg, and marked externally with numerous annular wrinkles. Sometimes it comes cut into two transverse segments. It is distinguished by the name of *curcuma rotunda*, the former being called *curcuma longa*. The two varieties have a close resemblance in sensible properties, and are thought to be derived from the same plant, though formerly ascribed to different species of Curcuma. The odour of turmeric is peculiar; the taste warm, bitterish, and feebly aromatic. It tinges the saliva yellow. Analyzed by Pelletier and Vogel, it was found to contain lignin, starch, a peculiar yellow colouring matter called *curcumin*, a brown colouring matter, gum, an odorous and very acrid volatile oil, and a small quantity of chloride of calcium. Curcumin is obtained, mixed with a little volatile oil, by digesting the alcoholic extract of turmeric in ether, and evaporating the ethereal tincture. It may be procured perfectly pure by separating it from its combination with oxide of lead. M. Lepage procures it by exhausting turmeric with sulphuret of carbon, which does not dissolve curcumin, drying the residue, and treating it with 8 times its weight of distilled water, containing 2 or 3 per cent. of caustic potassa or soda, then filtering, and precipitating with a slight excess of dilute muriatic acid, which takes the alkali, and throws down the curcumin. To obtain it quite pure, the precipitate is washed, dried, and treated with ether, which dissolves only the curcumin, and yields it by spontaneous evaporation. (*Rev. Pharmaceut.*, A.D. 1857, p. 8.) It is brown in mass, but yellow in the state of powder, without odour or taste, insoluble in benzine, scarcely soluble in water, but very soluble in alcohol, ether, and the oils. The alkalies rapidly change its colour to a reddish-brown; and paper tinged with tincture of turmeric is employed as a test of their presence. Berzelius, however, states that its colour is changed to red or brownish-red by the concentrated mineral acids, by pure boracic acid, especially when dissolved in alcohol, and by numerous metallic salts; so that its indications cannot be certainly relied on. Its alcoholic solution produces coloured precipitates with acetate of lead, nitrate of silver, and other salts. Turmeric is used for dyeing yellow; but the colour is not permanent.*

Medical Properties, &c. This root is a stimulant aromatic, bearing some resemblance to ginger in its operation, and is much used in India as a condiment. It is a constant ingredient in the curries so generally employed in the East. In former times it had some reputation in Europe as a remedy in jaundice and other visceral diseases; but at present it is employed only to impart colour to ointments, and other pharmaceutic preparations.

Turmeric paper, used as a test, is prepared by tinging white unsized paper with a tincture or decoction of turmeric. The tincture may be made with one part of turmeric to six parts of proof spirit; the decoction, with one part of the root to ten or twelve of water. The access of acid or alkaline vapours should be carefully avoided. W.

* *African Turmeric.* Dr. Wm. F. Daniell has brought into notice a product, much used by the native Africans of Sierra Leone in dyeing, consisting of rhizomas, closely resembling the E. Indian turmeric, having a similar odour and taste, and in like manner tinging the saliva yellow, and imparting their colouring matter readily to alcohol and water. He found it to be derived from a species of Canna, supposed to be the *C. speciosa* of Roscoe. (*Pharm. Journ.*, Nov. 1859, p. 258.)—*Note to the twelfth edition.*

Cydonia vulgaris. Persoon, *Enchir.* ii. 40.—*Pyrus Cydonia.* Willd. *Sp. Plant.* ii. 1020; Woodv. *Med. Bot.* p. 505, t. 182. The common quince-tree is characterized as a species by its downy deciduous leaves It is supposed to be a native of Crete, but grows wild in Austria, on the banks of the Danube. It is abundantly cultivated in this country. The fruit is about the size of a pear, yellow, downy, of an agreeable odour, and a rough, astringent, acidulous taste: and in each of its five cells contains from eight to fourteen seeds. Though not eaten raw, it forms a very pleasant confection; and a syrup prepared from it may be used as a grateful addition to drinks in sickness, especially in looseness of the bowels, which it is supposed to restrain by its astringency. The seeds are the officinal portion.

They are ovate, angled, reddish-brown externally, white within, inodorous, and nearly insipid, being slightly bitter when long chewed. Their coriaceous envelope abounds in mucilage, which is extracted by boiling water. Two drachms of the seeds will render a pint of water thick and ropy. It has been proposed to evaporate the decoction to dryness, and powder the residue. Three grains of this powder form a sufficiently consistent mucilage with an ounce of water. According to M. Garot, one part communicates to a thousand parts of water a semi-syrupy consistence. (*Journ. de Pharm.*, 3e *sér.*, iii. 298.) Dr. Pereira considers the mucilage as peculiar, and proposes to call it *cydonin*. It differs from arabin in not yielding a precipitate with silicate of potassa, and from bassorin and cerasin, in being soluble in water both hot and cold.

Medical Properties, &c. The mucilage of quince seeds may be used for the same purposes as other mucilaginous liquids. It is preferred by some practitioners as a local application in conjunctival ophthalmia, but in this country is less used for that purpose than the infusion of sassafras pith. W.

CYPRIPEDIUM. *U. S. Secondary.*

Cypripedium.

The root of Cypripedium pubescens. *U. S.*

Cypripedium. *Sex. Syst.* Gynandria Diandria.—*Nat. Ord.* Orchidaceæ.

Gen. Ch. Sepals spreading; the two anterior generally united into one under the lip. *Petals* similar but usually narrower, spreading. *Lip* a large inflated sac, somewhat slipper-shaped. *Column* short, three-lobed; the lateral lobes bearing an anther under each, the middle dilated and petal-like. *Gray.*

Under the common name of *ladies' slipper*, or *moccasin plant*, several species of Cypripedium inhabit the woods in different parts of the United States They are small plants, with large many-nerved, plaited leaves, sheathing at the base, and large often beautiful flowers, of a shape not unlike the Indian moccasin, whence they derive one of their common names. Their generic name of Cypripedium (Κύπρις, Venus, and πόδιον, sock) had a similar origin. Several of them have been used by American physicians, the root being the part employed. Dr. R. P. Stevens, of Ceres, Pennsylvania, says of them, that he has found the

C. spectabile and *C. acaule*, especially when growing in dark swamps, to be possessed of narcotic properties, and to be less safe than the *C. parviflorum*, which is gently stimulant with a tendency to the nervous system, and is quite equal to valerian. He has employed it advantageously in hysteria, and in the pains of the joints following scarlet fever. (*N. Y. Journ. of Med.*, iv. 359.) Dr E. Ives considers *C. pubescens*, *spectabile*, and *humile* identical in their effects, but *C. pubescens* the most powerful (*Trans. of Am. Med. Assoc.*, iii. 312.) C. pubescens is the only one designated in the U. S. Pharmacopœia.

Cypripedium pubescens. Willd. *Sp. Plant.* iv. 142; Darlington, *Flor. Cestric.* p. 514. The *yellow ladies' slipper*, as this plant is called from the colour of its flowers, has a simple often flexuous, pubescent, leafy stem, from one to two feet high The leaves are pubescent, ovate-lanceolate, acuminate, narrowing at the base, about four or five inches long by two in breadth, alternate, sessile, and sheathing. The flower is usually solitary and terminal; with four divisions of the perianth, the two outer cohering nearly to the apex, the inner longer, narrower, undulatory or twisted, and the lip an inch or two in length, swelling sac-like, and of a yellow colour. The fruit is an oblong capsule, tapering at each end, recurved, pubescent, and peduncled. (*Darlington.*) The plant is indigenous, growing abundantly in rich, moist woods throughout the United States. The root is the part used.

Properties. The dried root, as brought to the shops, has a small, knotted head or caudex, with numerous somewhat contorted fibres or radicles, considerably thicker than those of serpentaria, from four to six inches long, of a yellowish-brown colour, which is darker in the caudex, of a somewhat aromatic odour which diminishes by time, and a bitter, sweetish, peculiar, and in the end somewhat pungent taste. It yields its virtues to water and alcohol. The root has been analyzed by Mr. Henry C. Blair, who found it to contain a volatile oil, a volatile acid, tannic and gallic acids, two resins, gum, glucose, starch, and lignin. (*Am. Journ. of Pharm.*, Nov. 1866, p. 494.) The so-called eclectics prepare what they improperly call *cypripedin* by precipitating with water a concentrated tincture of the root. The substance thus obtained is complex, and has no claim to the name given it, which ought to be reserved for the active principle when discovered. It is probable that the virtues of the root reside in a volatile oil and bitter principle.

Medical Uses. Cypripedium appears to be a gentle nervous stimulant or antispasmodic, and has been used for the same purposes as valerian, though less powerful. Dr. E. Ives, of New Haven, Conn., has employed the remedy in a variety of nervous diseases with advantage, and has known it even to cure epilepsy. The other complaints mentioned by him are hypochondriasis, neuralgia, and morbid sensitiveness of the nervous system generally, and especially of the eye. The medicine may be used in powder, infusion, or tincture. The dose of the powder given by Dr. Ives was fifteen grains three times a day. The oleoresin obtained by precipitating the tincture has been given in doses varying from half a grain to three grains. W.

DELPHINIUM. *U. S. Secondary.*

Larkspur.

The root of Delphinium Consolida. *U. S.*

Pied d'allouette, *Fr.;* Feld Rittersporn, *Germ.*

DELPHINIUM. *Sex. Syst.* Polyandria Trigynia.—*Nat. Ord.* Ranunculaceæ.

Gen. Ch. Calyx none. *Petals* five. *Nectary* bifid, horned behind. *Pods* three or one. *Willd.*

Delphinium Consolida. Willd. *Sp. Plant.* ii. 1226; Loudon's *Encyc. of Plants*, p. 473, 7832. The larkspur is a showy annual plant, with an erect, branched, slightly pubescent stem. Its leaves are divided into linear segments, widely separated, and forked at the summit. The flowers are usually of a beautiful azure-blue colour, and disposed in loose terminal racemes, with peduncles

longer than the bractes. The nectary is one-leaved, with an ascending horn nearly equalling the corolla. The seeds are contained in smooth, solitary capsules. This species of larkspur has been introduced from Europe into the United States, where it has become naturalized, growing in the woods and fields, and flowering in June and July.

Various parts of the larkspur have been employed in medicine; and the plant is said to have properties closely analogous to those of *Delphinium Staphisagria*. (See *Staphisagria*.) The flowers are bitter and acrid, and, having formerly been supposed to possess the power of healing wounds, gave the name of *consolida* to the species. *Aconitic acid* has been obtained from the expressed juice by W. Wicke. (*Journ. de Pharm.*, Juillet, 1854, p. 79.) The seeds were analyzed by Mr. Thomas C. Hopkins, of Baltimore, and found to contain *delphinia*, volatile oil, fixed oil, gum, resin, chlorophyll, gallic acid, and salts of potassa, lime, and iron. (*Am. Journ. of Pharm.*, xi. 8.)

The flowers were formerly considered diuretic, emmenagogue, and vermifuge; but are not now used. The seeds are very acrid, are esteemed diuretic, and in large doses produce vomiting and purging. A tincture, prepared by macerating an ounce of them in a pint of diluted alcohol, has been found useful in spasmodic asthma and dropsy. The dose is ten drops, to be gradually increased till some effect upon the system is evinced. The remedy has been employed both in America and England; and the seeds of an indigenous species, *D. exaltatum*, have been applied to a similar purpose. The root probably possesses the same properties as other parts of the plant; but, though designated in the Pharmacopœia, is little if at all used. W.

DIGITALIS. *U. S.*

Digitalis. Foxglove.

The leaves of Digitalis purpurea, from plants of the second year's growth. *U.S.*

Off. Syn. DIGITALIS FOLIA. *Digitalis Leaf.* The dried leaf of Digitalis purpurea, Purple Foxglove. Collected from the wild indigenous plant, when about two-thirds of the flowers are expanded. *Br.*

Digitalis. *Sex. Syst.* Didynamia Angiospermia. — *Nat. Ord.* Scrophulariaceæ.

Gen. Ch. Calyx five-parted. *Corolla* bell-shaped, five-cleft, ventricose. *Capsule* ovate, two-celled. *Willd.*

Digitalis purpurea. Willd. *Sp. Plant.* iii. 383; Woodv. *Med. Bot.* p. 218, t. 78. The foxglove is a beautiful plant, with a biennial or perennial fibrous root, which, in the first year, sends forth large tufted leaves, and in the following summer, a single erect, downy, and leafy stem, rising from two to five feet, and terminating in an elegant spike of purple flowers. The lower leaves are ovate, pointed, about eight inches in length and three in breadth, and stand upon short, winged footstalks; the upper are alternate, sparse, and lanceolate; both are obtusely serrate, and have wrinkled velvety surfaces, of which the upper is of a fine deep green, the under paler and more downy. The flowers are numerous, and attached to the upper part of the stem by short peduncles, in such a manner as generally to hang down upon one side. At the base of each peduncle is a floral leaf, which is sessile, ovate, and pointed. The calyx is divided into five segments, of which the uppermost is narrower than the others. The corolla is monopetalous, bell-form, swelling on the lower side, irregularly divided at the margin into short obtuse lobes, and in shape and size not unlike the end of the finger of a glove, a circumstance which has suggested most of the names by which the plant is designated in different languages. Its mouth is guarded by long soft hairs. Externally, it is in general of a bright purple; internally, is sprinkled with black spots upon a white ground. There is a variety with white flowers. The filaments are white, curved, and surmounted by large yellow an-

thers. The style is simple, and supports a bifid stigma. The seeds are numerous, very small, grayish-brown, and contained in a pyramidal two-celled capsule.

The foxglove grows wild in the temperate parts of Europe, where it flowers in the middle of summer. In this country it is cultivated both for ornament and for medical use. The leaves are the part generally employed. Much care is requisite in selecting, preparing, and preserving them, in order to ensure their activity. They should be gathered in the second year, immediately before or during the period of inflorescence, and those only chosen which are full-grown and perfectly fresh. (*Geiger.*) It is said that those plants are preferable which grow spontaneously in elevated places, exposed to the sun (*Duncan.*) As the leafstalk and midrib are comparatively inactive, they may be rejected. Withering recommends that the leaves should be dried either in the sunshine, or by a gentle heat before the fire; and care should be taken to keep them separate while drying. Pereira states that a more common, and, in his opinion, a preferable mode, is to dry them in a basket, in a dark place, in a drying stove. It is probably owing, in part, to the want of proper attention in preparing digitalis for the market, that it is so often inefficient. Much of the medicine kept in our shops is obtained from the Shakers, and is in oblong compact masses, into which the leaves have been compressed. In some of these cakes the digitalis is of good quality; but we have seen others in which it was quite the reverse, and some which were mouldy in the interior; and, upon the whole, cannot but consider this mode of preparing the drug as objectionable. The dried leaves should be kept in tin canisters, well closed so as to exclude light and moisture; or they may be pulverized, and the powder preserved in well-stopped and opaque bottles. As foxglove deteriorates by time, it should be frequently renewed, as often, if possible, as once a year. Its quality must be judged of by the degree in which it possesses the characteristic properties of colour, smell, and especially taste. It is said to be sometimes adulterated; but if it be bought in leaf, there can be little difficulty with one acquainted with the characters of the genuine leaves in detecting the sophistication.

The seeds contain more of the active principle than the leaves, are less apt to suffer in drying, and keep better; but are little used. So far as the relative strength of these two parts can be determined from that of their alcoholic extracts, it would appear, from the experiments of Prof. Hirtz, that the seeds are ten times stronger than the leaves. (See *Am. Journ. of Pharm.*, xxxiii. 414.)

Properties. Foxglove is without smell in the recent state, but acquires a faint narcotic odour when dried. Its taste is bitter and nauseous. The colour of the dried leaf is a dull pale green, modified by the whitish down upon the under surface; that of the powder is a fine deep green. Digitalis yields its virtues both to water and alcohol. These virtues reside in a peculiar bitter principle, which was first isolated by M. Homolle. In the extraction of this principle, called *digitaline*, he employed the agency of tannic acid, as originally proposed by M. O. Henry. The latter chemist has somewhat simplified the process of M. Homolle. An alcoholic extract is first prepared. This is treated with distilled water acidulated with acetic acid, and heated to about 110° F., a little animal charcoal being added. To the liquor, filtered, and partially neutralized by ammonia, a fresh concentrated infusion of galls is gradually added, so long as a precipitate is produced. This precipitate, which is tannate of digitaline, is obtained separate by decanting the liquid, is washed with pure water mixed with a little alcohol, and then rubbed in a mortar with one-third of its weight of very finely powdered litharge. The mixture is heated gently, and submitted to the action of twice its volume of alcohol at about 90°. The alcoholic solution is treated with a little animal charcoal, filtered, and evaporated at a very gentle heat. The residue is acted on twice or three times with cold and very pure sulphuric ether, which removes impurities, and leaves the digitaline. This may be powdered, or obtained in small scales by dissolving it in the least quantity of alcohol, and allowing the concentrated solution to evaporate in a stove upon plates of glass. From 1000 parts of the leaves, M. Henry obtained between 9 and 10 parts of digitaline. (*Journ. de Pharm.*, 3e

sér., vii. 462.) This substance is white, inodorous, crystallizable with difficulty, intensely bitter, sternutatory when powdered, slightly decomposed at a boiling heat, soluble in about 2000 parts of cold water, more soluble in boiling water, which retains one part in 1000 when it cools, very soluble in alcohol cold or hot, very slightly soluble in ether, incapable of precipitating salts, without alkaline or acid reaction, and destitute of nitrogen. According to Mr. Guy, it is fusible at 310° F., and volatilizable at the same temperature. (*Pharm. Journ and Trans.*, Feb. 1868, p. 374.) It forms an insoluble compound with tannic acid. It has the characteristic property of giving a fine emerald-green colour to concentrated muriatic acid. In the plant, it is rendered soluble in water by means of saline or extractive matters. It has all the effects of digitalis on the system, at least upon the heart. Besides the bitter principle, digitalis contains a volatile oil, a fatty matter, a red colouring substance analogous to extractive, chlorophyll, albumen, starch, sugar, gum, lignin, and salts of potassa and lime, among which, according to Rein and Haase, is superoxalate of potassa. M. Morin, of Geneva, has discovered in the leaves two acids; one fixed, called *digitalic acid*, the other volatile and resembling valerianic acid, which he proposes to name *antirrhinic acid*. (*Ibid.*, vii. 294.) Dr. Morries obtained a narcotic empyreumatic oil by the destructive distillation of the leaves.

It appears, from the experiments of M. Kosmann, that digitaline must be ranked among the glucosides; as, when boiled with dilute sulphuric acid, it is resolved into glucose (grape sugar) and a peculiar substance to which he gives the name of *digitaliretin*, a compound of carbon, hydrogen, and oxygen, having feeble acid properties, and somewhat bitter in solution, though much less so than digitaline itself. Under the influence of caustic soda digitaline is converted into a substance decidedly acid, which M. Kosmann names *digitalinic acid*. The same chemist has shown that digitaline exists in two states, hydrous and anhydrous, the former being converted into the latter at 212° F., with the loss of eight eqs. of water; the formula of the hydrous being, according to Kosmann, $C_{54}H_{53}O_{38}$=681, that of the anhydrous $C_{54}H_{45}O_{30}$=609. It is always the anhydrous which is used in medicine. Digitalinic acid is somewhat bitter, but less so than its original. Like digitaline, it is converted by diluted sulphuric acid and heat into glucose and digitaliretin. (*Journ. de Pharm.*, Juillet, 1860, p. 6, and Août, p. 87.)

From more recent researches by Waltz, and by MM. Homolle and Quevenne themselves, it has been determined that the digitaline of Homolle, though sufficiently pure for practical use, yet contains more or less of two other principles, from which it may be separated by the agency of ether and alcohol.*

* The following are the results of the chemical examination of digitalis, as given by MM. Homolle and Quevenne, in Bouchardat's *Archives de Physiologie, &c.*, for January, 1854. Unfortunately these authors employ the very similar names *digitaline* and *digitalin* to designate different substances; the former being applied by them to the bitter active principle, the latter to a tasteless and probably inert constituent. In conformity with their example, and to prevent confusion, we employ the term digitaline as the name of the active principle, though digitalin would be in accordance with our general usage. Besides the proper active constituent, digitalis contains, according to MM. Homolle and Quevenne, three peculiar neuter principles, *digitalin*, *digitalose*, and *digitalide*; four organic acids, the *digitalic*, *antirrhinic*, *digitaleic*, and *tannic*; various other neuter organic substances, *viz.*, starch, sugar, pectin, an albuminoid substance, an orange-red crystallizable colouring matter, chlorophyll, volatile oil, and lignin; and, lastly, various inorganic salts and earthy matters. It is to the digitaleic acid, which is a fatty substance, that M. Homolle ascribes the nauseating and emetic properties and effects on vision, from which pure digitaline is exempt. (*Ann. de Thérap.*, A D. 1862, p. 71.)

Digitalin (*digitasolin* of Waltz) is a white, imperfectly crystalline powder, tasteless or very slightly acrid, soluble in water and alcohol, and insoluble in ether. *Digitalose* (*digitalierin* of Waltz) is of a white, crystalline, almost micaceous appearance, tasteless, insoluble in water, and soluble in alcohol and ether. These two principles are often contained in the digitaline procured as directed in the text. To separate them, advantage may be taken of the fact, that, though but slightly soluble in perfectly pure ether, digitaline is readily dissolved by that liquid containing but a very small proportion of alcohol. If the impure digitaline be submitted to the action of ether, brought by the addition of alcohol to the sp. gr. 0·780, the digitaline and digitalose will be dissolved, and digitalin left; and, by a repetition of the treatment, almost the whole of the bitter principle may

About four years since it was announced that a *volatile alkaloid* had been obtained by W. Englehardt from the leaves of digitalis, by a process similar to that by which conia is extracted from hemlock. It is described as an exceedingly volatile liquid, of an oily consistence, a very penetrating odour, an alkaline reaction, soluble with difficulty in water, readily dissolved by alcohol, soluble in pure ether, and but slightly so in chloroform. Should this discovery be confirmed and the alkaloid prove to be one of the active principles of digitalis, it should receive the name of *digitalia*. In the mean time, the discoverer calls it *digitalinum fluidum*. (See *Am. Journ. of Pharm.*, March, 1864, p. 126.)

From recent observations of M. Homolle and of M. Lefort, there would appear to be two forms of digitaline, or perhaps two principles to which the same name is attached, differing from each other as the several cinchona alkaloids differ, and probably one a derivative of the other. The chief difference between them is in their degree of solubility in water; one being almost insoluble, the other freely soluble. The former is represented in the market by the French digitaline, the latter by the German. More will be said on this subject under the head of *Digitalinum*, in Part II. of this work.

Medical Properties and Uses. Digitalis is narcotic, sedative, and diuretic. Administered in quantities sufficient to bring the system decidedly under its influence, it is apt to produce a sense of tightness or weight with dull pain in the head, vertigo, dimness or other disorder of vision, and more or less confusion of thought. At the same time it occasionally gives rise to irritation in the pharynx and œsophagus, which extends to the larynx and trachea, producing hoarseness; and, in more than one instance, ptyalism has been observed to result. It sometimes also disturbs the bowels, and excites nausea, or even vomiting. Another and highly important effect is an augmented flow of urine. This has been ascribed by some to increased absorption; and, in support of this opinion, it is stated that its diuretic operation is observable only when dropsical effusion exists; but the fact seems to be, that it is capable of augmenting the quantity of urine in health, and it probably exerts a directly stimulating influence upon the secretory function of the kidneys. This influence is said sometimes to extend to the genital organs. Besides the effects above detailed, digitalis has a remarkably sedative action upon the heart. This is exhibited in the reduction both of the force and frequency of the pulse, which sometimes sinks to 50, 40, or even 30 strokes in the minute. In some instances, however, it undergoes little change; in others only becomes irregular; and we are told that it is even occasionally increased in frequency. It was observed by Dr. Baildon that the effects of digitalis upon the circulation were much influenced by posture. Thus, in his own case, the pulse, which had been reduced from 110 to 40 in the recumbent position, was increased to 72 when he sat, and to 100 when he stood. We do not discover anything remarkable in this circumstance. It is well known that the pulse is always more frequent in the erect than in the horizontal posture, and the difference is greater in a state of debility than in health. Digitalis diminishes the frequency of the pulsations of the heart by a directly depressing power; and

be extracted. If the ethereal solutions thus obtained be mixed, the ether distilled off until the residue has a pap-like consistence, and this residue be treated with boiling alcohol of 60°, the digitaline will be taken up, and most of the digitalose remain undissolved. The former may now be obtained by a gentle evaporation of the alcohol; and by repetitions of the process, may be rendered very nearly free from digitalose, though not perfectly so.

In its purest state, digitaline, instead of being white, has a pale-yellow tint, and is crystallizable with even greater difficulty than in its ordinary condition. Indeed, MM. Homolle and Quevenne are disposed to consider it quite uncrystallizable when perfectly pure. One of its peculiarities is a disposition to assume a globular form when deposited from its solution. If its alcoholic or ethereal solution be concentrated until it becomes turbid, and then examined with a microscope, innumerable globules will be seen of variable size, closely resembling those of milk. These coalesce, and, when deposited, adhere to the bottom of the vessel in grains or masses of a resinoid appearance. (*Op. cit.*, pp. 21 and 22.) As a test of the sufficient purity of digitaline, the authors state that its bitterness should be such as to require, in order to be rendered imperceptible, the addition of 10 litres (about 21 pints) of water to 5 centigrammes (about 0·77 gr.) of the digitaline. (*Ibid.*, p. 126.)—*Note to the eleventh and twelfth editions.*

this very depression, when any exertion is made which calls for increased action in that organ, causes it to attempt, by an increase in the number of its contractions, to meet the demand which it is unable to supply by an increase in their force. According to Dr. Traube, it directly diminishes animal temperature in febrile and inflammatory diseases, without antecedent effect on the circulation. (See *Archives Gén.*, 4e sér., xxviii. 338.) It is said also to have a powerful sedative influence on the generative organs. This statement is not altogether incompatible with that already made, that the medicine sometimes stimulates these organs. The normal depressing effect may be experienced through the nervous centres; while the occasional irritation may proceed, either from the direct action of the medicine through the blood on the tissues affected, or a sympathetic influence extended from the urinary organs. Dr. A. Buchner states that digitaline arrests vinous fermentation, and consequently poisons the yeast plant. (See *Am. Journ. of Pharm.*, xxiv. 154.)

The effects above detailed may result from digitalis given in remediate doses. In larger quantities its operation is more violent. Nausea and vomiting, stupor or delirium, cold sweats, extreme prostration of strength, hiccough, convulsions, and syncope are among the alarming symptoms which indicate its poisonous character. These effects are best counteracted by stimulants, such as brandy, the volatile alkali, opium, and strong coffee. Should any of the poison be suspected to remain, it would be proper, before employing other measures, to evacuate the stomach by the free use of warm liquids. From the experiments of M. Bonjean, it appears that powdered digitalis may be given to fowls, in large quantities, with entire impunity. (*Journ. de Pharm.*, 3e sér., iv. 21.)

A peculiarity of digitalis is that, after having been given in moderate doses for several days without apparent effect, it sometimes acts suddenly with an accumulated influence, even endangering life. It is, moreover, very permanent in its operation, which, having once commenced, is maintained for a considerable period without fresh accessions of the medicine. The practical inferences deducible from these properties of digitalis are, first, that, after it has been given for some time without effect, care should be taken not to increase the dose too greatly; and, secondly, that, after its effects have begun to appear, it should be suspended for a time, or exhibited in smaller doses, lest a dangerous accumulation should be experienced. In numerous instances death has resulted from its incautious employment.

Digitalis has been long known to possess medicinal powers; but it was never regarded as a standard remedy till after its application by Withering to the treatment of dropsy, about the year 1775. It is at present employed very extensively, both for its diuretic power, and for its sedative influence over the circulation. The former renders it highly useful in dropsical diseases, though like all other remedies it frequently fails; the latter adapts it to cases in which the action of the heart requires to be controlled. The idea was at one period entertained, that it might serve as a substitute for the lancet in febrile and inflammatory complaints; and it has been much employed for this purpose by the advocates of the *contra-stimulant* doctrine in Italy; but experience has proved that it is a very frail support where the symptoms of inflammation are such as to call for the loss of blood. Nevertheless, it is even at present highly valued by some practitioners in febrile diseases, and in acute inflammatory rheumatism has been recommended as a most efficient remedy, being itself capable of effecting cures in many cases, sometimes as early as in five or six days, but more frequently by the twelfth or fifteenth. (*Arch. Gén.*, 6e sér., ix 733.) As an adjuvant to the lancet, and when circumstances forbid the employment of that remedy, it is often useful. Good may be expected from it in all fevers where one of the chief indications is to reduce the frequency of the pulse. We have ourselves employed it with this view in scarlet fever with apparent advantage. Though it certainly has not the power, at one time ascribed to it by some, of curing phthisis, it acts beneficially as a palliative in that complaint by depressing the excited movements of the heart. In the same way it proves

advantageous in aneurism, hypertrophy and dilatation of the heart, palpitations from rheumatic or gouty irritation, and in various forms of hemorrhage, after action has been sufficiently reduced by the lancet. Some consider it especially efficient in menorrhagia. It has also been prescribed in nervous headache, mania, epilepsy, pertussis, and spasmodic asthma; and highly respectable testimony can be adduced in favour of its occasional efficacy in these complaints. In delirium tremens it has been recommended as a specific, given in infusion, in the full dose, repeated every two hours till symptoms of narcotism are induced; but the practice is somewhat hazardous, unless the patient is carefully watched. (*Am. Journ. of Med. Sci.*, xvii. 501.) Much testimony has recently been given in favour of large doses of digitalis in this affection; the tincture having been taken in doses of from half a fluidrachm to half a fluidounce, and repeated afterwards in smaller quantities, at intervals of two, four, or six hours till sleep was obtained. (*Ibid.*, Jan. 1861, p. 257.) The same practice has been recommended in acute mania. But we would reiterate the necessity of caution; for, though the tincture, as found in the shops, may no doubt often be administered safely in large doses, yet, if the medicine is of good quality, they cannot but be hazardous. Digitalis is said to be a very efficient remedy in spermatorrhœa. Externally applied, it sometimes acts speedily and powerfully as a diuretic, and has proved useful in dropsy. For this purpose the fresh leaves bruised, or the tincture, may be rubbed over the abdomen and on the inside of the thighs. (*Revue Médicale*, May, 1834.) Ch Hoffman has shown by experiments on himself that the active matter of digitalis is capable of being absorbed through the skin, and that its effects on the system may be obtained by means of baths.* A case is recorded in which a cataplasm of the leaves applied to the abdomen for the relief of obstinate and dangerous suppression of urine, and repeated in six hours, brought on excessive diuresis, with a discharge amounting to probably 8 gallons in less than 24 hours, producing fatal exhaustion. (*Med. Times and Gaz.*, Jan. 1868, p. 86.)

Digitalis is administered in substance. The dose of the powder is one grain, repeated twice or three times a day, and gradually increased till some effect is produced upon the head, stomach, pulse, or kidneys, when it should be omitted or reduced. The infusion and tincture are officinal preparations often resorted to. (See *Infusum Digitalis* and *Tinctura Digitalis.*) The extract has also been employed; and Orfila found it, whether prepared with water or alcohol, more powerful than the powder. Enormous doses of this medicine have been given with asserted impunity; and, when they occasion full vomiting, it is possible that they may sometimes prove harmless; but, when the alarming effects sometimes experienced from comparatively moderate doses are considered, the practice must be condemned as exceedingly hazardous.

Digitaline has been used internally, but its employment requires caution. With all the powers of digitalis, it possesses the advantage of more equable strength, and consequently greater precision and certainty in regard to the dose. It may be used for any of the purposes to which the leaves are applicable; and may be administered in pill, or alcoholic solution. The dose to begin with should not exceed the fiftieth or sixtieth of a grain, and should not be carried beyond the twelfth. It is much administered in the form of granules, made by saturating small globules of sugar with an alcoholic solution of digitaline. The granules of Homolle, which are commonly used in Europe, contain each a milligramme, or about the seventieth of a grain; equivalent, on the average, to perhaps a grain and a half of digitalis of medium strength. One of these globules may be given as a commencing dose. Forty of them taken with a view to suicide, though

* M. Hoffman, during a period of 44 days, took 16 baths prepared with 300 litres of water and 250 grammes of digitalis leaves. After the third bath he began to feel the effects of the medicine; a peculiar uneasiness, namely, and a reduction of the pulse 4 or 5 pulsations per minute; and this condition persisted several hours. At the eighth bath the uneasiness was increased, and the pulse decreased from 68 to 51. After the sixteenth bath, the pulse fell to 48. (*Journ. de Pharm. et de Chim.*, Juillet, 1867, p. 37.)—*Note to the thirteenth edition.*

followed by copious vomiting, so that most of the poison was probably discharged, produced the most alarming prostration, with a pulse weak, 46 to 48 in a minute, intermittent, and sometimes scarcely perceptible. The patient, however, ultimately recovered. (*Ann. de Thérap.*, A.D. 1858, p. 103.)

DIOSPYROS. *U. S. Secondary.*

Persimmon.

The unripe fruit of Diospyros Virginiana. *U. S.*

Diospyros. *Sex. Syst.* Diœcia Octandria. — *Nat. Ord.* Ebenaceæ.

Gen. Ch. Male. *Calyx* four to six-cleft. *Corolla* urceolate, four to six-cleft. *Stamens* eight to sixteen; filaments often producing two anthers. Female. *Flower* as the male. *Stigmas* four to five. *Berry* eight to twelve-seeded. *Nuttall.*

Diospyros Virginiana. Willd. *Sp. Plant.* iv. 1107; Michaux, *N. Am. Sylv.* ii. 219. The persimmon is an indigenous tree, rising sometimes in the Southern States to the height of sixty feet, with a trunk twenty inches in diameter; but seldom attaining more than half that size near its northern limits, and often not higher than fifteen or twenty feet. The stem is straight, and in the old tree covered with a furrowed blackish bark. The branches are spreading; the leaves ovate-oblong, acuminate, entire, smooth, reticulately veined, alternate, and supported on pubescent footstalks. The buds are smooth. The male and female flowers are on different trees. They are lateral, axillary, solitary, nearly sessile, of a pale-orange colour, and not conspicuous. The fruit is a globular berry, dark-yellow when ripe, and containing numerous seeds in a soft yellow pulp.

This tree is very common in the Middle and Southern States, but, according to Michaux, does not flourish beyond the forty-second degree of north latitude. The flowers appear in May or June; but the fruit is not ripe till the middle of autumn. While green, the fruit is excessively astringent, and, we presume, will retain its astringency if carefully sliced and dried in this state; but, when perfectly mature, and after having been touched by the frost, it is sweet and palatable. Michaux states that, in the Southern and Western States, it is made into cakes with bran, and used for preparing beer with the addition of water, hops, and yeast. A spirituous liquor may be obtained by the distillation of the fermented infusion. The unripe fruit was examined by Mr. B. R. Smith, of Philadelphia, and found to contain tannic acid, sugar, malic acid, colouring matter, and lignin. (*Am. Journ. of Pharm.*, xviii. 167.) The tannic acid has been ascertained by Mr. John E. Bryan not to be of the kind existing in galls and oak-bark. (*Ibid.*, xxxii. 215.) The fact that tannin is a glucoside may throw some light on the rapid and complete change which the fruit undergoes from astringency to sweetness during maturation. It has been used by Dr. Mettauer, of Virginia, in diarrhœa, chronic dysentery, and uterine hemorrhage. He gave it in infusion, syrup, and vinous tincture, prepared in the proportion of about an ounce of the bruised fresh fruit to two fluidounces of the vehicle, and administered in the dose of a fluidrachm or more for infants, and half a fluidounce or more for adults. The bark is astringent and very bitter, and is said to have been used advantageously in intermittents, and in the form of a gargle in ulcerated sorethroat. W.

DRACONTIUM. *U. S. Secondary.*

Skunk Cabbage.

The root of Dracontium fœtidum, Ictodes fœtidus (*Bigelow*), Symplocarpus fœtidus (*Salisbury*). *U. S.*

Botanists have had some difficulty in arranging this plant. It was attached by Willdenow to the genus *Dracontium*, by Michaux and Pursh was considered

a *Pothos*, and by American botanists has been erected into a new genus, which Nuttall calls *Symplocarpus* after Salisbury, and Dr. Bigelow proposes to name *Ictodes*, expressive of the odour of the plant. The term *Symplocarpus*, though erroneous in its origin, was first proposed, and, having been adopted by several botanists, should be retained.

Symplocarpus. *Sex. Syst.* Tetrandria Monogynia. — *Nat. Ord.* Araceæ.

Gen. Ch. Spathe hooded. *Spadix* covered with perfect flowers. *Calyx* with four segments. *Petals* none. *Style* pyramidal. *Seeds* immersed in the spadix.

Symplocarpus fœtida. Barton, *Med. Bot.* i. 123. — *Ictodes fœtidus.* Bigelow, *Am. Med. Bot.* ii. 41. The *skunk cabbage* is a very curious plant, and the only one of the genus. The root is perennial, large, abrupt, and furnished with numerous fleshy fibres, which penetrate to the depth of two feet or more. The spathe which first appears, is ovate, acuminate, obliquely depressed at the apex, auriculated at the base, folded inwards at the edges, and of a brownish-purple colour, varied with spots of red, yellow, and green. Within the spathe, the flowers, which resemble it in colour, are placed in great numbers upon a globose peduncled spadix, for which they form a compact covering. After the spathe has decayed, the spadix continues to grow, and when the fruit is mature, has attained a size exceeding several times its original dimensions. At the base of each style is a roundish seed, immersed in the spadix, about the size of a pea, and speckled with purple and yellow. The leaves, which appear after the flowers, are numerous and crowded, oblong-cordate, acute, smooth, strongly veined, and attached to the root by long petioles, which are hollowed in front, and furnished with coloured sheathing stipules. At the beginning of May, when the leaves are fully developed, they are very large, being from one to two feet in length, and from nine inches to a foot in breadth.

The plant is indigenous, growing abundantly in meadows, swamps, and other wet places throughout the northern and middle sections of the Union. Its flowers appear in March and April, and in the lower latitudes often so early as February. The fruit is usually quite ripe, and the leaves are decayed before the end of August. The plant is very conspicuous from its abundance, and the magnitude of its leaves. All parts of it have a fetid odour, thought to resemble that of the offensive animal after which it is named. This odour resides in an extremely volatile principle, which is rapidly dissipated by heat, and diminished by desiccation. The root is the part employed. It should be collected in autumn, or early in spring, and dried with care.

The root, as found in the shops, consists of two portions; the body either whole or in transverse slices, and the separated radicles. The former, when entire, is cylindrical or in the shape of a truncated cone, two or three inches long by about an inch in thickness, externally dark-brown and very rough from the insertion of the radicles, internally white and amylaceous. The latter are of various lengths, about as thick as a hen's quill, very much flattened and wrinkled, white within, and covered by a yellowish reddish-brown epidermis, considerably lighter coloured than the body of the root. More or less of the fetid odour remains for a considerable period in the dried root. The taste, though less decided than in the fresh, is still acrid, manifesting itself, after the root has been chewed for a short time, by a pricking and smarting sensation in the mouth and throat. The acrimony, however, is dissipated by heat, and is quite lost in decoction It is also diminished by time and exposure; and the root should not be kept longer than a single season. The radicles are said to have less acrimony than the caudex. The seeds are very acrid, and, though inodorous when whole, give out strongly, when bruised, the peculiar odour of the plant.

Medical Properties and Uses. The root is stimulant, antispasmodic, and narcotic. In large doses it occasions nausea and vomiting, with headache, vertigo, and dimness of vision. Dr. Bigelow has witnessed these effects from thirty grains of the recently dried root. The medicine was introduced into notice by the Rev. Dr. Cutler, who recommended it highly in asthma; and it has been subsequently employed with apparent advantage in chronic catarrh, chronic

rheumatism, hysteria, and dropsy. Dr. Heintzelman thinks it expectorant as well as antispasmodic, and has used it beneficially in hooping-cough and pulmonary consumption. (*N. J. Med. Reporter*, iv. 310.)

It is best given in powder, of which the dose is from ten to twenty grains, to be repeated three or four times a day, and gradually increased till some evidence of its action is afforded. A strong infusion is sometimes employed, and the people in the country prepare a syrup from the fresh root; but the latter preparation is very unequal. The root itself, as kept in the shops, is of uncertain strength, in consequence of its deterioration by age. W.

DULCAMARA. *U. S.*, *Br.*

Bittersweet.

The stalks of Solanum Dulcamara. *U. S.* The dried young branches of Solanum Dulcamara, Bittersweet, from indigenous plants which have shed their leaves. *Br.*

Douce-amère, *Fr.*; Bittersüss, Alpranken, *Germ.*; Dulcamara, *Ital.*, *Span.*

Solanum. *Sex. Syst.* Pentandria Monogynia. — *Nat. Ord.* Solanaceæ.

Gen. Ch. Corolla wheel-shaped. *Anthers* somewhat coalescing, opening by two pores at the apex. *Berry* two-celled. *Willd.*

This genus includes numerous species, of which several have been used in medicine. Besides *S. Dulcamara*, which is the only officinal species, a few others merit notice. 1. *Solanum nigrum*, the *common garden* or *black nightshade*, is an annual plant from one to two feet high, with an unarmed herbaceous stem, ovate, angular-dentate leaves, and white or pale-violet flowers, arranged in peduncled nodding umbel-like racemes, and followed by clusters of spherical black berries, about the size of peas. There are numerous varieties of this species, one of which is a native of the United States. The leaves are the part employed. They are said to produce diaphoresis, sometimes diuresis and moderate purging, and in large doses nausea and giddiness. As a medicine they have been used in cancerous, scrofulous, and scorbutic diseases, and other painful ulcerous affections, being given internally, and applied at the same time to the parts affected in the form of poultice, ointment, or decoction. A grain of the dried leaves may be given every night, and gradually increased to ten or twelve grains, or till some sensible effect is experienced. The medicine, however, is scarcely used at present. By some persons the poisonous properties ascribed to the common nightshade are doubted. M. Dunal, of Montpellier, states, as the result of numerous experiments, that the berries are not poisonous to man or the inferior animals; and the leaves are said to be consumed in large quantities in the Isles of France and Bourbon as food, having been previously boiled in water. In the latter case, the active principle of the plant must have been extracted by decoction. 2. The leaves, stalks, and unripe berries of *Solanum tuberosum*, or the *common potato*, are asserted to be narcotic; and an extract prepared from the leaves has been employed in cough and spasmodic affections, in which it is said to act like opium. (*Geiger.*) From half a grain to two grains may be given as a dose. Dr. Latham, of London, found the extract to produce favourable effects in protracted cough, chronic rheumatism, angina pectoris, cancer of the uterus, &c. Its influence upon the nervous system was strongly marked, and, in many instances, the dose could not be increased above a few grains without giving rise to threatening symptoms. It appeared to Dr. Latham to be analogous in its operation to digitalis. His experiments were repeated in Philadelphia by Dr. Worsham with different results. The extract was found, in the quantity of nearly one hundred grains, to produce no sensible effect. (*Philad. Journ. of the Med. and Phys. Sciences*, vi. 22.) We can reconcile these opposite statements only upon the supposition, that the properties of the plant vary with the season, or with the place and circumstances of culture. Dr. Julius Otto found *solania* in the germs of the potato. He was induced to make the investigation by observing that cattle were destroyed by feeding on the residue of germi-

nated potatoes, used for the manufacture of brandy. A case of death in a girl of fourteen, from eating the unripe fruit of the potato, is recorded in the *British Med. Journ.* for Sept. 3d, 1859. The prominent symptoms were partial stupor, speechlessness, jactitation, hurried breathing, lividness of the skin, cold sweats, very frequent and feeble pulse, and a constant spitting through the closed teeth of viscid frothy phlegm. Death occurred on the second day. C. Haaf has found the same alkaloid in old potatoes which had begun to germinate, in the proportion of 0·16 to 500 parts; and in very young potatoes, deprived of their coating, precisely the same quantity. Fully ripe potatoes, which had not begun to sprout, gave a negative result. (*Neues Repert. für Pharm.*, A.D. 1864, p. 559.) 3. The well-known *tomato*, so much used as a vegetable at the table, and so advantageous through its nutritive, laxative, and antiscorbutic properties, is the fruit of a species of Solanum, denominated *S. Lycopersicum*. Though the juice of the fruit is free from solania, the seeds probably contain it, as their alcoholic extract has a bitter, pungent taste. (See *Am. Journ. of Pharm.*, xxxiv. 519.) 4. Several instances of poisoning are on record from the fruit of *S. pseudocapsicum*, or *Jerusalem cherry*, which, from its resemblance to the common cherry, is liable to be eaten by children. 5. In the *Edin. Med. Journ.* (Nov. 1867, p. 398), several cases are recorded by Dr. Manners, of Jamaica, W. I., of poisoning by the *susumber berries*, of which one proved fatal, and several others recovered, probably in consequence of the early evacuation of the stomach by a mustard emetic. The symptoms recorded were anxious countenance, dilated pupil, cold skin, and difficult articulation. The fatal case was not seen by Dr. Manners till after death. The susumber berries are the fruit of a species of Solanum, denominated by Lunnan, in his "Hortus Jamaicensis," *S. bacciferum*, of which there are two varieties, one relatively innocent, as its fruit is habitually used by the natives, the other poisonous, as would be inferred from the cases here noticed. 6. The *Solanum paniculatum*, called *jurubeba* in Brazil, is said to be largely used in S. America, in affections of the liver and spleen, catarrh of the bladder, anæmia, and amenorrhœa. The plant is thought to be one of the most powerful deobstruents. The leaves, fruit, and root are used, externally in the form of a plaster, internally in the form of syrup, wine, and extract. (*London Lancet*, Feb. 1866, p. 158.)

Solanum Dulcamara. Willd. *Sp. Plant.* i 1028; Woodv. *Med. Bot.* p. 237, t. 84; Bigelow, *Am. Med. Bot.* i. 169. The *bittersweet* or *woody nightshade* is a climbing shrub, with a slender, roundish, branching, woody stem, which, in favourable situations, rises six or eight feet in height. The leaves are alternate, petiolate, ovate, pointed, veined, soft, smooth, and of a dull-green colour. Many near the top of the stem are furnished with lateral projections at their base, giving them a hastate form. Some have the projection only on one side. Most of them are quite entire, some cordate at the base. The flowers are disposed in elegant clusters, somewhat analogous to cymes, and standing opposite to the leaves. The calyx is very small, purplish, and divided into five blunt persistent segments. The corolla is wheel-shaped, with five pointed, reflected segments, which are of a violet-blue colour, with a darker purple vein running longitudinally through their centre, and two shining greenish spots at the base of each. The filaments are very short, and support large, erect, lemon-yellow anthers, which cohere in the form of a cone around the style. The berries are of an oval shape and a bright scarlet colour, and continue to hang in beautiful bunches after the leaves have fallen.

This plant is common to Europe and North America. It flourishes most luxuriantly in damp and sheltered places, as on the banks of rivulets, and among the thickets which border our natural meadows. It is also found in higher and more exposed situations, and is frequently cultivated in gardens. In the United States it extends from New England to Ohio, and is in bloom from June to August. The root and stalk have medicinal properties, though the latter only is officinal. The berries, which were formerly esteemed poisonous, and thought to act with great severity on the stomach and bowels, have of late been said to

be innoxious. A case, however, of death from their use in a child has been recorded. (See *Pharm. Journ.*, Feb. 1861, p. 436.) Bittersweet should be gathered in autumn, after the fall of the leaf; and the extreme twigs should be selected. That grown in high and dry situations is said to be the best.

The dried twigs, as brought to the shops, are of various lengths, cylindrical, about as thick as a goose-quill, externally wrinkled, and of a grayish-ash colour, consisting of a thin bark, an interior ligneous portion, and a central pith. They are inodorous, though the stalk in the recent state emits, when bruised, a peculiar, rather nauseous smell. Their taste, which is at first bitter and afterwards sweetish, has given origin to the name of the plant. Boiling water extracts all their virtues. These are supposed to depend, at least in part, upon a peculiar alkaline principle called *solanin* or *solania*, which was originally discovered by M. Desfosses, of Besançon, in the berries of *Solanum nigrum*, and has subsequently been found in the stalks, leaves, and berries of *S. Dulcamara* and *S. tuberosum*. It is supposed to exist in the bittersweet combined with malic acid.* *Solania* is in the form of a white opaque powder, or of delicate acicular crystals, somewhat like those of sulphate of quinia, though finer and shorter. It is inodorous, of a bitter taste, fusible at a little above 212°, scarcely soluble in water, soluble in alcohol and ether, and capable of neutralizing the acids. It is distinguished by the deep-brown, or brownish-yellow colour which iodine imparts

* Solania is most conveniently obtained from the sprouts of the common potato. The following is Wackenroder's process for extracting it. The sprouts, collected in the beginning of June, and pressed down in a suitable vessel by means of pebbles, are macerated for twelve or eighteen hours in water enough to cover them, previously acidulated with sulphuric acid, so as to have a strongly acid reaction during the maceration. They are then expressed by the hand; and the liquor, with the addition of fresh portions of sulphuric acid, is added twice successively, as at first, to fresh portions of sprouts, and in like manner separated by expression. After standing for some days, it is filtered, and treated with powdered hydrate of lime in slight excess. The precipitate which forms is separated by straining, dried in a warm air, and boiled several times with alcohol. The alcoholic solution, having been filtered while hot, will, upon cooling, deposit the solania in flocculent crystals. An additional quantity of the alkaloid may be obtained by evaporating the mother-liquor to one-quarter, and then allowing it to cool. The whole residuary liquor will assume a gelatinous consistence, and, upon being dried, will leave the solania in the form of a translucent, horny, amorphous mass. (*Pharm. Central Blatt.* 1843, p. 174.)

Opinion at present seems to be unsettled as to the nature of solanin or solania; and the results obtained by different chemists vary so much as almost to necessitate the conclusion that they have operated on different substances. Indeed, M. Moitessier states expressly that the alkaloids obtained from different species of Solanum differ perceptibly in their physical properties. By this chemist the alkaloid, as obtained from dulcamara, was found, after a careful examination, to have the formula $C_{45}H_{75}NO_{14}$, though M. Blanchet had previously given it as $C_{81}H_{63}NO_{28}$. It appears to have very feeble alkaline properties, and forms amorphous compounds with the acids. (*Comptes Rendus*, Nov. 17, 1856.) Mr. Guy found it to have the same point of fusion and volatilization, which he states to be 350° F. (*Pharm. Journ. & Trans.*, Feb. 1868, p. 374.) As obtained from the potato and black nightshade, Dr. Frommüller describes it as a white crystalline substance, having when moist an acrid smell like that of potatoes, and a nauseous taste. With sulphuric acid it gives a blood-red colour passing into brown. In doses of from one to four grammes, it caused a slight burning in the throat and eructation, and the pupil was dilated in one instance. In larger doses it caused vomiting, loss of appetite, giddiness, &c., but produced no decided soporific effect. (*B. & F. Med.-chir. Rev.*, April, 1867, p. 527.) It would, we think, be hazardous to begin with any specimen of solania which may be under observation, in doses so large as the smallest of those mentioned.

Zwenger and Kind ascertained that, when boiled with sulphuric or muriatic acid, solania is resolved into grape sugar and a much stronger alkaloid, which they name *solanidin* (*solanidia*). This has a decided alkaline reaction and a bitter taste, and forms crystallizable salts. According to this statement, solania ranks among the glucosides. (*Liebig's Annalen*, cix.) The reaction between solania and sulphuric acid, resulting in the production of a red colour, is said by these chemists actually to take place between the acid and solanidin, which has been first produced by it.

Still more recently, the astonishing information is given, on the basis of experiments by Otto Gmelin, that not only are solanin and solanidin glucosides, but that neither of them contains nitrogen, the formula of the former being $C_{88}H_{72}O_{30}$, that of the latter $C_{52}H_{40}O_4$. (*Ibid.*, ex. p. 167.) To us it seems impossible that the many experienced chemists who have found nitrogen in solania should have been mistaken; and the inference is that Gmelin has probably operated on a different substance. (*Note to the twelfth and thirteenth editions.*)

to its solution, and by its reaction with sulphuric acid, which becomes first reddish-yellow, then purplish-violet, then brown, and lastly, again colourless, with the deposition of a brown powder. (*Pharm. Cent. Blatt*, A.D. 1843, p 177.) Given to a cat, it was found by M. Desfosses to operate at first as an emetic, and afterwards as a narcotic. Dr. J. Otto observed, among its most striking effects, a paralytic condition of the posterior limbs of animals. One grain of the sulphate of solania was sufficient to destroy a rabbit in six hours. Dr. Frass did not observe paralysis of the lower limbs of animals as one of its effects. Given to different animals, he found it to occasion loss of appetite, vomiting, sometimes diarrhœa, excitement of the circulation, dilatation of the pupils, and, in large doses, heaviness, apathy, slowness of movement, and sometimes convulsions. Injected into the jugular vein, it caused accelerated circulation, difficult and even spasmodic respiration, convulsions, tetanic spasms, and death. Two grains of the acetate, injected into the rectum of a rabbit, killed it in six hours. Ten grains given to a dog, and confined by a ligature round the œsophagus, though it occasioned great disturbance, did not prove fatal. Twenty grammes (℥v) produced no effect on a hog. (*B. & F. Medico chirurg. Rev.*, Am. ed , July, 1854, p. 189.) Besides solania, the stalks of S. Dulcamara contain, according to Pfaff, a peculiar principle to which he gave the name of *picroglycion*, indicative of the taste, at once bitter and sweet, which it is said to possess. This was obtained by Blitz, in the following manner. The watery extract was treated with alcohol, the tincture evaporated, the residue dissolved in water, the solution precipitated with subacetate of lead, the excess of this salt decomposed by sulphuretted hydrogen, the liquor then evaporated to dryness, and the residue treated with acetic ether, which yielded the principle in small isolated crystals by spontaneous evaporation. Pfaff found also in dulcamara a vegeto-animal substance, gummy extractive, gluten, green wax, resin, benzoic acid, starch, lignin, and various salts of lime.

Medical Properties and Uses. Dulcamara possesses feeble narcotic properties, with the power of increasing the secretions, particularly those of the kidneys and skin. We have observed, in several instances, when the system was under its influence, a dark-purplish colour of the face and hands, and at the same time considerable languor of the circulation. Its narcotic effects do not become obvious, unless when it is taken in large quantities. In overdoses it produces nausea, vomiting, faintness, vertigo, and convulsive muscular movements. A case is recorded in Casper's *Wochenschrift*, in which a man took, in one forenoon, from three to four quarts of a decoction made from a peck of the stalks, and was attacked with pain in the joints, numbness of the limbs, dryness of the mouth, and palsy of the tongue, with consciousness unimpaired, the pulse quiet, but small and rather hard, and the skin cool. The symptoms disappeared under the use of stimulants. (*Lond. Med. Gaz.*, Sept. 1850, p. 548.)* Dulcamara has been recom-

* Prof. Caylus, of Leipsick, has made numerous experiments upon man and animals, in relation to the physiological effects and relative strength of dulcamara, and its preparations, including solania, with the following results. 1. They are poisonous, and may prove fatal in overdoses. 2. In the character of their operation they are identical. 3. The extract of the twigs is from five to ten times stronger than the twigs themselves, that of solania 30 times stronger than the extract. 4. They produce congestion of the kidneys, and sometimes an increased flow of urine, which, in that case, is always albuminous. 5. They cause a constant and remarkable diminution in the frequency of respiration, and death from their action is ascribed to a paralyzing influence on the respiratory nerve-centres. 6. In the last period of their operation, they weaken while they accelerate the action of the heart. 7. Prof. Caylus thinks that they act especially on the spinal marrow and medulla oblongata, as evinced not only by their influence on the breathing, but also by the tetanic contraction they occasioned in the muscles of the chest and extremities. 8. They produce little direct effect on the brain, and cause but a feeble contraction of the pupil. 9. They increase the sensibility of the skin, and have no direct irritant influence on the stomach and bowels.

They are applicable, the Professor thinks, to spasmodic and irritative affections of the respiratory organs; and inflammation either of the lungs or bowels constitutes no contra-indication to them. He recommends solania in the form of acetate, in the dose of from one-sixth of a grain to a grain. He prefers the alcoholic extract to the aqueous. (*Ann. de Thérap.*, A.D. 1859, p. 24, and *Arch. Gén.*, Mars, 1859, p. 350.)—*Note to the twelfth edition.*

mended in various diseases, but is now chiefly employed in the treatment of cutaneous eruptions, particularly those of a scaly character, as lepra, psoriasis, and pityriasis. In these complaints it is often beneficial, especially in combination with minute doses of the antimonials. Its influence upon the secretions is insufficient to account for its favourable effects. Perhaps they may be ascribed to its sedative influence on the capillary circulation. It is said to have been beneficially employed in chronic rheumatism and chronic catarrh. Antaphrodisiac properties have been ascribed to it. We have seen it apparently useful in mania connected with strong venereal propensities. The usual form of administration is that of decoction, of which two fluidounces may be taken four times a day, and gradually increased till some slight disorder of the head indicates the activity of the medicine. (See *Decoctum Dulcamaræ.*) An extract and fluid extract are officinal. The dose of the former is from five to ten grains, of the latter from thirty minims to a fluidrachm. That of the powder would be from thirty grains to a drachm. In cutaneous affections, a strong decoction is often applied to the skin, at the same time that the medicine is taken internally.

ELATERIUM. *U.S., Br.*

Elaterium.

A substance deposited by the juice of the fruit of Momordica Elaterium, Ecbalium agreste (*Richard*). *U. S.* A sediment from the juice of the Squirting Cucumber fruit. *Br.*

The British Pharmacopœia recognises the fruit under the name of *Ecbalii Fructus, Squirting Cucumber Fruit*, and defines it as the fruit, very nearly ripe, of Ecbalium Officinarum.

Elaterion, *Fr.;* Elaterium, *Germ.;* Elaterio, *Ital., Span.*

Momordica. *Sex. Syst.* Monœcia Monadelphia.—*Nat. Ord.* Cucurbitaceæ. *Gen. Ch.* Male. *Calyx* five-cleft. *Corolla* five-parted. *Filaments* three. Female. *Calyx* five-cleft. *Corolla* five-parted. *Style* trifid. *Gourd* bursting elastically. *Willd.*

Momordica Elaterium. Willd. *Sp. Plant.* iv. 605; Woodv. *Med. Bot.* p. 192, t. 72.—*Ecbalium agreste.* Richard; Lindley, *Med. and Œcon. Bot.* p. 95.—*Ecbalium officinarum.* Br.—*Ecbalium Elaterium.* French Codex, A.D. 1837. The *wild* or *squirting cucumber* is a perennial plant, with a large fleshy root, from which rise several round, thick, rough stems, branching and trailing like the common cucumber, but without tendrils. The leaves are petiolate, large, rough, irregularly cordate, and of a grayish-green colour. The flowers are yellow, and proceed from the axils of the leaves. The fruit has the shape of a small oval cucumber, about an inch and a half long, an inch thick, of a greenish or grayish colour, and covered with stiff hairs or prickles. When fully ripe, it separates from the peduncle, and throws out its juice and seeds with considerable force through an opening at the base, where it was attached to the footstalk. The name of squirting cucumber was derived from this circumstance, and the scientific and officinal title is supposed to have had a similar origin; though some authors maintain that the term *elaterium* was applied to the medicine, rather from the mode of its operation upon the bowels, than from the projectile property of the fruit.*

This species of Momordica is a native of the south of Europe, and is cultivated in Great Britain, where, however, it perishes in the winter.† Elaterium is the substance spontaneously deposited by the juice of the fruit, when separated

* From the Greek ελαυνω I drive, or ελατης driver. The word elaterium was used by Hippocrates to signify any active purge. Dioscorides applied it to the medicine of which we are treating.

† On a visit to Spain, in the year 1861, the author noticed the plant growing abundantly in different localities upon the Rock of Gibraltar, especially on its southern declivity, which faces Africa, where in some spots it almost covered the ground. (*Note to the twelfth edition.*)

and allowed to stand. From the experiments of Dr. Clutterbuck, it has been supposed that only the free juice about the seeds, which is obtained without expression, affords the product. The substance of the fruit itself, the seeds, as well as other parts of the plant, have been thought to be nearly or quite inert. From the statements made by Mr. Bell (see *note* below), these opinions must be somewhat modified; but there is no doubt that strong expression injures the product. When the fruit is sliced and placed upon a sieve, a perfectly limpid and colourless juice flows out, which soon becomes turbid, and in the course of a few hours begins to deposit a sediment. This, when collected and carefully dried, is very light and pulverulent, of a yellowish-white colour, slightly tinged with green. It is the genuine elaterium, and was found by Clutterbuck to purge violently in the dose of one-eighth of a grain. But the quantity contained in the fruit is very small. Clutterbuck obtained only six grains from forty cucumbers. Commercial elaterium is often a weaker medicine, owing in part, perhaps, to adulteration, but much more to the mode in which it is prepared. In order to increase the product, the juice of the fruit is often expressed with great force; and there is reason to believe that it is sometimes evaporated so as to form an extract, instead of being allowed to deposit the active matter. The French elaterium is prepared by expressing the juice, clarifying it by rest and filtration, and then evaporating to a suitable consistence. As the liquid remaining after the deposition of the sediment is comparatively inert, it will be perceived that the preparation of the French Codex must be relatively feeble. The following are the directions of the British Pharmacopœia. "Cut the fruit lengthwise, and lightly press out the juice. Strain it through a hair sieve, and set aside to deposit. Carefully pour off the supernatant liquor; pour the sediment on a linen filter, and dry it on porous tiles, with a gentle heat. The decanted fluid may deposit a second portion of sediment, which can be dried in the same way." The latter portion deposited is of a lighter colour. (*Pereira.*) The slight pressure directed is necessary for the separation of the juice from the somewhat immature fruit employed. The perfectly ripe fruit is not used; as, in consequence of its disposition to part with its contents, it cannot be carried to market. In the British Pharmacopœia, the former name of Extractum Elaterii of the London College has been very properly abandoned; as the preparation is in no correct sense of the word an extract. As the plant is not cultivated in this country for medicinal purposes, our Pharmacopœia very properly adopts, as officinal, the medicine as found in commerce. It is brought chiefly from England; but it is probable that a portion of the elaterium, of which Dr. Pereira speaks as coming from Malta, reaches our market also.*

* The following notice of the cultivation of the elaterium plant, and the preparation of the drug at Mitcham, in Surrey, England, condensed from a paper by Mr. Jacob Bell in the *Pharm. Journ.* for October, 1850, may have some interest for the American reader. The seeds are sown in March, and the seedlings planted in June. In the luxuriant plants the stem sometimes acquires an extraordinary breadth. In one instance, though not thicker than the forefinger where it issued from the earth, it was in its broadest part four inches wide and half an inch thick. A wet season interferes with the productiveness of the plant. At the spontaneous separation of the fruit, it throws out its juice sometimes to the distance of twenty yards; and hazard of injury to the eyes is incurred by walking among the plants at their period of maturity. A bushel of the fruit weighs 40 pounds, and the price varies from 7 to 10 shillings sterling. In the manufacture of elaterium, which begins early in September, the fruit, having been washed, if necessary, to cleanse it from earthy matters, is sliced longitudinally into halves, and then submitted to expression, wrapped in a hempen cloth, in a common screw-press. Considerable force is used in the expression. The juice is then strained through hair, cypress, or wire sieves, and set aside for deposition. The deposit usually takes place in three or four hours. When this part of the process is completed, the supernatant liquor is carefully poured off, the deposit is placed on calico cloths resting on hair sieves, and allowed to drain for about twelve hours, after which it is removed by a knife, spread over small cloths, and dried on canvas frames in the drying stove. About half an ounce of fine elaterium is obtained from a bushel of fruit. Some obtain more; but the product is inferior, in consequence of the use of too much force in the expression. Good elaterium has a pale pea-green tint; that of inferior quality is of a duller hue. The juice expelled in bursting is said to undergo very little change in the air, while that expressed from the ripe fruit immediately afterwards becomes

Properties. The *best elaterium* is in thin flat or slightly curled cakes or fragments, often bearing the impression of the muslin upon which it was dried, of a greenish-gray colour becoming yellowish by exposure, of a feeble odour, and a bitter somewhat acrid taste. It is pulverulent and inflammable, and so light that it swims when thrown upon water. When of *inferior quality*, it is sometimes dark-coloured, much curled, and rather hard, breaking with difficulty, or presenting a resinous fracture. The *Maltese elaterium* is in larger pieces, of a pale colour, sometimes without the least tinge of green, destitute of odour, soft, and friable; and not unfrequently gives evidence of having been mixed with chalk or starch. It sinks in water.

Dr. Clutterbuck first observed that the activity of elaterium resided in the portion of it soluble in alcohol and not in water. This fact was afterwards confirmed by Dr. Paris, who found that the alcoholic extract, treated with boiling distilled water, and afterwards dried, had the property of purging in minute doses, while the remaining portion of the elaterium was inactive. The subsequent experiments of Mr. Hennell, of London, and Mr. Morries, of Edinburgh, which were nearly simultaneous, demonstrated the existence of a crystallizable matter in elaterium, which is the active principle, and has been named *elaterin*. According to Mr. Hennell, 100 parts of elaterium contain 44 of elaterin, 17 of a green resin (*chlorophyll*), 6 of starch, 27 of lignin, and six of saline matters. The alcoholic extract which Dr. Paris called *elatin*, is probably a mixture of elaterin and the green resin or chlorophyll.*

milky, and deposits elaterium. The recently burst fruit, therefore, is nearly if not quite as good for the preparation of the drug as that collected before perfect maturity. For a paper on the cultivation of the elaterium plant at Hitchin, Herts, England, taken from the Pharmaceutical Journal, see the *American Journal of Pharmacy*, March, 1860, p. 163. (*Note to the ninth and twelfth editions.*)

* *Chlorophyll.* The substance to which Pelletier gave this name, under the impression that it was a peculiar proximate principle, was subsequently supposed by that chemist to be a mixture of wax and a green fixed oil. (*Journ. de Pharm.*, xix. 109.) Afterwards, M. Frémy succeeded, by the joint action of a menstruum composed of two parts of ether and one of muriatic acid diluted with a little water, in separating chlorophyll into two colouring principles, one yellow and the other blue; the former being dissolved by the ether, and the latter by the muriatic acid. The yellow, M. Frémy proposed to name *phylloxanthin*, the blue *phyllocyanin*. (*Ibid.*, Avril, 1860, p. 241.) More recently MM. Frémy and Filhol have separately made further very interesting investigations into the subject. The following is a brief abstract of the proceedings of the former of these chemists. Those of the latter, which do not differ materially in their results, may be seen in the *Journ. de Pharm. et de Chim.* (4e sér., ii. 304). Chlorophyll, treated either with the alkaline bases or acids, is resolved into the two principles above mentioned, which, however, cannot be readily separated. The bases act in three different modes, according to the nature of the base itself. 1. The earthy bases, and especially alumina, shaken with an alcoholic solution of chlorophyll, form true lakes; being thrown down in combination with the green matter, and leaving a little yellow matter, and a fixed oil which always accompanies chlorophyll, and renders it so difficult to be obtained pure. But this lake with baryta is easily decomposed, and yields the green principle readily to boiling alcohol, from which it may be obtained by evaporation; and this is the easiest mode of preparing pure chlorophyll. 2. The alkalies, as potassa and soda, if boiled with chlorophyll, saponify the fatty matter, and resolve the pure chlorophyll into the two principles already referred to; but these cannot be separated. 3. The alkaline earths, as lime and baryta, and especially the latter, act in a very remarkable manner. By long boiling with chlorophyll, baryta resolves it into phylloxanthin and phyllocyanin. The former being insoluble in water is precipitated; and along with it is also precipitated an insoluble compound of the latter with baryta, constituting a true salt, in which the phyllocyanin acts the part of an acid; and, as it acts in like manner with other bases, Frémy considers it as a true acid, and changes its name accordingly to *phyllocyanic acid*. Chlorophyll may, therefore, be considered as a peculiar principle analogous to the natural fats, which, under the action of energetic bases, undergoes a kind of saponification; the phylloxanthin representing the glycerin, and the phyllocyanic acid a fatty acid coloured bluish-green. By treating the mass thus obtained with alcohol, we obtain a solution of the phylloxanthin, which, as the alcohol evaporates, separates in a crystalline form. By treating with sulphuric acid the phyllocyanate of baryta left behind, we obtain the phyllocyanic acid, which is soluble in alcohol and ether. Thus the two principles may be isolated.

Phylloxanthin is neuter, insoluble in water, soluble in alcohol and ether, and crystallizable, sometimes in yellow plates, sometimes in reddish prisms, resembling bichromate of potassa, and possessing dyeing powers analogous to those of chromic acid

Elaterin, according to Mr. Morries, crystallizes when pure in colourless microscopic rhombic prisms, having a silky appearance when in mass. It is extremely bitter and somewhat acrid, insoluble in water and alkaline solutions, soluble in alcohol, ether, and hot olive oil, and sparingly soluble in dilute acids. At a temperature between 300° and 400° it melts, and at a higher heat is dissipated in thick, whitish, pungent vapour, of an ammoniacal odour. It has no alkaline reaction. It may be procured by evaporating an alcoholic tincture of elaterium to the consistence of thin oil, and throwing the residue while yet warm into a weak boiling solution of potassa. The potassa holds the green resin in solution, and the elaterin crystallizes as the liquor cools. Mr. Hennell obtained it by treating with ether the alcoholic extract procured by the spontaneous evaporation of the tincture. This consists of elaterin and the green resin, the latter of which, being much more soluble in ether than the former, is completely extracted by this fluid, leaving the elaterin pure. But, as elaterin is also slightly soluble in ether, a portion of this principle is wasted by Mr. Hennell's method. By evaporating the ethereal solution, the green resin is obtained separate. Mr. Hennell says that this was found to possess the purgative property of elaterium, as it acted powerfully in a dose less than one-third of a grain. But the effect was probably owing to the presence of a portion of elaterin which had been dissolved by the ether. The late Dr. Duncan, of Edinburgh, ascertained that the crystalline principle or elaterin produced, in the quantity of $\frac{1}{12}$ or $\frac{1}{16}$ of a grain, all the effects of a dose of elaterium. The proportion of elaterin varies exceedingly in different parcels of the drug. Mr. Morries obtained 26 per cent. from the best British elaterium, 15 per cent. from the worst, and only 5 or 6 per cent. from the French; while a portion, procured according to the directions of the London College, yielded to Mr. Hennell upwards of 40 per cent. The Br. Pharmacopœia directs that the proportion of elaterin should not be less than 20 per cent. Experiments by Mr. John Williams satisfactorily prove that the fruit, exhausted of the free juice from which elaterium is obtained, contains very little if any elaterin, certainly not enough to compensate for the cost of its extraction. (*Chem. News*, Feb. 18, 1860, p. 124.) Mr. Williams substitutes the name of *ecbalin* for that of elaterin; a change which, we think, is uncalled for, at least so long as that of elaterium is retained for the medicine.

Choice of Elaterium. The inequality of elaterium depends probably more on diversities in the mode of preparation than on adulteration. Sometimes, however, it is greatly sophisticated; and large quantities are said to have been imported into this country, consisting mainly of chalk, and coloured green artificially. (B. Canavan, *N. Y. Journ. of Pharm.*, iii. 385.) It should possess the sensible properties above indicated as characterizing good elaterium, should not effervesce with acids, and should yield from one-sixth to one-fourth of elaterin.

Medical Properties and Uses. Elaterium is a powerful hydragogue cathartic, and in a large dose generally excites nausea and vomiting. If too freely administered, it operates with great violence both upon the stomach and bowels, producing inflammation of these organs, which has in some instances eventuated fatally. It also increases the flow of urine. The fruit was employed by the ancients, and is recommended in the writings of Dioscorides as a remedy in mania and melancholy. Sydenham and his contemporaries considered elaterium highly useful in dropsy; but, in consequence of some fatal results from its incautious

Phyllocyanic acid is soluble in water, alcohol, and ether, giving to these an olive-like colour, with bronzed-red, or violet reflections. All its salts are brown or green; but only the alkaline are soluble in water. This acid dissolves in sulphuric and muriatic acid, giving rise to solutions which, according to their strength, are green, reddish, violaceous, or beautifully blue. This M. Frémy considers the important fact of the investigation, as it explains the various tints which chlorophyll offers in vegetation.

It follows, from all that has been said, that chlorophyll is an immediate proximate principle, of great motility, which undergoes diversified changes of colour in the progress of vegetation, and other changes, such as have been mentioned, under the influence of different reagents. (*Journ. de Pharm. et de Chim.*, 4e sér., ii. 185, A.D. 1865.)—***Note to the twelfth and thirteenth editions.***

employment, it fell into disrepute, and was generally neglected till again brought into notice by Dr. Ferriar. It is now considered one of the most efficient hydragogue cathartics in the treatment of dropsical diseases, in which it has sometimes proved successful after all other remedies have failed. The full dose of commercial elaterium is often from one to two grains; but, as in this quantity it generally vomits, if of good quality, the best plan is to give it in the dose of a quarter or half of a grain, repeated every hour till it operates. The dose of Clutterbuck's elaterium is the eighth of a grain. That of elaterin is from the sixteenth to the twelfth of a grain, and is best given in solution. One grain may be dissolved in a fluidounce of alcohol with four drops of nitric acid, and from 30 to 40 minims may be given diluted with water. W.

ELEMI. *Br.*

Elemi.

Botanical source undetermined, probably from Canarium commune. A concrete resinous exudation. *Br.*

Résine élemi, *Fr.;* Oelbaumharz, Elemi, *Germ.;* Elemi, *Ital.;* Goma de limon, *Span.*

Amyris. *Sex. Syst.* Octandria Monogynia.—*Nat. Ord.* Terebintaceæ, *Juss.;* Amyrideæ, *R. Brown, Lindley.*

Gen. Ch. Calyx four-toothed. *Petals* four, oblong. *Stigma* four-cornered. *Berry* drupaceous. *Willd.*

Some botanists separate from this genus the species which have their fruit in the form of a capsule instead of a nut, and associate them together in a distinct genus with the name of *Icica.* This is recognised by De Candolle.

Most of the trees belonging to these two genera yield, when wounded, a resinous juice analogous to the turpentines. It is not improbable that the drug, usually known by the name of *elemi,* is derived from several different trees. That known to the ancients is said to have been obtained from Ethiopia, and all the elemi of commerce was originally brought from the Levant. The tree which afforded it was not accurately known, but was supposed to be a species of Amyris. At present the drug is said to be derived from three sources, namely, Brazil, Mexico, and Manilla. The Brazilian is believed to be the product of a plant mentioned by Maregrav under the name of *icicariba,* and called by De Candolle *Icica Icicariba.* It is a lofty tree, with pinnate leaves, consisting of three or five pointed, perforated leaflets, smooth on their upper surface and woolly beneath. It is erroneously stated in some works to be a native of Carolina. The elemi is obtained by incisions into the trees, through which the juice flows and concretes upon the bark. The Mexican is said by Dr. Royle to be obtained from a species of Elaphrium, which that author has described from dried specimens, and proposes to name *E. elemiferum.* (*Mat. Med.,* Am. ed., p. 339.) The Manilla elemi is conjecturally referred to *Canarium commune.* (*Ibid.,* p. 340.)

Elemi is in masses of various consistence, sometimes solid and heavy like wax, sometimes light and porous; unctuous to the touch; diaphanous; of diversified colours, generally greenish with intermingled points of white or yellow, sometimes greenish-white with brown stains, sometimes yellow like sulphur; fragile and friable when cold; softening by the heat of the hand; of a terebinthinate somewhat aromatic odour, diminishing with age, and said, in some varieties, to resemble that of fennel; of a warm, slightly bitter, disagreeable taste; entirely soluble, with the exception of impurities, in boiling alcohol; and affording a volatile oil by distillation. A variety examined by M. Bonastre was found to consist of 60 parts of resin, 24 of a resinous matter soluble in boiling alcohol, but deposited when the liquid cools, 12·5 of volatile oil, 2 of extractive, and 1·5 of acid and impurities. M. Baup found the resin to be of two kinds, one amorphous, the other crystallizable; the latter of which he proposes to call *elemin.* (*Journ. de Pharm.,* 3e sér., xx. 331.) Elemi is sometimes adulterated with colophony and turpentine. The Manilla elemi is in masses of a light-yellowish colour, internally soft, and of a strong odour of fennel. (*Royle.*) We have been told that

a considerable amount of elemi is used in this country by the hatters. Dr. Emil Mannkoff obtained from Brazilian elemi about 6 per cent. of a colourless volatile oil, insoluble in water, but easily dissolved both by alcohol and ether, of a not unpleasant odour, and a somewhat acrid and bitter taste, and of a composition represented, according to Stenhouse and Deville, by the formula C_5H_6. Dr. Mannkoff considers the oil as coinciding in medical properties with oil of turpentine, for which it may be substituted, with the advantage of a less disagreeable taste. (*B. and F. Medico-chir. Rev.*, July, 1859, p. 170, from *Virchow's Archiv.*)

Medical Properties and Uses. Elemi has properties analogous to those of the turpentines; but is exclusively applied to external use. In the United States it is rarely employed even in this way. In the Pharmacy of Europe it enters into the composition of numerous plasters and ointments. We are told that it is occasionally brought to this country in small fragments, mixed with the coarser kinds of gum arabic from the Levant and India.

Off. Prep. Unguentum Elemi, *Br.* W.

ERGOTA. *U. S., Br.*

Ergot.

The diseased seed of Secale cereale. *U. S.* The sclerotium (compact mycelium or spawn of Claviceps purpurea, *Tulasne*), produced within the paleæ of the common rye, Secale cereale. *Br.*

Spurred rye; Secale cornutum; Siegle ergoté, *Fr.;* Mutterkorn, *Germ.*

In all the *Graminaceæ* or grass tribe, and in some of the *Cyperaceæ*, the place of the seeds is sometimes occupied by a morbid growth, which, from its resemblance to the spur of a cock, has received the name of *ergot*, adopted from the French. This product is most frequent in the rye, *Secale cereale*, and, having been found, as occurring in that plant, to possess valuable medicinal properties, was adopted in the first edition of the U. S. Pharmacopœia, under the name of *secale cornutum* or *spurred rye*. In the edition of 1840, this name was changed for *ergota*, in conformity with the nomenclature of the London and Edinburgh Colleges. It is probable that this morbid growth has similar properties from whatever plant derived; and the fact has been proved in relation to the ergot of wheat. (See *Am. Journ. of Med. Sci.*, N. S., xxxii. 479.) Indeed, in a case reported by Dr. D. L. McGugin (*Iowa Med. Journ.*, iv. 93), this variety of ergot is said to have succeeded promptly, when that of rye, previously tried, had failed.*

Different opinions have been held in relation to the nature of this singular substance. In a note on the next page are contained the observations made on the subject in former editions of the dispensatory. More recent investigations by M. L.-R. Tulasne, while they confirm the opinion of De Candolle that the ergot is a new product, altogether distinct from the grain of the rye, have developed, in an apparently quite satisfactory manner, the whole history of this mushroom, which, if only for the curious and highly interesting stages of its progress,

* *Ergot of Wheat.* M. Leperdriel, jun., of Montpellier, in France, recommends this product as preferable to the ergot of rye, on the grounds that it is destitute of the poisonous properties of the latter, and is more certain as a remedy, in consequence of being less liable to change. The former point is, to say the least, very uncertain; but in relation to the latter there is some reason to think that M. Leperdriel is right; for Prof. Bentley, of London, found that of two specimens, one of the ergot of rye, the other of wheat, which had been kept under similar circumstances for ten years, the former was quite destroyed, while the latter was apparently unchanged. Ergot is rarer in wheat than in rye; and in the head of the former there is generally but one and very rarely more than two of the diseased grains. It is produced usually in wheat in wet seasons, and on that side of the head most exposed to the dampness. It is shorter and much thicker than the ergot of rye, being about half an inch long and three-quarters of an inch or more in circumference, and cleft into two or three divisions. In colour and smell it resembles the spurred rye. (*Pharm. Journ. and Trans.*, March and April, 1863, pp. 423 and 442.)—*Note to the twelfth edition*

merits a brief notice here.* The chief source of failure in the investigation of this subject has been, that observers have fixed their attention on some one stage in the development of the fungus, and ceased to push their inquiries further. There are three successive stages, in each of which the plant presents a peculiar form. It has already been largely developed, when it begins to project beyond the glume, which has protected its early growth; but there are usually other flowers at the same time which present it in a rudimentary state. It begins with a structure which M. Tulasne calls the *sphacelia*. This appears on the outside of the ovary of the flower, and is intimately attached to it. Its development commences with that of the pistil, which serves as a soil for it. The ovary of the rye consists of a cellular membrane of two coats, the outer of which has a thick parenchyma, white and gorged with juice, the inner is very delicate and green. The *sphacelia*, when it takes possession of the ovary, identifies itself with the outer parenchyma, and in some measure replaces it, being as it were borne by the inner membrane. It rapidly increases, taking the form of the ovary, and almost obliterating its cavity. The ovule is either entirely wanting, or may be seen, on a careful examination, in an imperfect form. For some time the parasite is represented entirely by the *sphacelia*, which is an oblong, fungous mass, almost homogeneous, soft and tender, marked on its surface by numerous sinuous furrows, and having within many irregular cavities,

* Ergot was at one time thought to be merely the seed altered by disease; the morbid condition being ascribed by some to the agency of an insect, by others to excess of heat and moisture. A second opinion considered it a parasitic fungus, occupying the place of the seed. This was entertained by De Candolle, who called the fungus *Sclerotium Clavus*. According to a third and intermediate opinion, the ergot is the seed, diseased and entirely perverted in its nature by the influence of a parasitic fungus, attached to it from the very beginning of its development. This view was put forth by M. Léveillé, in a memoir published in the *Annals of the Linnæan Society of Paris* for the year 1826. He gave to the supposed fungus the name of *Sphacelia segetum;* but his observations as to its characters have not been sustained. Until within a very few years, the credit was ascribed to the late Mr. E. J. Quekett, of London, of having fully investigated this subject, and established the last-mentioned view of the nature of ergot. According to Mr. Quekett, the beginning of the growth of the ergot is marked by the appearance, about the young grain and its appendages, of multitudes of minute filaments like cobwebs, which run over all its parts, cementing anthers and stigmas together, and of a white coating upon the surface of the grain, from which, upon immersion in water, innumerable minute particles separate, which after a time sink in the fluid. These particles, when examined by the microscope, prove to be the germs or *sporidia* of a species of fungus, and may be observed to sprout and propagate in various ways under favourable circumstances. Their length, upon the average, is about the four-thousandth of an inch. The filaments are the results of the growth of these singular germs. The sporidia and filaments do not increase with the increase of the ergot; and, when this has projected beyond the palæ and become visible, it has lost a portion of its white coating, and presents a dark-violet colour. It now increases with great rapidity, and attains its full size in a few days. When completely developed, it exhibits very few of the filaments or sporidia upon its surface. But Mr. Quekett believed that the germs of the fungus emit their filaments through the tissue of the ergot when young and tender, and that, as this increases, it is made up partly of the diseased structure of the grain, and partly of the fungus. The plant was named by Mr. Quekett *Ergotætia abortifaciens;* for which title Dr. Pereira, at the suggestion of the Rev. M. J. Berkeley, substituted that of *Oidium abortifaciens*. This view of the nature and cause of ergot is supported by the asserted facts, that the microscopic fungus has an existence independent of the morbid grain, being found in various other parts of the plant, and growing even when entirely separated from it; and that the sporidia or white dust upon the surface of ergot, if applied to the seeds of certain Graminaceæ before germination, or sprinkled on the soil at the roots of the plants after they have begun to grow, will give rise to ergotized fruit. That the ergot is not itself a peculiar fungus, but the perverted grain, was supposed to be evinced by the frequent remains of the stigma upon its summit, by the scales at its base, and by the circumstance that in some instances only a portion of the seed is ergotized. (See *Am. Journ. of Pharm.*, xi. 116 and 237.) It is a curious fact, that the observations of Mr. Quekett were generally correct, and have been verified by M. Tulasne himself; yet the plant is only accidentally present, and is wholly distinct from the true ergot fungus. The fact noted that the sporidia of Mr. Quekett's fungus are apparently capable, if applied to the seeds of certain Graminaceæ, or sprinkled on the soil where they grow, of giving rise to ergot in these plants, is readily explicable on the supposition, that the sporidia might have been mixed with those of the proper ergot.

which, as well as the outer coat, are uniformly covered with linear parallel cells. From the summits of these peripheric cells, internal as well as external, issue oval corpuscles, from the 5 to the 7 thousandths of a millimeter in length, which spread upon neighbouring objects, and especially the glumes of the flowers they inhabit. They are a kind of reproductive cells, called conidia, which are produced by many fungi, long before the perfect plant is developed. M. Tulasne calls them "*spermatie.*" In the early stage, the *sphacelia* respects the top of the ovary and the stigmas attached. The stamens often abort; but the filaments and anthers may sometimes be seen buried in the tissue of the sphacelia, and altered by its action. Sometimes the ovule is not completely aborted, but is certainly never developed into a monster grain. In all ergotted plants, the top of the pistils and stigmas, when they remain, are often covered with a mouldiness, consisting of spores and entangled filaments, which end by covering the parts with an abundant ashy or sooty powder. This is a different fungus, and was confounded by Mr. Quekett with the ergot plant. It is found as well in the non-ergotted as the ergotted flowers, and in those of plants which do not bear ergot. At a somewhat advanced period of the development of the sphacelia, there exudes, especially from the summit, a very adhesive juice, which spreads over that structure, bearing along with it an immense number of the seedlets or "*spermaties*" This leaves on the surface when dry an oily appearance, and afterwards the spots, where it remains, become brownish or blackish. But this exudation does not appear until the *sphacelia* has ceased to constitute the whole plant.

At the base of the sphacelia is produced a compact body, violet-black without and white within, which is the ergot in a rudimentary state. With this commences the second stage in the development of the fungus. The young ergot is everywhere invested by the tissue of the *sphacelia* (which Tulasne calls also *spermagonia*, from its office); but, as it increases, it seems to be placed below the *spermatopherous apparatus*, and raises it steadily out of the floral bractes which concealed it, ending by supporting it wholly at its summit. Sometimes are carried with it the atrophied ovary, which still shows the hairs that crowned it, and some remains of the stigmas. It results that the ergot, which is technically the *sclerotium* of the fungus, remains for some time concealed in the sphacelia, so that this seems to constitute the whole plant. But, when the function belonging to this has been fulfilled, which is apparently to impregnate the sclerotium, it begins to become dry, and is much deformed. The ergot, on the contrary, increases in all directions, and soon appears above the glume. As it augments, the thin coating which it has received from the spermatopherous tissue, especially below, gradually becomes thinner, and seems to disappear; so that its surface, instead of being uniformly violet-black, is only here and there covered with the remains of the tissue, or by a deposit of the conidia or "*spermatie.*" Nevertheless, the sphacelia, deformed, shrunken, and worn away by rains and other causes, remains long at the top of the ergot, along with the abortive ovary, &c., and may even continue to adhere when the ergot is detached from the plant.

The time required for the full development of the sphacelia and the ergot or sclerotium varies, no doubt; but a rapidity of growth has been claimed for it which the truth will not warrant. The period has even been estimated at three days; but this is much too short. In an example under the observation of M. Tulasne, at least a month elapsed after the appearance of the sphacelia, before the growth was completed.

Apart from an obscure resemblance to the seed of the plant supporting it, the ergot has absolutely nothing in common with the normal grain, and it is surprising how it should have come, after investigation, to be considered as the hypertrophied seed. The anatomical structure and all the physical characters of ergot are those of the mushrooms, or rather of a sclerotic mycelium. The parenchyma, which is white, dry, and brittle, consists in all its parts of minute utricles, globular or polyhedric, with rather thick walls, intimately united, and filled with a limpid oil, but feebly coloured with iodine. The superficial

utricles, which alone are coloured, have an outer wall thicker than the inner, and the colour of these is what gives its characteristic hue to ergot. Not the least trace of starch is to be detected.

The germination of the ergot, and the growth of a minute mushroom, are the last stage in the development of this fungus. About three months after ergot has been planted in a suitable soil, evidences of germination are seen in the sprouting of little globular prominences at points on its surface, which gradually enlarge, and raise themselves from the surface upon cylindrical stems, imitating in a diminutive way the growth of ordinary mushrooms. These little fungi belong to the genus *Sphæria*. As they increase, the interior of the ergot becomes exhausted, no doubt by contributing to their growth; so that this product seems to act the part of certain tubers, in the higher forms of vegetation, containing germs, and nourishment for their development. Falling to the ground, in its natural course, the ergot in the soil germinates, and produces mushrooms, the spores of which, carried up with the juices of rye, become lodged in the ovary, where they begin the course of life and progress which has been delineated. Tulasne has given the name of *Claviceps purpurea* to the whole fungus. There may be other species of Claviceps, giving rise to ergot in other plants. Thus M. Tulasne believes that the ergot of the reed is a different species; but there is no reason to think that any other species is concerned in the product of any variety of ergot that has been in medical use. (*Annales des Sciences Naturelles*, 3e sér., xx. 5, A.D. 1853.)

The ergot usually projects out of the glume or husk beyond the ordinary outline of the spike or ear. In some spikes the place of the seeds is wholly occupied by the ergot, in others only two or three spurs are observed. It is said to be much more energetic when collected before than after harvest. Rye has generally been thought to be most subject to the disease in poor and wet soils, and in rainy seasons; and intense heat succeeding continued rains has been said to favour its development, especially if these circumstances occur at the time the flower is forming. It is now, however, asserted that moisture has little or nothing to do with its production.* It should not be collected until some days after it has begun to form; as, according to M. Bonjean, if gathered on the first day of its formation, it does not possess the poisonous properties which it exhibits when taken on the sixth day. (See *Pharm. Journ.*, Jan. 1842.)

Properties. Ergot is in solid, brittle yet somewhat flexible grains, from a third of an inch to an inch and a half long, from half a line to three lines in thickness, cylindrical or obscurely triangular, tapering towards each end, obtuse at the extremities, usually curved like the spur of a cock, marked with one or two longitudinal furrows, often irregularly cracked or fissured, of a violet-brown colour and often somewhat glaucous externally, yellowish-white or violet-white within, of an unpleasant smell when in mass resembling that of putrid fish, and of a taste which is at first scarcely perceptible, but ultimately disagreeable and slightly acrid. Under the microscope the surface appears more or less covered with sporidia, which occasion its glaucous aspect; and the interior structure is found to be composed of minute roundish cells, containing, according to Quekett, particles of oil. Ergot yields its virtues to water and alcohol. The aqueous infusion or decoction is claret-coloured, and has an acid reaction. It is precipitated by acetate and subacetate of lead, nitrate of silver, and tincture of galls; but affords with iodine no evidence of the presence of starch. Long boiling impairs the virtues of the medicine.

Ergot has been analyzed by Vauquelin, Winckler, Wiggers, Wright, Legrip, and several others. The analysis by M. Legrip is among the most complete. That chemist obtained from 100 parts of ergot 34·50 parts of a thick, fluid,

* Mr. J. Price Wetherill informed the author that, in two seasons, he had found rye, sown very late, so as scarcely to come up before spring, to be almost universally ergotized; while neighbouring rye, sown at the proper season, in the same kind of soil precisely, had nothing of the disease, though the seed was the same in both cases. (*Note to the sixth edition.*)

fixed oil, of a fine yellow colour; 2·75 of starch; 1·00 of albumen; 2·25 of inulin; 2·50 of gum; 1·25 of uncrystallizable sugar; 2·75 of a brown resin; 3·50 of *fungin;* 13 50 of vegeto-animal matter; 0·75 of osmazome; 0·50 of a fatty acid; 24·50 of lignin; 0 50 of colouring principles; an odorous principle not isolated; 2·25 of fungate of potassa; 0·50 of chloride of sodium; 0·50 of sulphate of lime and magnesia; 1·25 of subphosphate of lime; 0·25 of oxide of iron; 0·15 of silica; and 2·50 of water, with 2·35 loss. (*Ann. de Thérap.*, 1845, p. 44) Wiggers obtained a substance which he denominated *ergotin*, under the impression that it was the active ingredient. It was reddish-brown, of a peculiar nauseous odour and bitter slightly acrid taste, soluble in alcohol, but insoluble in water or ether. It was obtained by digesting ergot in ether and afterwards in alcohol, evaporating the alcoholic solution, and treating the extract thus obtained with water, which left the ergotin undissolved. It was given with fatal effects to a hen. But, though the ergotin of Wiggers may exercise some influence on the system, it is very obvious that it cannot be the active principle of ergot, which yields its virtues to water, and partially at least to ether. Dr. Wright supposed the virtues of ergot to reside in the fixed oil, which he therefore recommended as a substitute for the medicine. The *oil of ergot*, when obtained from grains recently collected, is, according to Dr. Wright, often quite free from colour; but, as usually prepared, is reddish-brown. It has a disagreeable, somewhat acrid taste, is lighter than water, and is soluble in alcohol and alkaline solutions. It is prepared by forming an ethereal tincture of ergot by the process of displacement, and evaporating the ether with a gentle heat. Experience has shown that, though the oil thus prepared with ether may have produced effects analogous to those of ergot, they were to be ascribed rather to some principle extracted along with the oil by the menstruum than to the oil itself; for, when procured by expression, this has been found to be inactive. Indeed, Prof. Procter has ascertained that it contains a little secalin, one at least of the active principles of ergot, which may be separated from it by washing with acidulated water. According to Mr. T. R. Baker, the oil has a taste and smell similar to those of castor oil, with which it also agrees in ultimate composition, and yields analogous results in saponification. (*Am. Journ. of Pharm.*, xxiv. 101–2.) The *sugar of ergot* was found by Mitscherlich to be peculiar, and was named by him *mycose*. He described it as crystallizable, very soluble in water, almost insoluble in cold but dissolved by about 100 parts of boiling alcohol, quite insoluble in ether, and without the action of glucose on the salts of copper. Its formula is $C_{12}H_{11}O_{11}+2HO$. (*Am. Journ. of Pharm.*, xxx. 346.) Dr. F. L. Winckler discovered a *peculiar colouring matter* in ergot, which he considered, if not identical with hematin, as closely resembling it. (*Pharm. Journ.*, xii. 86.)

Secalia. Propylamia. By the same chemist a volatile alkaloid was detected in ergot, which he named *secalin* (*secalia*), and believed to exist in the drug in the form of *ergotate of secalin*, being combined with the ergotin of Wiggers, to which he ascribed acid properties, and therefore gave the name of *ergotic acid*. This alkaloid has been ascertained to be identical with *propylamin* (*propylamia*), the odorous principle of herring pickle. Winckler obtained it by distilling the watery extract of ergot with potassa. The following process, employed by Prof. Procter, yields it with facility. Ergot, having been exhausted by ether, is submitted to percolation with water; the aqueous solution, after the addition of four times its bulk of alcohol, which precipitates the gummy and albuminous matter, is filtered; the liquid is concentrated and mixed with milk of lime, and the mixture distilled into a receiver containing water acidulated with sulphuric acid. The secalia escapes freely, and is condensed in the receiver, forming a sulphate with the acid present. If to a little of this liquid a drop of solution of potassa is added, the odour of ergot is perceived; and the presence of a rod moistened with muriatic acid produces visible vapours of muriate of secalia. (*Proceed. of the Am. Pharm. Assoc.*, A.D. 1857.) It can scarcely be doubted that the virtues of ergot are connected in some degree with this alkaloid; and the conjecture of

Winckler that the ergotate of secalia is the active principle of ergot, if wrong, is so probably only by its exclusiveness.*

The odour of ergot is no doubt owing to the liberation of its volatile alkaloid, probably in consequence of a slow decomposition of the native salt. A method of detecting ergot in a mixed powder, rye flour for example, is thus afforded. If, on the addition of solution of potassa, the odour of ergot is perceived, its presence is sufficiently proved.

Ergot, when perfectly dry and kept in well-stopped bottles, will retain its virtues for a considerable time; but, exposed to air and moisture, it speedily undergoes chemical change and deteriorates. It is, moreover, apt to be attacked by a minute worm, which consumes the interior of the grain, leaving merely the exterior shell and an excrementitious powder. This insect is sometimes found in the ergot before removal from the plant. In the state of powder, the medicine still more readily deteriorates. It is best, as a general rule, to renew it every year or two. M Viel recommends that it should be well dried at a gentle heat, and incorporated with double its weight of loaf sugar, by means of which, if protected from moisture, it will retain its virtues for many years. According to M. Zanon, the same result is obtained by stratifying it with well washed and perfectly dried sand, in a bottle from which air and light are excluded. Camphor is said to prevent injury from worms.

Medical Properties and Uses. Given in small doses, ergot produces, in the system of the male, no obvious effect; but, in the female, exhibits a strong tendency to the uterus, upon the contractile property of which it operates with great energy. In the quantity of half a drachm or a drachm it often occasions nausea

* *Ergotina. Ecbolina.* Experiments were a few years since made on ergot by Mr. Wm. T. Wenzell, of La Crosse, Wisconsin, which, if confirmed by future observation, will throw new and most valuable light upon the intricate subject of the composition of that drug. Mr. Wenzell claims to have discovered in it two new fixed alkaloids, which he proposes to name respectively ecbolina and ergotina, and in which, along with the volatile alkaloid propylamia, the virtues of the medicine reside. Mr. Wenzell claims also to have ascertained that ergotic acid, the peculiar acid of ergot, with which the alkaloids are probably combined, is volatile. The acid reaction, however, which is evinced by an infusion of ergot, is not, he thinks, owing to this acid, but to an acid phosphate of magnesia.

Ecbolina was obtained by precipitating a cold infusion of ergot with acetate of lead, throwing down the lead with sulphuretted hydrogen, filtering and concentrating the liquid, adding gradually bichloride of mercury so long as a precipitate was produced, washing the precipitate, treating it with sulphuretted hydrogen, and filtering. The chloride (muriate) of ecbolina thus obtained was treated with an excess of phosphate of silver, the chloride of silver formed and the excess of the phosphate were removed by filtration, the phosphoric acid was separated by hydrate of lime, the liquid was again filtered, lime was removed by a stream of carbonic acid, and the gas expelled by a gentle heat. The liquid now contained the pure alkaloid, which was obtained by evaporation at a low temperature.

Ergotina was obtained by filtering the liquid which remained after precipitation with bichloride of mercury, treating it with phospho-molybdic acid, washing the precipitate obtained, suspending it in water with an excess of carbonate of baryta, and digesting until the yellowish colour of the mixture was exchanged for a pure white, with the evolution of carbonic acid. Nothing now remained but to filter and carefully evaporate the solution, which yielded the ergotina.

The alkaloids thus obtained are brownish, apparently uncrystallizable, slightly bitter, alkaline in their reaction on litmus and turmeric, soluble in alcohol and water, and insoluble in pure ether and chloroform. They form salts with the acids, which are uncrystallizable and generally deliquescent. Ignited, they are entirely consumed, leaving no residue. As they yield ammonia when heated with lime, they contain nitrogen.

With ecbolina in solution bichloride of platinum produces a deep orange-coloured, and cyanide of potassium a white precipitate, while a solution of ergotina is affected by neither of these reagents.

As to their operation upon the system, ecbolina in the dose of half a grain, supposed to be equivalent to 30 grains of ergot, produced decided effects on the brain and spinal marrow, with involuntary contractions of the muscles, followed by nausea and general depression, with little change in the pulse, and is believed by Mr. Wenzell to be the ingredient which causes uterine contraction in women. Ergotina was found less active, but produced some cerebral disturbance with reduction of the pulse.

Ergotic acid was obtained by distilling ergot with sulphuric acid. It is supposed by Mr. Wenzell to be combined naturally with ecbolina, ergotina, and potassa: while the propylamia exists in ergot as a phosphate. (*Am. Journ. of Pharm.*, May, 1864, p. 193.) —*Note to the twelfth edition.*

or vomiting, and in still larger doses produces a sense of weight and pain in the head, giddiness, dilatation of the pupils, delirium, and even stupor, proving that it possesses narcotic properties. It is said also to excite febrile symptoms; but our own observation coincides with that of authors who ascribe to it the power of reducing the frequency of the pulse. We have seen this effect produced by it in a remarkable degree, even without nausea. A case is recorded in which it produced great prostration, with an almost absent pulse, paleness and coldness of the surface, partial palsy, with pricking of the limbs, and great restlessness, without stupor or delirium. (*Gazette Med. de Paris*, Juillet 25, 1857.) Dr. Hardy, of the Dublin Lying-in Hospital, found it to diminish the pulsations of the fœtal heart. Its long-continued and free use is highly dangerous, even when no immediate effects are perceptible. Fatal epidemics in different parts of the continent of Europe, particularly in certain provinces of France, have long been ascribed to the use of bread made from rye contaminated with this fungus. Dry gangrene, typhus fever, and disorder of the nervous system attended with convulsions, are the forms of disease which have followed the use of this unwholesome food. It is true that ergot has been denied to be the cause; but accurate investigations, made by competent men upon the spot where the epidemics have prevailed, together with the result of experiments made upon inferior animals, leave no room for reasonable doubt that at least the gangrenous affection alluded to may result from it. Very large quantities are required for immediate poisonous effects. From two to eight drachms have been given at one dose to a man without very serious results; and three ounces, according to Dr. Wright, were required to kill a small dog. Death from single doses, in inferior animals, is preceded by symptoms indicating irritation of the stomach and bowels, great muscular prostration, loss of sensation, and sometimes slight spasms. A case of acute poisoning from ergot is recorded by Dr. Pratschke, in which uneasiness in the head, oppression of stomach, diarrhœa, urgent thirst, burning pains in the feet, tetanic spasms, violent convulsions, and death ensued upon eating freely of ergotized grain. (*Lond. Med. Gaz.*, Oct. 1850, p. 579.)

Ergot has been much used for promoting the contraction of the uterus. On the continent of Europe, in Germany, France, and Italy, it has long been empirically employed by midwives for this purpose; and its German name of *mutterkorn* implies a popular acquaintance with its peculiar powers. But the attention of the medical profession was first called to it by a letter from Dr. Stearns, of Saratoga County, N. Y., addressed to Dr. Ackerly, in 1807, and published in the eleventh volume of the *New York Medical Repository*. The journals afterwards teemed with communications attesting its efficacy in facilitating parturition; and, though it sometimes failed, the general opinion was so much in its favour, that it soon took a place among the established articles of the materia medica. When it proves wholly inefficient, the result is ascribable to peculiarity of constitution in the individual, or inferiority in the ergot used. In its operation upon the pregnant uterus, it produces a constant unremitting contraction and rigidity, rather than that alternation of spasmodic effort and relaxation which is observable in the natural process of labour. Hence, unless the os uteri and external parts are sufficiently relaxed, the medicine is apt to produce injury to the fœtus by the incessant pressure which it maintains; and the death of the child is thought not unfrequently to have resulted from its injudicious employment. The cases to which it is thought to be especially adapted are those of lingering labour, when the os uteri is sufficiently dilated, and the external parts sufficiently relaxed, when no mechanical impediment is offered to the passage of the child, and the delay is ascribable solely to want of energy in the uterus. Other cases are those in which the death of the fœtus has been ascertained, and when great exhaustion, or dangerous constitutional irritation imperiously calls for speedy delivery. The medicine may also be given to promote the expulsion of the placenta, to restrain inordinate hemorrhage after delivery, and to hasten the discharge of the fœtus in protracted cases of abortion. In women subject to dangerous flooding, a dose of ergot given immediately before delivery is said to have the happiest effects.

It has also been recommended for the expulsion of coagula of blood, polypi, and hydatids from the uterine cavity. It has been accused of producing puerperal convulsions, hour-glass contraction of the uterus, and hydrocephalus in the new-born infant. In uterine hemorrhage, unconnected with pregnancy, the medicine is deemed very useful; and it has been employed in other hemorrhages with asserted advantage. We have seen it promptly effectual in pulmonary hemorrhage, after all the usual means had failed. May it not have the power of producing contraction of the capillaries in general, or of interfering in some other way with the circulation of the blood in these vessels, as by the exertion of a direct sedative or paralyzing influence upon them? We might in this way account for the dry gangrene which results from its abuse, as well as for its influence in restraining hemorrhage. It has also been employed in amenorrhœa, but not with encouraging success. Gonorrhœa, gleet, leucorrhœa, dysmenorrhœa, chronic dysentery and diarrhœa, inordinate thirst, excessive sensitiveness of the eyes with pain upon use, paraplegia, paralysis or debility of the bladder and of the rectum, spermatorrhœa, hooping-cough, hysteria, intermittent fever, chorea, and phthisis are among the complaints in which it has been recommended.

Ergot is usually given in substance, infusion, or decoction. The dose of the powder to a woman in labour is fifteen or twenty grains, to be repeated every twenty minutes till its peculiar effects are experienced, or till the amount of a drachm has been taken. Of an infusion made with a drachm of ergot and four fluidounces of water, one-third may be given for a dose, and repeated with the same interval. For other purposes the dose of the medicine is ten or fifteen grains, repeated three times a day, and gradually increased, but not continued for a great length of time. In urgent cases of hemorrhage, the dose may be repeated every two hours, or oftener if necessary. A wine and fluid extract of ergot are directed in the U. S. Pharmacopœia. (See *Vinum Ergotæ* and *Extractum Ergotæ Fluidum.*) The *oil of ergot*, prepared by means of ether, as already described (*page* 381), was given by Dr. Wright in the dose of from twenty to fifty drops, diffused in cold water, warm tea, or weak spirit and water.

Under the name of *ergotin*, Bonjean's purified extract is sometimes used in the dose of from five to ten grains. It is made by exhausting ergot with water, evaporating to the consistence of syrup, precipitating the albumen, gum, &c., by a large excess of alcohol, decanting the clear liquid, and evaporating to the consistence of a soft extract.

Ergot has been employed externally. Dr. Müller found it to check the bleeding from divided arteries; and Dr. Wright states that in powder or infusion it acts promptly in arresting hemorrhage. It is recommended by the latter as an injection in uterine hemorrhage. It should be used, however, with caution, as the powder applied to abraded surfaces has produced sloughing in the lower animals.

Ergot should be powdered only when wanted for use.*

W.

* It is said that, in Germany, persons sleeping upon grain which contained much ergot have been attacked with disease in consequence; and the case is related of a gentleman who, having gathered some fine specimens of ergot fresh from the plant, and put them in his trowsers-pocket, found himself, about half a day afterwards, incommoded by a tensive spasmodic pain on the skin of the inside of the thigh against which the pocket lay. Ascribing this to a long walk, he did not think of the real cause, until, the pain having returned on the following day, and for several days afterwards, he at length recalled to mind the forgotten ergot, and, supposing that this might be the source of inconvenience, removed it. After a time he found much, though not entire, relief, and did not succeed in wholly removing his trouble, until he had caused the offending pocket to be well washed, after which the affection ceased. He afterwards tried the experiment with other specimens of ergot, with the same results. Perhaps it is only the fresh ergot, yet moist, that is capable of producing this effect. The skin was not reddened, but covered with minute wrinkles, as in cholera patients. (*Neues Repert.*, band x. p. 439, A.D. 1863.)—*Note to the thirteenth edition.*

ERIGERON. *U. S.*

Fleabane.

The herb of Erigeron heterophyllum and of Erigeron Philadelphicum. *U. S.*

ERIGERON. *Sex. Syst.* Syngenesia Superflua.—*Nat. Ord.* Compositæ-Asteroideæ. *De Cand.* Asteraceæ. *Lindley.*

Gen. Ch. Calyx imbricated, sub-hemispherical, in fruit often reflected. *Florets of the ray* linear, very narrow, numerous. *Receptacle* naked. *Pappus* double, exterior minute, interior pilose, of few rays. *Nuttall.*

1. *Erigeron heterophyllum.* Willd. *Sp. Plant.* iii. 1956; Barton, *Am. Med. Bot.* i. 231. — *E. annuum.* Persoon, *Synop.* ii. 431; Torrey and Gray, *Flor. of N. Am.* ii. 175. This is a biennial herbaceous plant, belonging both to North America and Europe. It has a branching root, with several erect, roundish, striated, pubescent stems, much divided near the top, and two or three feet high. The lower leaves are ovate, acute, deeply toothed, with long winged footstalks; the upper are lanceolate, acute, deeply serrate in the middle, and sessile; the floral leaves are lanceolate and entire; all, except the radical, are ciliate at the base. The flowers are in terminal corymbs. The florets of the disk are yellow; those of the ray numerous, very slender, and of a white, pale-blue, or pale-purple colour. The flowering period is from June to October.

2. *Erigeron Philadelphicum.* Barton, *Med. Bot.* i. 227. — *E. strigosum.* Willd. *Sp. Plant.* iii. 1956; Torrey and Gray, *Flor. of N. Am.* ii. 176. The Philadelphia fleabane is perennial and herbaceous, with a branching yellowish root, and from one to five erect stems, which rise two or three feet in height, and are much branched at top. The whole plant is pubescent. The lower leaves are ovate-lanceolate, nearly obtuse, ciliate on the margin, entire or marked with a few serratures, and supported on very long footstalks; the upper are narrow, oblong, somewhat wedge-shaped, obtuse, entire, sessile, and slightly embrace the stem; the floral leaves are small and lanceolate. The flowers are numerous, radiate, and disposed in a panicled corymb, with long peduncles bearing from one to three flowers. They resemble those of the preceding species in colour, and make their appearance about the same period.

We include these two species under one head because they grow together, possess identical medical properties, and are indiscriminately employed. They are found in various parts of the United States, and abound in the fields about Philadelphia, where they are known and used under the common though inaccurate name of *scabious.* The whole herb is used, and should be collected while the plants are in flower. It has a feebly aromatic odour, and bitterish taste, and imparts its properties to boiling water. Mr. F. L. John, of Philadelphia, obtained from E. Philadelphicum a volatile oil by distillation, but in exceedingly small proportion; 45 pounds of the herb having yielded only half a drachm of the oil. As described by Prof. Procter, this is of a greenish-yellow colour, a powerful, penetrating, aromatic odour, and a bitterish, pungent, disagreeable taste. It is more viscid than the oil of E. Canadense, has a higher sp. gr. (0·946), and contains more oxygen. (*Am. Journ. of Pharm.*, xxvii. 105.)

Medical Properties and Uses. Fleabane is diuretic, without being offensive to the stomach. It has been a favourite remedy, with some highly respectable practitioners of Philadelphia, in gravel and other nephritic diseases, and has been used advantageously in dropsy. By the late Prof. Wistar it was recommended in hydrothorax complicated with gout. It cannot be relied on for the cure of dropsy; but may be employed as an adjuvant to more efficient medicines. It is most conveniently given in infusion or decoction, of which a pint, containing the virtues of an ounce of the herb, may be taken in twenty-four hours.

In a communication by Dr. Wilson, of Philadelphia, to the College of Physicians, Nov. 1, 1854, it is stated that the *oil of Philadelphia fleabane* had been employed with great advantage by Dr. Bournonville and himself in uterine hemorrhage, in the dose of five drops every two hours. (*Transact. of Col. of*

Phys., N. S., ii. 330.) There can be little doubt, from the account of the oil at the same time given, that it was the *oil of E. Canadense*, and not that of E. Philadelphicum, which was really used. W.

ERIGERON CANADENSE. *U. S.*

Canada Fleabane.

The herb of Erigeron Canadense. *U. S.*

ERIGERON. See ERIGERON.

Erigeron Canadense. Willd. *Sp. Plant.* iii. 1954. This is an indigenous annual plant, with a stem from two to six feet high, covered with stiff hairs, and divided into many branches. The leaves are linear-lanceolate, and edged with hairs; those at the root are dentate. The flowers are very small, numerous, white, and arranged in terminal panicles. They differ from those of the other species of Erigeron in having an oblong calyx, the rays very minute and more numerous than the florets of the disk, and the seed-down simple. Hence by some botanists the plant is placed in a sub-genus with the title *Cænotus*. Another variety of *E. Canadense*, which Mr. Nuttall makes a distinct species, with the title *E. pusilum*, is not more than from four to six inches high, and has an erect smooth stem, less branched than the preceding, with all its leaves entire, and scabrous on the margin. The panicle is simple, and the peduncles filiform, nearly naked, divaricate, each bearing two or three flowers.

Canada fleabane is very common throughout the northern and middle sections of the United States, and has become naturalized in many parts of Europe. It abounds in neglected fields, and blooms in July and August. The plant, all parts of which are medicinal, should be collected while in flower. The leaves and flowers are said to possess its peculiar virtues in greatest perfection.

This species of Erigeron has an agreeable odour, and a bitterish, acrid, somewhat astringent taste. Among its constituents, according to Dr. De Puy, are bitter extractive, tannin, gallic acid, and volatile oil. Both alcohol and water extract its virtues. Its acrimony is diminished by decoction, in consequence, probably, of the escape of the oil, upon which its virtues in part depend. The oil is included among the Preparations in the U. S. Pharmacopœia, and will be described in *Part II.* of this work. (See *Oleum Erigerontis Canadensis.*)

Medical Properties and Uses. From the observations of Dr. De Puy, Canada fleabane appears to be diuretic, tonic, and astringent; and has proved useful in dropsical complaints and diarrhœa. It may be given in substance, infusion, tincture, or extract. The dose of the powder is from thirty grains to a drachm; of an infusion, prepared with an ounce of the plant and a pint of boiling water, from two to four fluidounces; of the aqueous extract, from five to ten grains. The dose should be repeated every two or three hours. The oil has been employed for arresting hemorrhage, in the dose of five drops every two hours.

EUONYMUS. *U. S. Secondary.*

Wahoo.

The bark of Euonymus atropurpureus. *U. S.*

EUONYMUS. *Sex. Syst.* Pentandria Monogynia.—*Nat. Ord.* Celastraceæ. *Lindley.*

Gen. Ch. Calyx four or five-parted, flat. *Corolla* four or five-petaled, inferior, flat. *Capsule* three to five-valved, three to five-celled, coloured, each cell containing one or two seeds, surrounded by a red arillus.

The plants belonging to this genus are shrubs or small trees, presenting in the autumn a striking appearance from the rich red colour of their fruit, which has obtained for them the name of *burning-bush*. *E. Americanus* and *E. Europæus* have been cultivated in gardens as ornamental plants. Two or more of the

species have been used in medicine. Their properties are probably similar, if not identical. Grundner, who experimented with the fruit of E. Europæus, found it to have no other effect than that of a diuretic. (*Pharm. Cent. Blatt*, A.D. 1847, p. 873.) An oil expressed from the seeds is used in Europe for the destruction of vermin in the hair, and sometimes also as an application to old sores (*Ibid.*, A.D. 1851, p. 641.) Dr. Griffith says that the seeds of this and other species are purgative and emetic, and that the leaves are poisonous to sheep and other animals feeding on them. He states also that the inner bark of *E. tingens* is beautifully yellow, and used in India for dyeing, and in diseases of the eye. (*Med. Bot.*, p 220.) About twenty years since, a bark was introduced into notice in this city, as a remedy for dropsy, under the name of Wahoo, by Mr. George W. Carpenter, who had obtained a knowledge of its virtues in the Western States. On a journey in the North West in the year 1845, the author made some inquiries into the source of this medicine, and, having had the opportunity of examining the plant producing it, found it to be *E. atropurpureus;* and this is recognised in the present edition of the U. S. Pharmacopœia. The name of wahoo (pronounced *wawhoo*) was given to it by the Indians. The same name has also been applied to *Ulmus alata*, of the Southern States, and has thus led to mistakes. It is probable that the product of *E. Americanus* has been indiscriminately used with that of the officinal species.

Euonymus Atropurpureus. Willd. *Sp. Plant.* i. 1132; Gray's *Manual*, p. 81; figured in Griffith's *Med. Bot.* p. 219. This plant has been named variously *wahoo, spindletree,* and *burning-bush.* It is a tall, erect shrub, with quadrangular branchlets, and opposite, petiolate, oval-oblong, pointed, serrate leaves. The flowers, which stand in loose cymes on axillary peduncles, are small and dark-purple, with sepals and petals commonly in fours. The capsule or pod is smooth and deeply lobed. The plant is indigenous, growing throughout the Northern and Western States, and sometimes cultivated for the beauty of its crimson fruit. The bark is the part used.

Properties. The dried bark is in thin pieces, whitish with a darker grayish epidermis, brittle, of a feeble, peculiar, not disagreeable odour, and a bitterish slightly sweetish taste, and somewhat pungent after-taste. It imparts its virtues to water and alcohol. Analyzed by Mr. Wm. T. Wenzell, it was found to contain a bitter principle which he named *euonymin*, asparagin, a soft resin, a crystallizable resin, a yellow resin, a brown resin, fixed oil, wax, starch, albumen, glucose, pectin, and various salts of organic and inorganic acids. Euonymin was obtained by agitating with chloroform a tincture made with diluted alcohol, separating the chloroformic solution and allowing it to evaporate spontaneously, treating the residue with ether, dissolving what was left in alcohol, adding acetate of lead to the solution, filtering, precipitating the lead with hydrosulphuric acid, and evaporating. The euonymin obtained was uncrystallizable, intensely bitter, soluble in water and alcohol, and neuter in its reactions. It was abundantly precipitated from its solution by subacetate of lead and phospho-molybdic acid. (*Am. Journ. of Pharm.*, Sept. 1862, p. 387.) Mr. W. P. Clothier found the bark to yield no volatile oil on distillation. According to the same writer, if a concentrated tincture is poured into water, a dark-yellow bitter substance is thrown down, containing resin and fixed oil, which is the euonymine of the Eclectics, very improperly so named, as, though it contains a portion of the active principle, it is a very complex substance. Mr. Clothier found it to purge actively without griping. (*Ibid.*, Nov. 1861, p. 491.) Kubel has discovered in the fresh inner bark of E. Europæus a saccharine, crystallizable substance, closely resembling mannite, but differing in its crystalline form, and melting point. He calls it *euonymite.* (*Journ. de Pharm.*, Dec 1862, p. 523.)

Medical Properties and Uses. The precise virtues of wahoo have not been determined. Mr. C. A. Santos, in a dissertation upon the American species, published in the *American Journal of Pharmacy* (xx. 80), speaks of the bark as tonic, hydragogue cathartic, diuretic, and antiperiodic. Dr. Twyman, of Westport, Missouri, informed the author that he had found it as a cathartic rather

to resemble rhubarb, than to possess hydragogue properties, and thought he had obtained useful effects from it as an alterative to the hepatic function. Similar information was obtained from other sources. On the whole, the character of its action must be considered as somewhat uncertain; and it might well form a subject of further examination. As a diuretic in dropsy it may be used in the form of decoction or infusion, made in the proportion of an ounce to a pint of water, and given in the dose of a wineglassful several times a day. A fluid extract, prepared with diluted alcohol, would no doubt be an efficient, and would probably be found a convenient preparation. W.

EUPATORIUM. *U.S.*

Thoroughwort.

The tops and leaves of Eupatorium perfoliatum, gathered after flowering has commenced. *U. S.*

Eupatorium. *Sex. Syst.* Syngenesia Æqualis.—*Nat. Ord.* Compositæ-Eupatoriaceæ. *De Cand.* Asteraceæ. *Lindley.*

Gen. Ch. Calyx simple or imbricate, oblong. *Style* long and semi-bifid. *Receptacle* naked. *Pappus* pilose, or more commonly scabrous. *Seed* smooth and glandular, quinquestriate. *Nuttall.*

Of this numerous genus, comprising not less than thirty species within the limits of the United States, most of which probably possess analogous medical properties, *E. perfoliatum* alone now holds a place in our national Pharmacopœia. *E. purpureum* and *E. teucrifolium* were originally in the *Secondary List*, but were discarded at the revision of 1840. They merit, however, a brief notice, if only from their former officinal rank.

Eupatorium purpureum, or *gravel root*, is a perennial herbaceous plant, with a purple stem, five or six feet in height, and furnished with ovate-lanceolate, serrate, rugosely veined, slightly scabrous, petiolate leaves, placed four or five together in the form of whorls. The flowers are purple, and consist of numerous florets contained in an eight-leaved calyx. It grows in swamps and other low grounds, from Canada to Virginia, and flowers in August and September. The root has, according to Dr. Bigelow, a bitter aromatic and astringent taste, and is said to operate as a diuretic. Its vulgar name of gravel root indicates the popular estimation of its virtues.

Eupatorium teucrifolium (Willd. *Sp. Plant.* iii. 1753), *E. pilosum* (Walt. *Flor. Car.* 199), *E. verbenæfolium* (Mich. *Flor. Am.* ii. 98), commonly called *wild horehound*, is also an indigenous perennial, with an herbaceous stem, which is about two feet high, and supports sessile, distinct, ovate, acute, scabrous leaves, of which the lower are coarsely serrate at the base, the uppermost entire. The flowers are small, white, composed of five florets within each calyx, and arranged in the form of a corymb. The plant grows in low wet places from New England to Georgia, and abounds in the Southern States. It is in flower from August to November. The whole herb is used. In sensible properties it corresponds with *E. perfoliatum*, though less bitter and disagreeable. It is said to be tonic, diaphoretic, diuretic, and aperient; and has been employed as a domestic remedy in intermittent and remittent fevers. Dr. Jones, formerly president of the Georgia Medical Society, first made its properties known to the profession. It is usually given in the form of infusion, made with an ounce to a quart of water, the whole to be taken during the day.

E Cannabinum, of Europe, the root of which was formerly used as a purgative, and *E. Aya-pana*, of Brazil, the leaves of which at one time enjoyed a very high reputation, have fallen into entire neglect. The *aya-pana* is an aromatic bitter, like *E. perfoliatum*, but weaker. A species of Eupatorium, probably *E. nervosum*, is said to be a favourite with the medical profession in Jamaica, where it is known by the name of *bitter bush*. It is thought to have proved very efficacious in cholera, and, being actively stimulant, is much used in typhus and typhoid fevers, and smallpox. Cholagogue properties have

been ascribed to it. Decoction and tincture are the forms in which it is given. (*Pharm. Journ. and Trans.*, Oct. 1866, p. 222.)

Eupatorium perfoliatum. Willd. *Sp Plant.* iii. 1761; Bigelow, *Am. Med Bot.* i. 33; Barton, *Med. Bot.* ii. 125, *Thoroughwhort*, or *boneset*, is an indigenous perennial plant, with numerous herbaceous stems, which are erect, round, hairy, from two to five feet high, simple below, and trichotomously branched near the summit. The leaves serve to distinguish the species at the first glance. They may be considered either as perforated by the stem, *perfoliate*, or as consisting each of two leaves, joined at the base, *connate*. In the latter point of view, they are opposite and in pairs, which decussate each other at regular distances upon the stem; in other words, the direction of each pair is at right angles with that of the pair immediately above or beneath it. They are narrow in proportion to their length, broadest at the base where they coalesce, gradually tapering to a point, serrate, much wrinkled, paler on the under than the upper surface, and beset with whitish hairs, which give them a grayish-green colour. The uppermost pairs are sessile, not joined at the base. The flowers are white, numerous, supported on hairy peduncles, in dense corymbs, forming a flattened summit. The calyx, which is cylindrical and composed of imbricated, lanceolate, hairy scales, encloses from twelve to fifteen tubular florets, having their border divided into five spreading segments. The anthers are five, black, and united into a tube, through which the bifid filiform style projects.

This species of Eupatorium inhabits meadows, the banks of streams, and other moist places, growing generally in bunches, and abounding in almost all parts of the United States. It flowers from the middle of summer to the end of October. All parts of it are active; but the herb only is officinal.

It has a faint odour, and a strongly bitter, somewhat peculiar taste. The virtues of the plant are readily imparted to water and alcohol. Mr. W. Peterson found it to contain a peculiar bitter principle, chlorophyll, resin, a crystalline matter of undetermined character, gum, tannin, yellow colouring matter, extractive, lignin, and salts. (*Am. Journ. of Pharm.*, xxiii. 210.) Mr. Bickley found also albumen, gallic acid, and signs of volatile oil. (*Ibid.*, xxvi. 495.) *Eupatorin* will be the proper name to apply to the bitter principle, when isolated and satisfactorily determined; but is wholly inapplicable to any complex substance, consisting of different proximate principles, however concentrated, and whether possessing or not the virtues of the leaves.

Medical Properties and Uses. Thoroughwort is tonic, diaphoretic, and in large doses emetic and aperient. It is said to have been employed by the Indians in intermittent fever, and has proved successful in the hands of several regular practitioners. The general experience, however, is not in its favour in that complaint. We have seen it arrest intermittents when given freely in warm decoction, immediately before the expected recurrence of the paroxysm; but it operated in this instance by its emetic rather than its tonic power. The medicine has also been used as a tonic and diaphoretic in remittent and typhoid fevers, and is said to have been productive of advantage in yellow fever. Given in warm infusion, so as to produce vomiting or copious perspiration, at the commencement of catarrh, it will frequently arrest that complaint; and has been especially recommended in influenza. It has also been recommended as a diaphoretic in acute rheumatism; and may prove serviceable in the absence of high arterial excitement. As a tonic it is given with advantage in dyspepsia, general debility, and other cases in which the simple bitters are employed.

With a view to its tonic effects, it is best administered in substance, or cold infusion. The dose of the powder is twenty or thirty grains, that of the infusion a fluidounce, frequently repeated. (See *Infusum Eupatorii.*) The aqueous extract has been used with advantage. When the diaphoretic operation is required in addition to the tonic, the infusion should be administered warm, and the patient remain covered in bed. As an emetic and cathartic, a strong decoction, prepared by boiling an ounce with three half pints of water to a pint, may be given in doses of one or two gills, or more.

Off Prep. Infusum Eupatorii, *U. S.* W.

EUPHORBIA COROLLATA. *U. S. Secondary.*

Large-flowering Spurge.

The root of Euphorbia corollata. *U. S.*

Euphorbia. *Sex. Syst.* Dodecandria Trigynia, *Linn.*; Moncœcia Monadelphia, *Michaux.* — *Nat. Ord.* Euphorbiaceæ.

Gen. Ch. Involucrum caliciform, eight to ten-toothed, exterior alternate dentures glanduloid or petaloid. *Stamina* indefinite, twelve or more, rarely less; *filaments* articulated. *Receptacle* squamose. *Female flower* solitary, stipitate, naked. *Capsule* three-grained. *Nuttall.*

In the flower of the Euphorbiæ, the stamina are arranged two or more together, in distinct parcels, corresponding in number with the inner segments of the calyx. These parcels were considered by Michaux as distinct male florets; while the central stipitate germ, with its three bifid styles, was considered as a distinct female floret, and the calyx as an involucre. He accordingly placed the genus in the class and order *Monœcia Monadelphia*, and in this respect has been followed by most American botanists. The genus Euphorbia contains numerous species, having the common property of yielding a milky juice. They are herbaceous or shrubby, with or without leaves; and the leafless species, which are chiefly confined to the African deserts, have fleshy, naked, or spiny stems, like those of the Cactus. They nearly all afford products which act powerfully as emetics and cathartics, and in overdoses occasion dangerous if not fatal prostration, with symptoms of inflamed gastro-intestinal mucous membrane. Their milky juice, which concretes on exposure, usually possesses these properties in a high degree, and, in addition, that of powerfully irritating the skin when applied to it. Two species are acknowledged in our national Pharmacopœia, *E. corollata* and *E. Ipecacuanha*, which are both indigenous. *E. hypericifolia*, which is also indigenous, has been highly commended as a remedy in dysentery after due depletion, diarrhœa, menorrhagia, and leucorrhœa by Dr. W. Zollikoffer. He infuses half an ounce of the dried leaves in a pint of boiling water, and gives half a fluidounce every hour in dysentery till the symptoms begin to yield, the same quantity after every evacuation in diarrhœa, and two fluidounces morning, noon, and night, in menorrhagia and fluor albus. The herb is at first sweetish, afterwards harsh and astringent to the taste, and appears to contain tannin. Its effects upon the system are those of an astringent and feeble narcotic. It differs, therefore, considerably, both in sensible and medicinal properties, from most of the other species. (*Am. Journ. of Med. Sci.*, xi. 22.) In a subsequent communication, it is stated that *E. maculata* possesses similar properties. (*Ibid.*, N. S., iii 125.) Dr. B. J. D. Irwin, of the U. S. Army, having heard much, while in New Mexico and Arizona, of the efficacy, among the native Mexicans, of a certain plant called by them *gollindrinera*, as an antidote to the poison of serpents, was induced to make trials of it, which convinced him that its reputation was not unmerited. A specimen of the plant having been sent to Prof. Torrey, it was pronounced by him to be *Euphorbia prostrata*, which is abundant in the Southwestern parts of the U. States and Mexico. Dr. Irwin thinks that the virtues reside in the milky juice of the plant, but the liquid obtained by bruising the herb is commonly used. Like other Euphorbiæ, it is emetic and cathartic in large quantities, but he has heard of no injurious effects from its use. (*Ibid.*, Jan. 1861, p. 89.) In Chili, the juice of the *Euphorbia Chilensis* is said to be used as a drastic purgative. (*Am. Journ. of Pharm.*, March, 1866, p. 102; from the *Revista Farmaceutica*, of Buenos Ayres.)

Euphorbia corollata. Willd. *Sp. Plant.* ii. 916; Bigelow, *Am. Med. Bot* iii. 119. The *blooming* or *large-flowering spurge*, frequently called *milk-weed*, is an erect plant, with a large, perennial, branching, yellowish root, which sends up several stems from two to five feet in height, round and generally simple. The leaves, which stand irregularly upon the stem, and without footstalks, are oblong-obovate, wedge-form or linear, flat or revolute at the margin, smooth in

some plants, and hairy in others. The flowers are disposed upon a large terminal umbel, with a five-leaved involucrum, and five trifid and dichotomous rays, at each fork of which are two oblong bractes. The calyx is large, rotate, white, with five obtuse segments closely resembling a corolla, from which the species has been named. At the base of these divisions are five interior smaller segments, which are described as nectaries by many systematic writers, while the larger are considered as belonging to a real corolla. The stamens are twelve, evolving gradually, with double anthers. Many flowers have only stamens. The pistil, when existing, is stipitate, nodding, rounded, with three bifid styles. The fruit is a smooth, three-celled, three-seeded capsule.

The plant grows in various parts of the United States, from Canada to Florida, and abounds in Western Pennsylvania, Maryland, and Virginia. It prefers a dry, barren, and sandy soil, seldom growing in woods or on the borders of streams. Its flowers appear in July and August. The root is the only part used.

This, when full grown, is sometimes an inch in thickness, and two feet in length. It is without unpleasant taste, producing only a sense of heat a short time after it has been taken. The medical virtues are said to reside in the cortical portion, which is thick, and constitutes two-thirds of the whole root. They are taken up by water and alcohol, and remain in the extract formed by the evaporation of the decoction or tincture.

Medical Properties and Uses. In a full dose, the root of *E. corollata* operates actively and with sufficient certainty as an emetic, producing ordinarily several discharges from the stomach, and sometimes acting with considerable energy upon the bowels. In quantities insufficient to vomit, it excites nausea, almost always followed by brisk purging. In still smaller doses it is diaphoretic and expectorant It cannot, however, like ipecacuanha, be given largely in cases of insensibility of stomach, without endangering hypercatharsis with inflammation of the mucous coat of the stomach and bowels. It is in fact greatly inferior to this emetic in mildness, while it is no less inferior to the tartarized antimony in certainty. It is objectionable as a purge, in consequence of the nausea which it occasions when given in cathartic doses. Dr. Zollickoffer was the first to introduce it to the particular notice of the medical profession. It is little prescribed, and seldom kept in the shops. The dose of the dried root as an emetic is from ten to twenty grains, as a cathartic from three to ten grains. The recent root, bruised and applied to the skin, produces vesication. W.

EUPHORBIA IPECACUANHA. *U. S. Secondary.*

Ipecacuanha Spurge.

The root of Euphorbia Ipecacuanha. *U. S.*

EUPHORBIA. See EUPHORBIA COROLLATA.

Euphorbia Ipecacuanha. Willd. *Sp. Plant.* ii. 900; Barton, *Med. Bot.* i. 211; Bigelow, *Am. Med. Bot.* iii. 108. *Ipecacuanha spurge*, or *American ipecacuanha*, is a singular plant, varying so much in the shape and colour of its leaves, and in its whole aspect, that mere individual peculiarities might without care be attributed to a specific difference. The root is perennial, yellowish, irregular, and very large, penetrating sometimes to the depth of six or seven feet in the sand, and in its thickest part, when full grown, from three-quarters of an inch to an inch and a half in diameter. The stems are numerous, herbaceous, erect or procumbent, smooth, dichotomous, jointed at the forks, white under the ground, red, pale-green, or yellow above, sometimes almost buried in the sand, usually forming thick low bunches upon its surface. The leaves are opposite, sessile, entire, smooth, generally oval, but sometimes round, obovate, or even lanceolate or linear. They are small early in the spring, and increase in size with the age of the plant. Their colour varies from green to crimson. The flowers are solitary, on long axillary peduncles. The calyx is spreading, with five exterior obtuse segments, and the same number of inner, smaller segments. The fertile

flowers have a roundish, drooping pedicelled germ, crowned with six revolute stigmas. The capsule is three-celled, and contains three seeds.

E. Ipecacuanha is indigenous, growing in pine-barrens and other sandy places in the Middle and Southern States, especially along the sea-board, and abundantly in New Jersey, on the banks of the Delaware. It blooms from May to August. The root, which is the officinal portion, is, according to Dr. Barton, equally efficacious at whatever period collected.

The dry root is light and brittle, of a grayish colour externally, white within, inodorous, and of a sweetish not unpleasant taste. Its active principle has not been isolated. Dr. Bigelow inferred from his experiments that it contained caoutchouc, resin, gum, and probably starch.

Medical Properties and Uses. Ipecacuanha spurge is an active, tolerably certain emetic, rather milder than *E. corollata*, but, like it, disposed to affect the bowels, and liable, if given in overdoses, to produce excessive nausea and vomiting, general prostration, and alarming hypercatharsis. It is, therefore, unfit to supersede ipecacuanha. In small doses it is diaphoretic. The specific name of the plant indicates that the emetic property of the root has been long known. The late Professor Barton alluded to it in his "Collections;" but it did not come into general notice till after the publication of Dr. W. P. C. Barton's Medical Botany. The late Dr. Hewson, of Philadelphia, informed us that this emetic was the subject of an inaugural essay by Dr. Royal, and that experiments, conducted with it among the convicts in the Walnut Street prison, proved it to be advantageously available for all the purposes of an emetic; while, in consequence of its want of nauseous taste, it seemed to answer even better than ipecacuanha as an expectorant and diaphoretic. The dose of the powdered root is from ten to fifteen grains. W.

EXTRACTUM CANNABIS. *U. S.*

Extract of Hemp.

An alcoholic extract of the dried tops of Cannabis sativa, var. *Indica. U. S. Off. Syn.* EXTRACTUM CANNABIS INDICÆ. *Br.*

CANNABIS. *Sex. Syst.* Diœcia Pentandria. — *Nat. Ord.* Cannabinaceæ.

Gen. Ch. MALE. *Calyx* five-parted. *Stamens* five. FEMALE. *Calyx* one-leaved, rolled up. *Styles* two. *Lindley.*

Cannabis sativa. Linn. *Sp. Plant.* 1457; Griffith, *Med. Bot.* p. 572. Hemp is an annual plant, from four to eight feet or more in height, with an erect, branching, angular stem. The leaves are alternate or opposite, on long, lax footstalks, roughish, and digitate with linear-lanceolate, serrated segments. The stipules are subulate. The flowers are axillary; the male in long, branched, drooping racemes; the female in erect simple spikes. The stamens are five, with long pendulous anthers; the pistils two, with long, filiform, glandular stigmas. The fruit is ovate and one-seeded. The whole plant is covered with a fine pubescence, scarcely visible to the naked eye, and is somewhat viscid to the touch. The hemp plant of India, from which the drug is derived, has been considered by some as a distinct species, and named *Cannabis Indica;* but the most observant botanists, upon comparing it with our cultivated plant, have been unable to discover any specific difference. It is now, therefore, regarded merely as a variety, and is distinguished by the epithet *Indica.* Dr. Pereira states that, in the female plant, the flowers are somewhat more crowded than in the common hemp; but that the male plants in the two varieties are in all respects the same. It is unfortunate that the name of *Indian hemp* has been attached to the medicinal product; as, in the United States, the same name has long been appropriated to *Apocynum cannabinum;* and some confusion has hence arisen.

C. sativa is a native of the Caucasus, Persia, and the hilly regions in the north of India. It is cultivated in many parts of Europe and Asia, and largely in our Western States. It is from the Indian variety exclusively that the medicine is

obtained; the heat of the climate in Hindostan apparently favouring the development of its active principle.*

The seeds, though not now officinal, have been used in medicine. They are about the eighth of an inch long, roundish-ovate, somewhat compressed, of a shining ash-gray colour, inodorous, and of a disagreeable, oily, sweetish taste. They yield by expression a fixed oil, which has the drying property, and is used in the arts. They contain also uncrystallizable sugar and albumen, and when rubbed with water form an emulsion, which may be used advantageously in inflammations of the mucous membranes, though without narcotic properties. They are much used as food for birds, which are fond of them. They are generally believed to be in no degree poisonous; but M. Michaud relates the case of a child, in which serious symptoms of narcotic poisoning occurred after taking a certain quantity of them. It is probable that some of the fruit eaten by the child was unripe; as, in this state, it would be more likely to partake of the peculiar qualities of the plant itself. (*Ann. de Thérap.*, A.D. 1860, p. 159.)

In Hindostan, Persia, and other parts of the East, hemp has long been habitually employed as an intoxicating agent. The parts used are the tops of the plant, and a resinous product obtained from it. The plant is cut after flowering, and formed into bundles from two to four feet long by three inches in diameter, which are sold in the bazaars under the name of *gunjah*. The *hashish* of the Arabs is essentially the same. The name *bang* is given to a mixture of the larger leaves and capsules without the stems. There is on the surface of the plant a resinous exudation to which it owes its clammy feel. Men clothed in leather run through the hemp fields, brushing forcibly against the plants, and thus separating the resin, which is subsequently scraped from their dress, and formed into balls. These are called *churrus*. In these different states of preparation, the hemp is smoked like tobacco, with which it is said to be frequently mixed. An infusion or decoction of the plant is also sometimes used as an exhilarating drink.

The *medicinal resin or extract of hemp*, directed by the U. S. Pharmacopœia, is made by evaporating a tincture of the dried tops. Dr. O'Shaughnessy directs it to be prepared by boiling the tops of the gunjah in alcohol until all the resin is dissolved, and evaporating to dryness by means of a water-bath. Mr. Robertson, of the Calcutta Medical College, prepares it by passing the vapour of boiling alcohol from the boiler of a still into the dried plant contained in a convenient receptacle, and evaporating the condensed liquor by a heat not exceeding 150° F. The Messrs. Smith, of Edinburgh, obtain a purer resin by the following process. Bruised gunjah is digested, first in successive portions of warm water, till the expressed liquid comes away colourless; and afterwards, for two days with a moderate heat, in a solution of carbonate of soda, containing one part of the salt for two of the dried herb. It is then expressed, washed, dried, and exhausted by percolation with alcohol. The tincture, after being agitated with milk of lime containing one part of the earth for twelve of the gunjah used, is filtered; the lime is precipitated by sulphuric acid; the filtered liquor is agi-

* On a visit to the botanical garden of Edinburgh, in the autumn of 1860, the author saw a full-grown specimen of Cannabis sativa, and was surprised to find that it was only about 4 feet high, had little or no odour, and was scarcely adhesive when handled. If this is the general character of the hemp plant in the north of Europe, it is not surprising that it should be destitute of the medicinal properties of the Indian plant. As cultivated in his own garden in Philadelphia, the plant attains a height usually of six or eight feet, has a decided narcotic odour, and exudes so much of its peculiar resin as to be very adhesive to the fingers. It is highly probable, therefore, that the hemp plant grown in this country might be advantageously used in medicine. On this occasion Dr. Christison informed the author, from information he had received from India, that the plant there cultivated in the hot plains, does not yield hashish satisfactorily; but that this product is chiefly if not exclusively obtained from it in the hilly regions. He said, moreover, that the story of the natives running through the hemp fields, and collecting the resin on their clothing, from which it is afterwards scraped, is, if not quite untrue, at least apocryphal. He had been informed that the real mode of gathering it is to rub the hemp-tops between the hands, and, when the palms and fingers are sufficiently loaded with the resin, to scrape it off. It is possible, however, that different methods may be followed in different localities. (*Note to the twelfth edition.*)

tated with animal charcoal, and again filtered; most of the alcohol is distilled off, and to the residue twice its weight of water is added; the liquid is then allowed to evaporate gradually; and, finally, the resin is washed with fresh water until it ceases to impart a sour or bitter taste to the liquid, and is then dried in thin layers. Thus obtained, it retains the odour and taste of the gunjah, of which 100 pounds yield 6 or 7 pounds of the extract. Much of the commercial extract is very impure, and is but partially soluble in alcohol.

Under the name of *Extractum Cannabis Purificatum*, the U. S. Pharmacopœia directs a preparation made by evaporating a tincture of the crude extract, which, from its greater uniformity of strength, is preferable for prescription. (See *Part II.*) The *British Pharmacopœia* directs the Extract of Indian Hemp to be prepared by macerating an avoirdupois pound of the dried tops of the hemp, in coarse powder, in four Imperial pints of rectified spirit, for seven days, then expressing, and evaporating to the proper consistence. From this a tincture is ordered to be prepared.

Properties. Fresh hemp has a peculiar narcotic odour, which is said to be capable of producing vertigo, headache, and a species of intoxication. It is much less in the dried tops, which have a feeble bitterish taste. According to Dr. Royle, *churrus* is when pure of a blackish-gray, blackish-green, or dirty olive colour, of a fragrant and narcotic odour, and a slightly warm, bitterish, and acrid taste. Schlesinger found in the leaves a bitter substance, chlorophyll, green resinous extractive, colouring matter, gummy extract, extractive, albumen, lignin, and salts. The plant also contains volatile oil in very small proportion, which probably has narcotic properties. The resin is probably the active principle, and has received the name of *cannabin*. It is neuter, soluble in alcohol and ether, and separable from the alcoholic solution by water as a white precipitate. According to M. Laneau, of Brussels, it is insoluble in cold alcohol of 80 or 90 per cent., but is soluble in the same liquid heated, in cold absolute alcohol, ether, acetic ether, spirit of nitric ether, muriatic ether, chloroform, and bisulphuret of carbon. (See *Am. Journ. of Pharm.*, xxviii. 362.) Its taste is warm, bitterish, acrid, somewhat balsamic, and its odour fragrant, especially when heated.*

Medical Properties. Extract of hemp is a powerful narcotic, causing exhilaration, intoxication, delirious hallucinations, and, in its subsequent action, drowsiness and stupor, with little effect upon the circulation. It is asserted also to act as a decided aphrodisiac, to increase the appetite, and occasionally to induce the cataleptic state. In overdoses it may produce poisonous effects. In morbid states of the system, it has been found to cause sleep, to allay spasm, to compose nervous inquietude, and to relieve pain. In these respects, it resembles opium; but it differs from that narcotic in not diminishing the appetite, checking the secretions, or constipating the bowels. It is much less certain in its effects; but may sometimes be preferably employed, when opium is contraindicated by its nauseating or constipating effects, or its disposition to produce headache, and to check the bronchial secretion. The complaints in which it

* From the effects on the system of the exhalations from fresh hemp, it was a very probable supposition that the plant owed its medical properties, in part at least, to a volatile principle. By repeated distillation of the same portion of water from relatively large quantities of hemp renewed at each distillation, M. J. Personne obtained a volatile oil, of a stupefying odour, and an action on the system such as to dispose him to think that it was the active principle of the plant. As the water distilled was strongly alkaline, he supposed that this volatile principle might be a new alkaloid; but the alkaline reaction was found to depend on ammonia; and the liquid obtained proved to be a volatile oil, lighter than water, of a deep-amber colour, a strong smell of hemp, and composed of two distinct oils, one colourless, with the formula $C_{36}H_{20}$, the other a hydrate of the first. For the former M. Personne proposes the name of *cannabene*. When this is inhaled, or taken into the stomach, a singular excitement is felt throughout the system, followed by a depression, sometimes amounting to syncope, with hallucinations which are generally disagreeable, but an action on the whole slighter and more fugitive than that of the resin. The pure resin of the Messrs. Smith, M. Personne considers to be complex, depending on volatile principles for its activity, deprived of which at a temperature of about 300° C., it becomes quite inert. (*Journ. de Pharm.*, A.D. 1857, p. 46.)—*Note to the twelfth edition.*

has been specially recommended are neuralgia, gout, rheumatism, tetanus, hydrophobia, epidemic cholera, convulsions, chorea, hysteria, mental depression, delirium tremens, insanity, and uterine hemorrhage. It has been found to cure obstinate intermittent fever, given before the paroxysm Dr. Alexander Christison, of Edinburgh, has found it to have the property of hastening and increasing the contractions of the uterus in delivery, and has employed it with advantage for this purpose. It acts very quickly, and without anæsthetic effect. It appears, however, to exert this influence only in a certain proportion of cases. (*Ed. Month. Journ. of Med. Sci*, xiii 117, and xv. 124.) The strength of the extract varies much as found in commerce; and therefore no definite dose can be fixed. When it is of good quality half a grain or a grain will affect the system. The Messrs. Smith found two-thirds of a grain of their extract to produce powerful narcotic effects. In some instances it will be necessary to give as much as ten or twelve grains of the extract; and half an ounce of it has been taken without sensible effect. The proper plan is to begin with one-quarter or half a grain, repeated at intervals of two, three, or four hours, and gradually increased until its influence is felt, and the strength of the parcel employed is thus ascertained. Afterwards the dose will be regulated by the ascertained strength; but, should a new parcel be employed, the same caution must be observed as to the commencing dose. A tincture is prepared by dissolving six drachms of the extract in a pint of alcohol. The dose of this, equivalent to a grain of the extract, is about twenty minims, or forty drops. Dr. O'Shaughnessy gave ten drops every half hour in cholera, and a fluidrachm every half hour in tetanus. As the resin is precipitated by water, the tincture should be administered in mucilage or sweetened water. Alarming effects have been produced by overdoses.*

EXTRACTUM GLYCYRRHIZÆ. *U.S., Br.*

Liquorice.

The extract of the root of Glycyrrhiza glabra. *U. S.*

Extrait de reglisse, *Fr.;* Süssholzsaft, *Germ.;* Sugo di liquirizia, *Ital.;* Regaliza en bollos, *Span.*

For an account of *Glycyrrhiza glabra*, see article GLYCYRRHIZA.

The British Pharmacopœia gives directions for preparing this extract; but, as it is seldom made in this country by the apothecary, it is very properly placed, in the U. S. Pharmacopœia, in the catalogue of the Materia Medica.

The *British* directions are to macerate *an avoirdupois pound* of liquorice root, in coarse powder, for twelve hours, in *two pints* of distilled water, strain and press; again to macerate the pressed marc with distilled water for six hours, strain and press; then to mix the strained liquors, heat to 212°, strain through flannel; and finally evaporate, by means of a water-bath, to a proper consistence for forming pills The object in heating the infusion to 212° is to coagulate the albumen, and thus exclude it from the extract.

Liquorice is an article of export from the north of Spain, particularly Catalonia, where it is obtained in the following manner. The roots of the *G. glabra*, having been dug up, thoroughly cleansed, and half dried by exposure to the air, are cut into small pieces, and boiled in water till the liquid is saturated. The decoction is then allowed to rest, and, after the dregs have subsided, is decanted, and evaporated to the proper consistence. The extract, thus prepared, is formed into rolls from five to six inches long by an inch in diameter, which are dried in the air, and wrapped in laurel leaves.

Much liquorice is also prepared in Calabria, according to M. Fée, from the

* A preparation of hemp has been recommended as an anodyne liniment in painful affections, made by heating together for five or six hours upon a salt-water bath one part of the bruised tops of Indian hemp and two parts of the oil of hempseed, and then expressing and filtering. (*Journ. de Pharm.*, Mars, 1863, p. 239.)—*Note to the twelfth edition.*

G. echinata, which abounds in that country. The process is essentially the same as that just described, but conducted with greater care; and the Italian liquorice is purer and more valuable than the Spanish. We have been informed that most of the extract brought to this country comes from the ports of Leghorn and Messina. It is in cylinders, generally somewhat smaller than the Spanish, and sometimes stamped with the manufacturer's name.* Perhaps in no part of the world is more liquorice consumed than in this country; from four to five thousand tons having been imported annually before the war. Much of it is used in the manufacture of tobacco. (*Am. Journ. of Pharm*, Sept. 1862, p. 449.)

Crude liquorice is in cylindrical rolls, somewhat flattened, and often covered with bay leaves. We have seen it in the London market in large cubical masses. When good, it is very black, dry, brittle, breaking with a shining fracture, of a very sweet, peculiar, slightly acrid or bitterish taste, and almost entirely soluble when pure in boiling water. Neumann obtained 460 parts of aqueous extract from 480 parts of Spanish liquorice. It is, however, considerably less soluble in cold water. It is often impure from accidental or fraudulent addition, or careless preparation. Starch, sand, the juice of prunes, &c. are sometimes added; and carbonaceous matter, and even particles of copper are found in it, the latter arising from the boilers in which the decoction is evaporated. Four pounds of the extract have yielded two drachms and a half of metallic copper. (*Fée.*) In different commercial specimens examined by Chevallier, he found from 9 to 50 per cent. of insoluble matter. (*Journ. de Pharm.*, xxx. 429.) This is by no means, however, always impurity. In the preparation of the extract by decoction, a portion of matter originally insoluble, or rendered so by decoction, is taken up, and is, in fact, necessary to the proper constitution of the liquorice. When this is prepared with cold water, or even with hot water by simple displacement, the extract attracts moisture from the air, becomes soft, and loses the characteristic brittleness of the drug. The additional substances taken up in decoction serve to protect the extract against this change. M. Delondre has obtained the same result by using steam as the solvent. He prepares from the root an excellent liquorice, having all the requisite qualities of colour, taste, and permanence, by passing steam, in suitable vessels, through the coarse powder of the root. The vapour thoroughly penetrates the powder, and is drawn off as it condenses. With about 500 lbs of the root, this treatment is continued for 12 hours, and repeated at the end of 5 days. The liquors are collected, decanted, clarified with about 4 lbs. of gelatin, and quickly evaporated. After being put into the form of cylinders, the extract is kept for ten days in a drying room, at a temperature of 77°. (*Ibid.*, p. 433.) A bitter or empyreumatic taste is a sign of inferior quality in liquorice. As ordinarily found in commerce it requires to be purified.

The *refined liquorice*, kept in the shops in small cylindrical pieces not thicker than a pipe stem, is prepared by dissolving the impure extract in water without boiling, straining the solution, and evaporating. The object of this process is to separate not only the insoluble impurities, but also the acrid oleo-resinous substance, which is extracted by long boiling from the liquorice root, and is necessarily mixed with the unrefined extract. It is customary to add, during the process, a portion of sugar, gum, flour, starch, or perhaps glue. These additions, or something equivalent, are necessary to obviate the deliquescent property of the pure liquorice. According to M. Delondre, 15 per cent. of gum is the proper proportion, when this substance is used; Dr. Geisler has found the

* Much liquorice is prepared in this country, chiefly at the laboratory of the Messrs Tilden, at New Lebanon, Columbia Co., New York. The best roots being selected, are ground into a coarse powder, which is submitted to the action of condensing steam, so as to make a concentrated infusion, which is then evaporated without access of air. The extract is prepared in three forms: 1, in boxes containing 25 lbs. in which it solidifies in mass; 2, in small rolls of 80 to the pound; and 3, in lozenges like those of the Pontefract liquorice. (See the *next page.*) In the two latter forms, the addition of gum arabic is necessary to give the extract a proper consistence; as, without this, it softens in warm weather, so as not to retain its form. It is much lighter-coloured than the imported liquorice, but darkens on exposure. (*Am. Journ. of Pharm.*, xxvii. 311.)—*Note to the eleventh edition.*

sugar of milk to lessen the disposition of the extract to absorb moisture; but he considers the best addition, on the whole, to be very finely powdered liquorice root, which should be used in the proportion of one part to 16 of the purified extract. (*Am. Journ. of Pharm.*, xxviii. 225.) The preparation is sometimes attacked by small worms, probably in consequence of the farinaceous additions. Excellent liquorice is prepared, in some parts of England, from the root cultivated in that country. The *Pontefract cakes* are small lozenges of liquorice of superior quality, made in the vicinity of Pomfret.

Medical Properties and Uses. Liquorice is a useful demulcent, much employed in cough mixtures, and frequently added to infusions or decoctions, in order to cover the taste or obtund the acrimony of the principal medicine. A piece of it, held in the mouth and allowed slowly to dissolve, is often found to allay cough by sheathing the irritated membrane of the fauces. It is used in pharmacy to impart consistence to pills and troches, and to modify the taste of other medicines. Much is also used in the preparation of tobacco for chewing.

FARINA.

Wheat Flour.

Off. Syn. FARINA TRITICI. *Wheat Flour.* The grain of wheat, Triticum vulgare, ground and sifted. *Br.*

Farine de Froment, *Fr.;* Waizenmehl, *Germ.;* Farina di frumento, *Ital.;* Flor del trigo, Acemite, *Span.*

TRITICUM. *Sex. Syst.* Triandria Digynia.—*Nat. Ord.* Graminaceæ.

Gen. Ch. Calyx two-valved, solitary, transverse, many-flowered, on a flexuose, toothed receptacle. *Rees's Cyclopædia.*

Triticum hybernum. Willd. *Sp. Plant.* i. 477.—*T. vulgare*, var. *β. hybernum.* Kunth, *Gramin.* 438. The *common winter wheat* has a fibrous root and one or more erect, round, smooth, jointed stems, which rise from three to five feet in height, and are furnished with linear, pointed, entire, flat, many-ribbed, rough, somewhat glaucous leaves, and jagged bearded stipules. The flowers are in a solitary, terminal, dense, smooth spike, two or three inches long. The calyx is four-flowered, tumid, imbricated, abrupt, with a short compressed point. In the upper part of the spike it is more elongated; and in this situation the corolla is more or less awned. The grain is imbricated in four rows.

The native country of wheat is unknown; but its cultivation is supposed to have spread from Sicily over Europe. It is now an object of culture in almost all countries having a temperate climate. Sown in the autumn, it stands the winter, and ripens its seeds in the following summer. Numerous varieties have been produced by cultivation, some of which are usually described as distinct species. Among these may perhaps be ranked *T. æstivum*, or spring wheat, distinguished by its long beards, and *T. compositum*, or Egyptian wheat, by its compound spikes. The seeds are too well known to need description. They are prepared for use by grinding and sifting, by which the interior farinaceous part is separated from the husk. The former is divided according to its fineness into different portions, but so far as regards its medical relations may be considered under one head, that of *farina* or *flour*. The latter is called *bran*, and constitutes from 25 to 33 per cent.

Flour is white, inodorous, and nearly insipid. Its chief constituents are starch, gluten, albumen, saccharine matter, and gum, the proportions of which are not constant. Vauquelin obtained, as an average product, from eight varieties of flour which he examined, 10·25 per cent. of water, 10·80 of gluten (including coagulated albumen), 68·08 of starch, 5·61 of sugar, and 4·11 of gum. According to Christison, subsequent experiments have given an average of 16

or 17 per cent. of gluten and albumen. The ashes of wheat, which amount only to about 0·15 per cent., contain, according to Henry, superphosphates of soda, lime, and magnesia. The gummy substance found in wheat flour is not precisely identical with ordinary gum; as it contains nitrogen, and does not yield mucic acid by the action of nitric acid. The starch, which is by far the most abundant ingredient, is much employed in a separate state. (See *Amylum.*) The gluten, however, is not less important; as it is to the large proportion of this principle in wheat flour, that it owes its superiority over that from other grains for the preparation of bread. The gluten here alluded to is the substance first noticed as a distinct principle by Beccaria It is the soft, viscid, fibrous mass which remains, when wheat flour, enclosed in a linen bag, is exposed to the action of a stream of water, and at the same time pressed with the fingers till the liquor comes away colourless. But this has been ascertained to consist, in fact, of two different substances When boiled in alcohol, one portion of it is dissolved, while another remains unaffected. Einhof ascertained that the part of the glutinous mass left behind by alcohol is identical with *vegetable albumen*, while the dissolved portion only is strictly entitled to the name of *gluten*, which had been previously applied to the whole mass. As these two principles are contained in numerous vegetable products, and as they are frequently referred to in this work, it is proper that they should be briefly noticed. They both contain nitrogen, and both, when left to themselves in a moist state, undergo putrefaction. From these circumstances, and from close resemblance to certain proximate animal principles in chemical habitudes and relations, they are sometimes called, in works on chemistry, *vegeto-animal substances*. They are separated from each other by boiling the gluten of Beccaria, above referred to, with successive portions of alcohol, till the liquid, filtered while yet hot, ceases to become turbid on cooling. The proper gluten dissolves, and may be obtained by adding water to the solution, and distilling off the alcohol. Large cohering flakes float in the liquor, which, when removed, form a viscid elastic mass, consisting of the substance in question with slight impurity. The part left behind by the alcohol is coagulated albumen.

Pure *gluten*, sometimes called *vegetable fibrin*, is a pale yellow, adhesive, elastic substance, which, by drying, becomes more deeply yellow and translucent. It is almost insoluble in water, and quite insoluble in ether, and in the oils both fixed and volatile. Hot alcohol dissolves it much more readily than cold; and from its solution in boiling alcohol it separates unchanged when the liquor cools. It is soluble in the dilute acids, and in caustic alkaline solutions, in consequence of forming soluble compounds with the acids and alkalies. With the earths and metallic oxides it forms nearly insoluble compounds, which are precipitated when earthy or metallic salts are added to the solution of gluten in liquid potassa. Corrosive sublimate precipitates it from its acid as well as alkaline solutions, and, added in solution to moist gluten, forms a compound with it, which, when dry, is hard, opaque, and incorruptible. Gluten is precipitated by infusion of galls. Its name originated in its adhesive property. It exists in most farinaceous grains, and in the seeds of some leguminous plants.

Vegetable albumen is destitute of adhesiveness, and, when dried, is opaque, and of a white, gray, or brown colour. Before coagulation, it is soluble in water, but insoluble in alcohol. By heat it coagulates and becomes insoluble in water. It is dissolved by solutions of the caustic alkalies. Most of the acids, if added to its solution in excess, precipitate compounds of the acids respectively with the albumen, which, though soluble in pure water, are insoluble in that liquid when acidulated. It is not, however, precipitated by an excess of phosphoric or acetic acid. Its relations to the earthy and metallic salts are similar to those of gluten. Corrosive sublimate precipitates it from its solutions, except from those in phosphoric and acetic acids, and, when added in a state of solution to moist albumen, forms with it a hard, opaque compound. It is also precipitated by infusion of galls. This principle derived its name from its very close resemblance to animal albumen. It is associated with gluten in most of the farinaceous grains,

is a constituent of all the seeds which form a milky emulsion with water, and exists in all the vegetable juices which coagulate by heat.

The mixture of vegetable fibrin and albumen which constitutes the gluten of Beccaria, exercises an important influence over starch, which, with the presence of water, and the aid of a moderate heat, it converts partly into gum and partly into sugar. The production of saccharine matter in the germination of seeds and in malting, which is an example of germination, is thus explained. The gluten becomes acid in the process, and loses the property of reacting on starch.

It is thought by many chemists that *vegetable albumen* is identical in all respects with *animal albumen*, and the *gluten* of vegetables with animal *fibrin;* and that both these principles, as well as another named *casein*, found also both in the animal and vegetable kingdoms, consist of a principle named *protein*, combined with a very small proportion of mineral substances, such as sulphur and phosphorus. *Protein* consists of nitrogen, carbon, hydrogen, and oxygen; and its formula, according to Liebig, is $C_{48}H_{36}N_6O_{14}$. It is procured by dissolving any one of the substances above named in a strong solution of potassa, keeping the solution for some time at a heat of 120°, and precipitating with acetic acid.

It is scarcely necessary to state that bread is formed by making flour into a paste with water, with the addition of yeast, setting it aside to ferment, and then exposing it to the heat of an oven. The fermentation excited by the yeast is accompanied with the extrication of carbonic acid gas, which, being retained by the tenacity of the gluten, forms innumerable little cells throughout the mass, and thus renders the bread light.

Medical Properties and Uses. Wheat flour in its unaltered state is seldom used in medicine. It is sometimes sprinkled on the skin in erysipelatous inflammation, and various itching or burning eruptions, particularly the nettlerash; though rye flour is generally preferred for this purpose.

Bread is more employed. An infusion of toasted bread in water is a nutritive drink, well adapted to febrile complaints. Within our experience, no drink has been found more grateful in such cases than this infusion, sweetened with a little molasses, and flavoured by lemon-juice. Boiled with milk, bread forms a good emollient poultice, which may be improved by the addition of a little perfectly fresh lard. Slices of it steeped in lead water, and the crumb mixed with the fluid and confined within gauze, afford convenient modes of applying this preparation to local inflammations. The crumb (*mica panis*) is, moreover, frequently used to give bulk to minute doses of very active medicines, administered in the form of pill. It should be recollected that it always contains common salt, which is incompatible with certain substances, as, for example, nitrate of silver.

Bran is sometimes used in decoction, as a demulcent in catarrhal affections and complaints of the bowels. When taken in substance, it is laxative, and may be used with advantage to prevent costiveness. Bran bread, made from the unsifted flour, is an excellent laxative article of diet in some dyspeptic cases. The action of the bran is probably mechanical, consisting in the irritation produced upon the mucous membrane of the bowels by its coarse particles. Bran also forms an excellent demulcent bath.

Off. Prep. Cataplasma Fermenti, *Br.* W.

FERMENTUM. *U. S.*

Yeast.

Off. Syn. CEREVISIÆ FERMENTUM. *Beer Yeast.* The ferment obtained in brewing beer. *Br.*

Levure, *Fr.;* Bierhefen, *Germ.;* Fermento di cervogia, *Ital.;* Espuma de cerveza, *Span.*

This is the substance which rises, in the form of froth, to the surface of beer, and subsides, during the process of fermentation. A similar substance is produced during the fermentation of other saccharine liquids.

It is flocculent, frothy, somewhat viscid, semifluid, of a dirty yellowish colour, a sour vinous odour, and a bitter taste. At the temperature of 60° or 70°, in

a close vessel or damp atmosphere, it soon undergoes putrefaction. Exposed to a moderate heat, it loses its liquid portion, becomes dry, hard, and brittle; and may in this state be preserved for a long time, though with the loss of much of its peculiar power. In France it is brought to the solid state by introducing it into sacks, washing it with water, then submitting it to pressure, and ultimately drying it.*

Yeast is insoluble in alcohol or water. It was analyzed by Westrumb, and found to contain, in 15,142 parts, 13 of potassa, 15 of carbonic acid, 10 of acetic acid, 45 of malic acid, 69 of lime, 240 of alcohol, 120 of extractive, 240 of mucilage, 315 of saccharine matter, 480 of gluten, 13,595 of water, besides traces of silica and phosphoric acid. Its bitterness is attributable to a principle derived from the hops. The property for which it is chiefly valued is that of exciting the vinous fermentation in saccharine liquids, and in various farinaceous substances. This property it owes to its azotized ingredient; for, if separated from this, it loses its powers as a ferment, and reacquires them upon its subsequent addition. It is also rendered ineffective by strong alcohol, by several of the acids, as sulphuric and concentrated acetic acids, by various other substances, and by a heat of 212°. At a high temperature it is decomposed, affording products similar to those which result from the decomposition of animal matters.

Examined with a microscope, yeast is seen to abound in minute transparent vesicles, which appear to contain one or more granules. These are now believed to be a fungous plant, which has the power of propagating itself at the expense of organic proximate principles with which it may be brought into contact; and attempts have been made to solve the mysteries of fermentation by the conjecture, that the sugar or other fermenting substance, while contributing to the nourishment of the fungus, undergoes a decomposition resulting in the formation of new products. Another theory, originally put forth by Liebig, is that fermentation is merely a chemical movement, excited by a movement of decomposition going on in the ferment. Mulder considers the cell-wall of the yeast

* M. C. Gutkind, of Paris, recommends the following process for preparing bakers' yeast. Barley, having been slightly malted, is dried in a rapid current of heated air, then reduced to fine flour without bolting, and placed in a vat, where it is made into dough with water of 104° F., and afterwards brought with water at the same temperature to the consistence of porridge. For each pound of flour about a pint and a half of water is required (100 kilogrammes and 2 hectolitres). The porridge is heated in a boiler to 178° F., beyond which degree the temperature is not to be raised, and introduced into canvas bags, in which it is submitted to expression. The expressed liquid is put into large vats, where it cools. The solid matter is again put into a vat, mixed with 2 pints of water at 114° F. for each pound, and stirred into a porridge, which is then heated to 201° F., and kept so for an hour. The mass is put into bags and expressed; and the two expressed liquids are mixed, and exposed to the air in large vats for a period of time varying from two to ten days according to the atmospheric temperature. To cause the liquid to ferment, it is heated to 90° F., and a little fresh yeast added. During the whole period of fermentation, which may be conducted in vats or vessels, an exterior temperature of at least 59° F. must be maintained. The yeast thus obtained is free from bitterness or acidity, is extremely white, and consequently does not require washing, and is superior in raising power to all others. The residuary liquid after fermentation may be used for making vinegar. (*Lond. Pharm. Journ.*, xiv. 331.)—*Note to the eleventh edition.*

Dried Yeast. For keeping, and for transmission from place to place, it is often desirable to have yeast in the dried state. Yeast cakes have appeared in commerce. They may be prepared by washing the ordinary yeast with water, expressing the liquid portion, and spreading out the residue, in thin layers, on linen or cotton cloth, in order to dry, in the sun, or in heated chambers, or on porous bricks to absorb the moisture. The layers may be cut in pieces of convenient shape, which may be occasionally turned to facilitate drying.

The following plan is recommended in the *Chemical News* (Aug. 29th, 1863, p. 109). To every pound of the yeast, previously washed and drained, a drachm of pure carbonate of potassa or soda, and three drachms of officinal alcohol are to be added, the whole to be thoroughly mixed by stirring, and the mass thus prepared to be allowed to stand for half an hour, and then put into bags and expressed. Two drachms of solution of gelatin, in the form of a nearly cold jelly, are now to be thoroughly incorporated by kneading with the mixture, which is to be exposed for twelve hours in a cold place, for the complete solidification of the gelatin. The mass is, finally, to be cut into slices of the desired shape and size, and dried on muslin at ordinary temperatures. (*Note to the twelfth edition.*)

plant to consist of a substance analogous to cellulose, and its contents to be a protein body, differing in some respects from gluten and albumen, and probably a superoxide of protein. During fermentation, this protein body makes its way through the vesicular coat, undergoes decomposition by the agency of heat, and, in the act of decomposition, sets on foot the changes in sugar which result in the formation of alcohol and carbonic acid. (*Chem. Gazette*, Feb. 15, 1845.)*

Medical Properties and Uses. Yeast has been highly extolled as a remedy in low fevers of a typhoid character, and is said to have been given with advantage in hectic. It is, however, little employed; as its somewhat tonic and stimulating effects, ascribable to the bitter principle of hops, the alcohol, and the carbonic acid, which are among its constituents, may be obtained with equal certainty from more convenient medicines. The late Dr. Hewson, of Philadelphia, informed the authors that, in a case of typhoid fever, attended with great irritability of the stomach, the patient was benefited and sustained by taking a pint of yeast daily for five days, during which period no other remedy was employed. We have used it with apparent advantage in diabetes. (See *Trans. of Col. of Phys. of Phil.*, N. S., i. 390.) It has also been recommended internally in boils. When largely taken, it generally proves laxative; and it may sometimes be necessary to obviate this effect by opium. Externally applied, it is very useful in foul and sloughing ulcers, the fetor of which it corrects while it affords a gentle stimulus to the debilitated tissue. It is usually employed mixed with farinaceous substances in the form of a cataplasm. The dose is from half a fluidounce to two fluidounces every two or three hours.

Iron.

Wrought iron in the form of wire or nails, free from oxide. *Br.*

Fer, *Fr.;* Eisen, *Germ.;* Ferro, *Ital.;* Hierro, *Span.*

In the U. S. Pharmacopœia, this metal is employed in different preparations, in the form either of wire or filings; and each of these forms, therefore, will be

* There can, we think, scarcely be a doubt, at present, that fermentation and the reproduction of yeast are best explained upon the basis of an organic process. The germs of various microscopic plants, *mucedineæ*, as they are called, are always floating in the air, which, incorporated with certain nitrogenous substances, such as albumen, gluten, &c., essential to their nutrition, constitute what are called ferments. These have the property, when mixed with other substances, of producing certain chemical changes, accompanied with phenomena called fermentation, and resulting in the decomposition of these substances, and the production of new ones. Different plants produce different results, each giving rise to a peculiar fermentation, characterized by its own peculiar product. The *vinous fermentation* is one of these. Yeast, containing its proper plant, *Torula cerevisiæ*, mixed with a solution of sugar and water at a sufficient temperature, causes a decomposition of the sugar, and the generation of alcohol and carbonic acid, with the phenomena of vinous fermentation, while the yeast itself, instead of being destroyed, is in fact greatly increased. The plants, by abstracting, in the process of their growth and reproduction, a portion of the constituents of the sugar, decompose this substance, the remaining constituents of which enter into new combinations, forming alcohol and carbonic acid. Thus the yeast is augmented by the growth of the old and the abundant generation of new plants; and in this way, much better than in any other, is explained the singular phenomenon of the generation of the new yeast. Pasteur has given a strong evidence of the truth of this explanation by the discovery, that, though the yeast plant, when exposed to the air, will grow freely, yet it has comparatively little effect on the sugar, while, with the air excluded, it operates on this substance energetically. In the former case, it derives the oxygen necessary to its respiration from the air, in the latter, exclusively from the sugar. Opposed to this view is the asserted fact, that the alcohol and carbonic acid produced exactly represent the sugar lost, which could not be if a part of the sugar were consumed as food by the plant. But this difficulty is removed by the consideration, that, as the plant exposed to the air, while absorbing oxygen, gives out carbonic acid, so, when it derives oxygen from the sugar, it yields an equivalent product of carbonic acid, the surplus carbon of the sugar being probably appropriated in the nutritive process. (*Note to the twelfth edition.*)

briefly noticed in the following article; the general properties of the metal having been first considered.

Iron is the most abundant and useful of the metals, and so interwoven with the wants of mankind, that the extent of its consumption by a nation may be taken as an index of its progress in civilization. It is universally diffused in nature, not only in the mineral, but also in the vegetable and animal kingdoms. There are very few minerals in which traces of it are not to be found, and it is an essential constituent in many parts of animals, but particularly in the blood. It is one of the few metals which are not deleterious to the animal economy.

Iron occurs, 1. native; 2. sulphuretted, forming magnetic and cubic pyrites; 3. oxidized, embracing the magnetic, specular, red, brown, and argillaceous oxides of iron; 4. in saline combination, forming carbonate, sulphate, phosphate, and arseniate of iron. Those minerals of iron which admit of being worked to advantage are called iron ores. These include the different native oxides, and the carbonate (sparry iron). The best iron is obtained from varieties of the native oxide, usually called magnetic iron ore and specular iron ore. These occur abundantly in Sweden, and furnish the superior iron of that country. As a general rule, those ores yield the best iron which occur in primitive formations.

Extraction. The mode of extracting iron from its ores varies somewhat with the nature of the ore; but the general principles of the operation are the same for all. The ore, previously broken into small pieces and roasted, is exposed to the action of an intense heat, in contact with carbonaceous matter, such as charcoal, coke, or anthracite, and in connection with some flux, capable of fusing with the impurities of the ore. The flux varies with the nature of the ore, and is generally either limestone or clay; limestone being employed when the ore is argillaceous, clay when it is calcareous. The flux, whatever it may be, enters into fusion with the impurities, and forms what is called the slag; while the carbonaceous matter, acting on the oxide of iron, reduces it to the metallic state. The reduced metal, from its density, occupies the lower part of the furnace, and is protected from the action of the air by the melted slag which floats on its surface. When the reduction is completed, the slag is allowed to run out by a hole in the side of the furnace, and the melted metal by an aperture at the bottom, the latter being received into long triangular moulds, where it solidifies in masses, known in commerce by the name of *pig* or *cast iron*. In this state the metal is brittle and far from being pure; as it contains about 10 per cent. of carbon, with silicon, phosphorus, sulphur, calcium, aluminium, and sometimes manganese. It is purified, and brought to the state of malleable iron, by being fused, and subjected, while stirred, to the action of a current of air on its surface. By these means the carbon is nearly burnt out, and the other impurities are oxidized and made to rise to the surface as a slag. As the metal approaches to purity, it becomes tough and less liquid, and its particles agglutinate so as to form semi-fused lumps, though the temperature of the furnace continues the same. These lumps are then taken out of the furnace, and their particles, by means of ponderous hammers moved by steam or water power, or by great pressure, are forced together so as to form one tenacious mass. The metal is finally rolled out into bars of a convenient size, when it constitutes the malleable iron of commerce.

Very pure malleable iron is now manufactured by the new process of Mr. W. Bessamer, from the crude metal while still in a state of fusion, by running it into a separate vessel, and there subjecting it to a blast of atmospheric air. The carbon is thus burnt out; and by the heat generated the temperature of the fused metal is increased, with the effect of dissipating the volatile impurities, such as sulphur, &c., and of burning some of the iron into oxide, which, fusing with the earthy impurities, separates them in the form of slag. The loss of weight is 18 per cent., against 28 per cent. by the old process. (*Pharm. Journ.*, Sept. 1856.)

Iron mines occur in most countries, but more particularly in northern ones. In Spain, the principal mines furnish sparry iron, and the red and brown oxides. The chief iron ores of France are the sparry iron, and the specular brown, and argillaceous oxides; of Germany, the sparry iron and brown oxide. The island of Elba is celebrated for its rich and abundant specular iron ore.

In the United States iron is abundant. The principal ores that are worked are the magnetic, brown, and argillaceous oxides. They occur in the greatest abundance in the States of New Hampshire, Massachusetts, Rhode Island, Connecticut, New York, New Jersey, and Pennsylvania. The ores of the three last-mentioned States rival the best Swedish in quality.

Properties. Iron is a hard, malleable, ductile, and tenacious metal, of a grayish-white colour and fibrous texture, a slightly styptic taste, and a sensible odour when rubbed. In tenacity it yields only to nickel and cobalt. (*Deville.*) Its sp. gr. is about 7·7, and its fusing point very high. It possesses the magnetic and welding properties. It is combustible, and, when heated to whiteness, burns in atmospheric air, and with brilliant scintillations in oxygen gas. At a red heat, its surface is converted into black oxide, and at common temperatures, by the combined agency of air and moisture, it becomes covered with a reddish matter, called *rust*, which is the hydrated sesquioxide. It combines with all the nonmetallic elements, except hydrogen and nitrogen, and with most of the metals. Its eq. is 28 and symbol Fe. It forms three principal compounds with oxygen, a protoxide and sesquioxide, which, by their union, form the native black oxide, and a teroxide, possessing acid properties, called ferric acid. The *protoxide* is of a dark-blue colour, attracted by the magnet, and spontaneously combustible in the air, being converted into sesquioxide. It is the base of green vitriol, and of the green salts of iron generally. It is very prone to absorb oxygen; and hence the salts which contain it are soon partially converted, when in solution, into salts of the sesquioxide. It consists of one eq. of iron 28, and one of oxygen 8 = 36. The *sesquioxide* is readily obtained by dissolving iron in nitromuriatic acid, precipitating by ammonia, and igniting the precipitate. It is of a red colour, not attracted by the magnet, and forms salts, which for the most part have a reddish colour. It is composed of two eqs. of iron 56, and three of oxygen 24 = 80. An allotropic variety of the sesquioxide, soluble in water, and not responding to the ordinary tests of iron, has been discovered by M. Pean de Saint-Gilles. The *native black oxide*, the magnetic oxide of mineralogists, consists of one eq. of protoxide 36, and one of sesquioxide 80 = 116. Under the name of *Ferri Oxidum Magneticum*, the British Pharmacopœia has a preparation consisting of this oxide with three eqs. of water. The *teroxide* or *ferric acid*, discovered by Fremy, may be obtained, in union with potassa, by passing chlorine through a very concentrated solution of the alkali, holding the hydrated sesquioxide in suspension. This acid consists of one eq. of iron 28, and three of oxygen 24 = 52. Iron, combined with a minute proportion of carbon, and perhaps of silicon and aluminium, forms *steel*, a modification of iron formerly used in medicine. It also forms a number of important salts, several of which are officinal.

Iron is readily detected, even in minute quantities, by bringing it to the state of sesquioxide in solution, and adding ferrocyanide of potassium or tincture of galls; the former of which will strike a deep-blue, the latter a black colour. The object of bringing it to the state of sesquioxide is readily effected by boiling the solution containing it with a little nitric acid.

General Therapeutic Effects of Iron. The preparations of iron are preeminently tonic, and peculiarly well fitted to improve the quality of the blood, when impoverished from any cause. Hence they are useful in diseases characterized by debility, especially when the consequence of inordinate discharges. The diseases in which they are usually employed are chronic anæmia or chlorosis, hysteria, fluor albus, scrofula, rickets, passive hemorrhages, dyspepsia when dependent on deficient energy of the digestive function, and neuralgia. They are contraindicated in all inflammatory diseases, producing, when injudiciously employed, heat, thirst, headache, difficulty of breathing, and other symptoms of an excited circulation. In order to understand their effect in improving the blood, it must be borne in mind that this fluid always contains iron, as an essential constituent of the red corpuscles. The amount in ten thousand parts of blood, according to different authorities, is 2·3 parts (Le Canu), 2·4 (Denis), 5·5 (Becquerel and Rodier), 8·7 (Poggiale), mean 4·7. In anæmia the blood

is deficient in iron, not because the red corpuscles contain less of the metal, for they, individually considered, always contain the normal quantity; but because there are fewer of them. (*Becquerel and Rodier.*) The question here arises, which are the preparations of iron best adapted to promote the formation of the red constituent of the blood, and what are the conditions of their administration most favourable to their efficient action? According to M. Bouchardat, the preparations most easily assimilated are metallic iron and the protoxide; and, when the latter is in saline combination, it should be united either with carbonic acid, or with some organic acid. He holds that, when the iron is combined with a mineral acid, such as the sulphuric or phosphoric, the preparation acts solely as an astringent. Quevenne did not go so far as this, but believed that the mineral acid salts were not well adapted for assimilation, and that they were less so in proportion to their astringent power.

Quevenne laid it down as a rule, that, when the iron preparations are given with the view of improving the blood, they should be taken with the meals, and not on an empty stomach. Doses, thus given, were well borne, which often caused uneasiness and pain, when taken fasting. The gastric juice of the empty stomach is usually alkaline; and Quevenne proved that reduced iron, introduced, through a fistulous opening, into the stomach of fasting dogs, was not acted on, and was without effect in exciting the secretion. The juice, during digestion, is acid, and has been shown by the experiments of Quevenne to be in a favourable state for dissolving iron. The ferruginous preparations, it is true, were found to be unequally soluble; for, while iron filings were freely soluble, the subcarbonate of iron was but slightly attacked. It was observed that the acidity of the gastric juice was but little diminished by the solution of the iron; which fact can be explained only by supposing that the presence of the metal caused a nearly proportional increase of the acid secretion. Assuming these observations to be accurate, it is easy to perceive why the ferruginous preparations should be taken with the food, selecting of course those most soluble in the gastric juice. The digested iron, being intimately blended with the digested food, is in a favourable state to fulfil its indispensable agency in sanguification.

In the use of ferruginous preparations, it is often necessary to persevere for several months, in order to reap the fullest benefit. Even after the cure appears to be accomplished, it is safest to continue them, in diminishing doses, for a considerable time. For further information on the properties of iron, the reader is referred to the able memoir of the late T. A. Quevenne, entitled *Mémoir sur l'Action Physiologique et Thérapeutique des Ferrugineux* (Paris, 1854).

The following table embraces all the preparations of iron to be found in the United States and British Pharmacopœias, together with their synonymes.

Iron is officinal—

I. In the metallic state.
- Ferrum, *U.S.*, *Br.* — *Iron.*
  - Mistura Ferri Aromatica, *Br.* — *Aromatic Mixture of Iron.*
  - Vinum Ferri, *Br.* — *Wine of Iron.*
- Ferrum Redactum, *U. S.*, *Br.* — *Reduced Iron. Powder of Iron.*
  - Trochisci Ferri Redacti, *Br.* — *Reduced Iron Lozenges.*

II. Oxidized.
- Ferri Oxidum Hydratum, *U.S.*; Ferri Peroxidum Humidum, *Br.* — *Hydrated Oxide of Iron. Moist Peroxide of Iron.*
- Ferri Oxidum Magneticum, *Br.* — *Magnetic Oxide of Iron.*
- Ferri Peroxidum Hydratum, *Br.* — *Hydrated Peroxide of Iron.*
  - Emplastrum Ferri, *Br.* — *Chalybeate Plaster.*

III. Sulphuretted.
- Ferri Sulphuretum, *U.S.* — *Sulphuret of Iron.*

IV. In saline combination.

Tinctura Ferri Acetatis, *Br.* — *Tincture of Acetate of Iron.*
Ferri Arsenias, *Br.* — *Arseniate of Iron.*
Ferri Carbonas Saccharata, *Br.* — *Saccharated Carbonate of Iron.*
Pilula Ferri Carbonatis, *Br.* — *Pill of Carbonate of Iron.*
Pilulæ Ferri Carbonatis, *U.S.* — *Pills of Carbonate of Iron. Vallet's ferruginous Pills.*
Pilulæ Ferri Compositæ, *U.S.* — *Compound Pills of Iron.*
Ferri Chloridum, *U.S.* — *Chloride of Iron.*
Tinctura Ferri Chloridi, *U.S.* — *Tincture of Chloride of Iron.*
Ferri Citras, *U.S.* — *Citrate of Iron.*
Liquor Ferri Citratis, *U.S.* — *Solution of Citrate of Iron.*
Vinum Ferri Citratis, *Br.* — *Wine of Citrate of Iron.*
Ferri et Ammoniæ Citras, *U.S., Br.* — *Citrate of Iron and Ammonia.*
Ferri et Ammoniæ Sulphas, *U.S.* — *Sulphate of Iron and Ammonia Ammonio-ferric Alum.*
Ferri et Ammoniæ Tartras, *U.S.* — *Tartrate of Iron and Ammonia.*

Ferri et Quiniæ Citras, *Br.* — *Citrate of Iron and Quinia.*
Ferri et Quiniæ Sulphas, *U.S.* — *Sulphate of Iron and Quinia.*
Ferri Ferrocyanidum, *U.S* — *Ferrocyanide of Iron Pure Prussian Blue.*
Potassii Ferrocyanidum, *U.S.*; Potassæ Prussias Flava, *Br.* — *Ferrocyanide of Potassium. Yellow Prussiate of Potassa.*
Pilula Ferri Iodidi, *Br.* — *Pill of Iodide of Iron.*
Pilulæ Ferri Iodidi, *U.S.* — *Pills of Iodide of Iron.*
Syrupus Ferri Iodidi, *U.S., Br.* — *Syrup of Iodide of Iron.*
Ferri Iodidum, *Br.* — *Iodide of Iron.*
Ferri Lactas, *U.S.* — *Lactate of Iron.*
Liquor Ferri Nitratis, *U.S.*; Liquor Ferri Pernitratis, *Br.* — *Solution of Nitrate of Iron.*
Liquor Ferri Perchloridi Fortior, *Br.* — *Strong Solution of Perchloride of Iron.*
Liquor Ferri Perchloridi, *Br.* — *Solution of Perchloride of Iron.*
Tinctura Ferri Perchloridi, *Br.* — *Tincture of Perchloride of Iron.*
Ferri Phosphas, *U.S., Br.* — *Phosphate of Iron.*
Syrupus Ferri Phosphatis, *Br.* — *Syrup of Phosphate of Iron.*
Ferri Pyrophosphas, *U.S.* — *Pyrophosphate of Iron.*
Ferri Subcarbonas, *U.S* — *Subcarbonate of Iron.*
Emplastrum Ferri, *U.S.* — *Plaster of Iron. Strengthening Plaster.*
Trochisci Ferri Subcarbonatis, *U.S.* — *Troches of Subcarbonate of Iron.*
Liquor Ferri Subsulphatis, *U.S.* — *Solution of Subsulphate of Iron.*
Ferri Sulphas, *U.S., Br.* — *Sulphate of Iron.*
Ferri Sulphas Exsiccata, *U.S., Br.* — *Dried Sulphate of Iron.*
Mistura Ferri Composita, *U.S., Br.* — *Compound Mixture of Iron.*
Ferri Sulphas Granulata, *Br.* — *Granulated Sulphate of Iron.*
Liquor Ferri Tersulphatis, *U.S.*; Liquor Ferri Persulphatis, *Br.* — *Solution of Tersulphate of Iron. Solution of Persulphate of Iron.*

Iron Wire. *Ferri Filum. U.S.* 1850.
Fil de fer, *Fr.*; Eisendraht, *Germ.*; Fil di Ferro, *Ital.*; Hilo de hierro, *Span.*
Iron Filings. *Ferri Ramenta. U.S.* 1850. *Limatura Ferri.*
Limailles de fer, *Fr.*; Eisenfeilicht, *Germ.*; Limatura di ferro, *Ital.*; Limatura de hierro, *Span.*

Iron, when employed in pharmaceutical operations, should be of the purest kind; and hence the Pharmacopœias generally direct it, when wanted in small masses, to be in the form of *iron wire*, which is necessarily made from the purest, because the softest and most ductile iron, and is readily cut into pieces.

Iron filings are usually obtained from the workshops of the blacksmith; but, as furnished from this source, they are generally very impure, and unfit for medicinal use. M. Gobley, upon examining thirty-six samples of iron filings, found but three exempt from copper. The rest, besides wood, sand, and oxide of iron, contained as high as 2 per cent. of this metal. Iron filings cannot be completely purified by the magnet; as they often have adhering to them bits of foreign matter, which are carried up with them. The only way to obtain them pure, is to file a piece of pure iron with a clean file. The French Codex directs iron in an *impalpable powder*, prepared by porphyrizing bright and clean iron filings without water. A dull black powder is formed, which must be carefully preserved from moisture. An impalpable powder of the metal, *Ferrum Redactum*, obtained by reducing the sesquioxide by hydrogen, is officinal.

Medical Uses. In the form of wire, iron is never used internally; in that of filings, it was formerly much employed. Though undoubtedly an efficacious remedy, iron filings have been entirely superseded by one of the forms of powdered iron which have lately been brought into use, and which have the great advantages of more entire purity and more ready solubility in the liquids of the stomach, while exempt, by their impalpable character, from the liability to produce irritation mechanically, which was objected against the filings.

FERRI SULPHURETUM. *U. S.*

Sulphuret of Iron.

"Protosulphuret of Iron, prepared by melting together Iron in small pieces, and Sublimed Sulphur." *U. S.*

This has been introduced into the U. S. Pharmacopœia as the material from which sulphuretted hydrogen may be obtained, which, though not officinal, is in constant use as a reagent, and is often employed with great advantage in processes for isolating the active principles of medicinal substances.

The officinal sulphuret of iron is best prepared by bringing iron and sulphur into contact at a red or white heat. The following are the processes of the late Dublin and Edinburgh Pharmacopœias.

"Take of rods of Iron, of the size employed in the manufacture of nails, *any convenient number*. Having raised them to a strong red or white heat, apply them in succession by their heated extremities to sticks of Sulphur, operating so that the melted Sulphuret, as it is formed, may drop into a stone cistern filled with water, and be thus protected from oxidation. The water being poured off, let the product be separated from the Sulphur with which it is mixed, and, when dried, let it be enclosed in a well stopped bottle." *Dub.*

"An inferior sort, good enough, however, for pharmaceutic purposes, is obtained by heating one part of Sublimed Sulphur and three of Iron Filings, in a crucible, in a common fire till the mixture begins to glow, and then removing the crucible, and covering it until the action, which at first increases considerably, shall come to an end." *Ed.*

Iron and sulphur form a number of sulphurets, among which the most important are the protosulphuret and sesquisulphuret, corresponding with the protoxide and sesquioxide of iron, the bisulphuret or *cubic pyrites*, and *magnetic pyrites*, which is a compound of five eqs. of protosulphuret, and one of bisulphuret. When the sulphuret is obtained by the application of solid sulphur to white-hot iron, the product corresponds with magnetic pyrites; but, when procured by heating flowers of sulphur with an excess of iron filings, as directed in the above Edinburgh process, a protosulphuret is formed mixed with metallic

iron. When sulphur is applied to white-hot iron over water, the metal appears to become hotter, burns with scintillations in the vapour of the sulphur, and forms instantly the sulphuret, which, being comparatively fusible, melts into globules, and drops into the water, which serves to extinguish them.

Properties, &c. The officinal sulphuret of iron has a yellowish colour and the metallic lustre. When obtained over water it is in the form of brownish-yellow globules, having a somewhat crystalline texture. When pure it furnishes a yellow powder, and dissolves in dilute sulphuric or muriatic acid without leaving a residue of sulphur, and with the production of hydrosulphuric acid gas (sulphuretted hydrogen), free from admixture of hydrogen. As prepared, however, by the officinal processes, it is not entirely soluble in dilute sulphuric acid, a portion of uncombined sulphur being left. The fused globules have the composition $5FeS+FeS_2$, or, according to some, $5FeS+Fe_2S_3$. This sulphuret is employed solely as a pharmaceutical agent for the production of hydrosulphuric acid. It yields this gas by reaction with diluted sulphuric acid. Water is decomposed; its hydrogen combines with the sulphur to form hydrosulphuric acid, while the oxygen converts the iron into protoxide, with which the sulphuric acid unites. *Hydrosulphuric acid* is a colourless gas, having a smell like that of putrid eggs. Its sp. gr. is 1·1782. It saturates bases, with which it forms salts called *hydrosulphates, sulphohydrates,* or *hydrosulphurets.* It consists of one eq. of sulphur 16, and one of hydrogen 1 = 17. B.

FICUS. *U. S., Br.*

Fig.

The dried fruit of Ficus Carica. *U. S., Br.*

Figues, *Fr.;* Feigen, *Germ.;* Fichi, *Ital.;* Higos, *Span.*

Ficus. *Sex. Syst.* Polygamia Dicœcia. — *Nat. Ord.* Urticaceæ.

Gen. Ch. Common receptacle turbinate, fleshy, converging, concealing the florets in the same or distinct individuals. Male. *Calyx* three-parted. *Corolla* none. *Stamens* three. Female. *Calyx* five-parted. *Corolla* none. *Pistil* one. *Seed* one, covered with the closed, persistent, somewhat fleshy calyx. *Willd.*

Ficus Carica. Willd. *Sp. Plant.* iv. 1131; Woodv. *Med. Bot.* p. 714, t. 244. The fig-tree, though often not more than twelve feet high, sometimes rises in warm climates twenty-five or even thirty feet. Its trunk, which seldom exceeds seven inches in diameter, is divided into numerous spreading branches, covered with a brown or ash-coloured bark. Its large, palmate leaves, usually divided into five obtuse lobes, are deep-green and shining above, pale-green and downy beneath, and stand alternately on strong, round footstalks. The flowers are situated within a common receptacle, placed upon a short peduncle in the axils of the upper leaves. This receptacle, the walls of which become thick and fleshy, constitutes what is commonly called the fruit; though this term is, strictly speaking, applicable to the small seed-like bodies found in great numbers on the internal surface of the receptacle, to which they are attached by fleshy pedicels. Cultivation has produced in the fig, as in the apple and peach, a great diversity in shape, size, colour, and taste. It is usually, however, turbinate, or top-shaped, umbilicate at the large extremity, of the size of a small pear, of a whitish, yellowish, or reddish colour, and of a mild, mucilaginous, saccharine taste.

The fig-tree is supposed to have come originally from the Levant. It was introduced at a very early period into various parts of the south of Europe, and is now very common throughout the whole basin of the Mediterranean, particularly in Italy and France. To hasten the maturation of the fruit, it is customary to puncture it with a sharp-pointed instrument covered with olive oil. The ancient process of *caprification* is still practised in the Levant. It consists in attaching branches of the wild fig-tree to the cultivated plant. The fruit of the former contains great numbers of the eggs of an insect of the genus Cynips, the larvæ of which, as soon as they are hatched, spread themselves over the cultivated fruit, and, by conveying the pollen of the male organs over which they

pass to the female florets, hasten the impregnation of the latter, and cause the fig to come quickly to perfection, which might otherwise ripen very slowly, or wither and drop off before maturity. Some authors attribute the effect to the piercing of the fruit by the young insects. According to Landerer, the unripe fig contains an irritant juice, which inflames the skin, and may even disorganize it. (See *Am Journ. of Pharm.*, xxxiii. 215.)

The figs, when perfectly ripe, are dried by the heat of the sun or in ovens. Those imported into this country come chiefly from Smyrna, packed in drums or boxes. They are more or less compressed, and are usually covered in cold weather with a whitish saccharine efflorescence, which melts in the middle of summer, and renders them moist. The best are yellowish or brownish, somewhat translucent when held to the light, and filled with a sweet viscid pulp, in which are lodged numerous small yellow seeds. They are much more saccharine than the fresh fruit. Their chief constituents are sugar and mucilage.

Medical Properties and Uses. Figs are nutritious, laxative, and demulcent. In the fresh state they are considered in the countries where they grow a wholesome and agreeable aliment, and have been employed from time immemorial. They are apt, however, when eaten freely, to produce flatulence, pain in the bowels, and diarrhœa. Their chief medical use is as a laxative article of diet in constipation. They occasionally enter into demulcent decoctions; and, when roasted or boiled, and split open, are sometimes applied as a suppurative cataplasm to parts upon which an ordinary poultice cannot be conveniently retained, as, for example, to the gums.

FILIX MAS. *U. S., Br.*

Male Fern.

The rhizoma of Aspidium Filix mas. *U. S.* The dried rhizome with the bases of the footstalks, and portions of the root fibres of Aspidium Filix mas. *Br.*

Fougère male, *Fr.;* Johanniswurzel, *Germ.;* Félce maschio, *Ital.;* Helecho, *Span.*

Aspidium. *Sex. Syst.* Cryptogamia Filices. — *Nat. Ord.* Filices, *Jussieu.* Filicales, *Lindley.*

Gen. Ch. Fructification in roundish points, scattered, not marginal. *Involucre* umbilicated, open almost on every side. *Smith.*

The root of a species of Aspidium, growing in South Africa, has been used by the Kaffirs in the vicinity of Natal, by whom it is called *inkomankomo*, or *uncomocomo* as the name is given by Dr. Theodore Martius. The plant is the *A. athamanticum*, and the root has received the name of *panna* in Europe, where it was first brought into notice in 1851. It is probably in no respect superior to the European species. (*Pharm. Journ.*, xvi. 447.)

Aspidium Filix mas. Willd. *Sp. Plant.* v. 259; Smith, *Flor. Britan.* — *Nephrodium Filix mas.* Lindley, *Flor. Med.* 619. — *Polypodium Filix mas*, Linn.; Woodv. *Med. Bot.* p. 795, t. 267. The male fern has a perennial, horizontal root or rhizoma, from which numerous annual fronds or leaves arise, forming tufts from a foot to four feet in height. The stipe or footstalk, and midrib are thickly beset with brown, tough, transparent scales; the frond itself is oval-lanceolate, acute, pinnate, and of a bright-green colour. The pinnæ or leaflets are remote below, approach more nearly as they ascend, and run together at the summit of the leaf. They are deeply divided into lobes, which are of an oval shape, crenate at the edges, and gradually diminish from the base of the pinna to the apex. The fructification is in small dots on the back of each lobe, placed in two rows near the base, and distant from the edges. The plant is a native of Europe, Asia, and the north of Africa. It is said also to be indigenous, growing in shady pine forests from New York to Virginia; but it may be doubted whether the American plant is identical with the European.

The proper period for collecting the root is during the summer, when, according to M. Peschier, of Geneva, it abounds more in the active principle than at

any other season. The same writer informs us that it deteriorates rapidly when kept, and in about two years becomes entirely inert. The roots of other species of fern are frequently substituted for the officinal; and in the dried state it is difficult to distinguish them.

Properties, &c. As taken from the ground, the root consists of a long cylindrical caudex, around which are closely arranged, overlapping each other like the shingles of a roof, the remains of the leafstalks or stipes, which are an inch or two in length, from two to four lines thick, somewhat curved and directed upwards, angular, brown, shining, and surrounded near their origin from the root with thin silky scales, of a light-brown colour. From between these remains of the footstalks emerge numerous small radical fibres. The whole root, thus constituted, presents a somewhat flexible, cylindrical mass, one or two inches thick, and a foot or more in length. In this form, however, it is not usually found in our shops. The whole is ordinarily broken up into fragments, consisting of the separated remains of the leafstalks before described, with a small portion of the substance of the root attached to their base, where they are surrounded by the silky scales. These fragments, as seen in the shops, often appear as if long kept, and are probably, in general, much deteriorated by time. The following observations are made by Geiger in relation to the collection and preservation of the root. The inner parts of the fresh root, and of the portions of stalk attached to it, are fleshy and of a light yellowish-green colour. In collecting them, all the black discoloured portions should be cut away, the fibres and scales separated, and only the sound green parts preserved. These should be immediately but carefully dried, and then pulverized; and the powder should be kept in small well-stopped glass bottles. The powder thus prepared has a pale-yellowish colour with a greenish tinge.

Dried fern root is externally of a brown colour, internally yellowish-white or reddish, with a peculiar but feeble odour which is most obvious in the powder and decoction, and a sweetish, bitter, astringent, nauseous taste. It has been analyzed by H. Bock, who gives, as its constituents, volatile oil, fixed oil, resin, starch, vegetable jelly, albumen, gum, sugar, tannic and gallic acids, pectin, lignin, and various salts. (See *Am. Journ of Pharm*, xxiv. 64.) Peschier ascertained that its active properties reside in the ethereal extract, which is the fixed oil in an impure state, containing volatile oil, resin, colouring matter, &c. It is a thick dark liquid, with the odour of the fern, and a nauseous, bitterish, somewhat acrid taste. Dr E. Luck has found in it a peculiar acid, which he denominates *filicic acid*, and has extracted from the root two others named *tannaspidic* and *pteritannic acids*. (*Chem. Gaz.*, ix. 407 and 452.) The *aspidin* of Pavesi is not entitled to the name, as, though it may contain, it does not itself constitute the active principle, and is probably little if at all superior to the ethereal extract.

Medical Properties and Uses. Male fern is slightly tonic and astringent; but produces, when taken internally, no very obvious effects upon the system. It was used by the ancients as a vermifuge, and is mentioned in the works of Dioscorides, Theophrastus, Galen, and Pliny. Its anthelmintic powers were also noticed by some of the earlier modern writers, among whom was Hoffman. But it does not appear to have been generally known to the profession, till brought into notice, about the year 1775, by the publication of the mode of treating tænia, employed by Madame Nouffer. This lady, who was the widow of a surgeon in Switzerland, had acquired great celebrity in the cure of tape-worm by a secret remedy. Her success was such as to attract the attention of the medical profession at Paris; and some of the most eminent physicians of that city, who were deputed to examine into the subject, having reported favourably of the remedy, the secret was purchased by the King of France, and published by his order. The outlines of her plan were to give a dose of the powdered root of the male fern, and two hours afterwards a powerful cathartic, to be followed, if it should not operate in due time, by some purging salt; and this process was to be repeated, with proper intervals, till the worm should be evacuated. A German physician, named Herrenschwand, had used the male fern in a manner

somewhat similar, before Madame Nouffer's secret was known. Different opinions have been held of the value of this anthelmintic; but the accounts of its efficacy in the treatment of tape-worm are too numerous and authentic to admit of reasonable doubt. Dr. Peschier stated that, in the course of nine months, 150 tape-worms had been expelled by the ethereal extract. Dr. Ebers found the same preparation completely successful in eight cases. The testimony of Brera is also strongly in favour of the remedy, which he found effectual even against the armed tænia. M. Ronzel cured with it more than 100 cases of tænia, and never found it to fail. (*Journ. de Pharm.*, 3e sér., iv. 474) Perhaps the different results obtained by different practitioners may be in part ascribed to the variable strength and character of the root employed. It is said that the remedy proves more effectual against the tape-worm of the Swiss (*Bothriocephalus latus*) than against the *Tænia solium*, which is more frequent in France and England. (*Bremser.*) It appears to act as a poison to the worm.

The medicine may be given in the form of powder or ethereal extract. The dose of the powder is from one to three drachms, to be administered in electuary or emulsion, and repeated morning and evening for one or two days. M. Ronzel gives half an ounce to adults, made into boluses, to be swallowed in fifteen minutes, in the morning, on an empty stomach. The dose of the ethereal extract (*oil of fern*) is from twelve to twenty-four grains. Dr. Mayor, of Geneva, recommends it in the dose of from thirty to fifty drops, one-half to be taken at night, the other half in the morning, and followed, at the interval of an hour, by an ounce and a half of castor oil. The decoction has also been employed, made with an ounce of the root and a pint of water. It is customary to follow the medicine by some brisk cathartic, though this is not considered essential.

Fennel.

The fruit of Fœniculum vulgare. *U. S.*

Off. Syn. FŒNICULI FRUCTUS. *Fennel Fruit.* The fruit of Fœniculum dulce, D.C. Imported from Malta. *Br.*

Sweet Fennel Fruit, *Br.*; Fenouil, *Fr.*; Fenchel, *Germ.*; Finnocchio, *Ital.*; Hinojo, *Span.*

The plant producing fennel-seed was attached by Linnæus to the genus *Anethum*, but was separated from it by De Candolle, and placed, with three or four others, in a new genus styled *Fœniculum*, which has been generally adopted by botanists. The *Anethum Fœniculum* of Linnæus embraced two varieties, the *common* or *wild Fennel*, and the *sweet fennel:* the latter being the plant usually cultivated in the gardens of Europe. These are considered by De Candolle as distinct species, and named respectively *Fœniculum vulgare* and *Fœniculum dulce*. In the U. S. Pharmacopœia, the former of these is recognised as the source of the medicine; in the British Pharmacopœia, the latter. In the late Ed. Pharmacopœia, the *F. officinale* of Allioni was recognised. The last-mentioned plant De Candolle considers as belonging to his *F. vulgare* (*Prodromus*, iv. 142); while Merat treats of it as a distinct species, differing both from the F. vulgare and F. dulce of De Candolle (*Dict. de Mat. Méd.*); and Dr. Christison, in his Dispensatory, is disposed to unite it with the last-mentioned plant. In this confusion it is impossible to arrive at any definite and satisfactory conclusion as to the botanical history of the drug under consideration. One thing, however, is certain, that there are two kinds of fennel-seed found in the shops; and it is highly probable that these are derived, if not from distinct species of fennel, at least from marked varieties of the plant. One of them corresponds closely with the description given of the fruit of F. vulgare, while the other is undoubtedly produced by the plant cultivated under the name of sweet fennel, whether that be the F. dulce of De Candolle, or F. officinale of Allioni and Merat.

FŒNICULUM. *Sex. Syst.* Pentandria Digynia. — *Nat. Ord.* Umbelliferæ or Apiaceæ.

Gen. Ch. *Calyx* a tumid obsolete rim. *Petals* roundish, entire, involute, with a squarish blunt lobe. *Fruit* nearly taper. *Half fruits* with five prominent bluntly keeled ridges, of which the lateral are on the edge, and rather broadest *Vittæ* single in the channels, 2 on the commissure. *Involucre* none. (*Lindley.*)

Fœniculum vulgare. De Cand. *Prodrom.* iv. 142. — *Anethum Fœniculum.* Linn.; Woodv. *Med. Bot.* p. 127, t. 49. *Common fennel* has a biennial or perennial tapering root, and an annual, erect, round, striated, smooth, green, and copiously branching stem, which usually rises three or four feet in height. The leaves, which stand alternately at the joints of the stem, upon membranous striated sheaths, are many times pinnate, with long, linear, pointed, smooth, deep-green leaflets. The flowers are in large, flat, terminal umbels, with from thirteen to twenty rays, and destitute both of general and partial involucres. The corolla consists of five petals, which, as well as the stamens, are golden-yellow. The fruit is ovate, rather less than two lines in length by about a line in breadth, and of a dark colour, especially in the channels. The plant is a native of Europe, growing wild upon sandy and chalky ground throughout the continent.

F. officinale. Merat and De Lens, *Dict. de Mat. Méd.* iii. 270; Allioni, *Ed. Pharm.* This, which is sometimes called *sweet fennel*, is also perennial, with shorter leaves and less elongated leaflets than the common fennel, but resembling it very closely except in the character of the fruit. This is twice as long as that of the former plant, a little curved, of a less dark colour, with prominent ridges, and a persistent peduncle. It is sweeter and more aromatic than common fennel-seed. The plant is a native of the south of Europe; but is cultivated elsewhere in gardens, and is probably the source of much of the fennel-seed of the shops. Whether it is a distinct species, or a mere variety of F. vulgare, is not determined. Some confound it with the following.

F. dulce. De Cand. *Prodrom.* iv. 142. This plant is eminently entitled to the name of *sweet fennel*. It bears a general resemblance to *F. vulgare*, but differs in having its stem somewhat compressed at the base, its radical leaves somewhat distichous, and the number of rays in the umbel only from 6 to 8. It is also a much smaller plant, being only about a foot high; its flowers appear earlier; and its young shoots or turiones are sweeter and edible. It is a native of Portugal, Italy, and perhaps other parts of Southern Europe; and is cultivated largely in Italy and Sicily for the sake of the shoots, which are eaten raw, or in salad, or boiled as potherbs. The fruit is described by Merat and De Lens as "being globular-ovate, twice the size of that of common fennel, and with prominent ridges" This description does not answer to the character of any of the fennel-seed we have seen in the shops.

In all these species or varieties, the whole plant has an aromatic odour and taste, dependent on a volatile oil by which it is pervaded. The roots were formerly employed in medicine, but are generally inferior in virtues to the fruit, which is now the only officinal portion. Our shops are partly supplied from our own gardens; but much the larger portion of the medicine is imported from Europe, and chiefly, as we have been informed, from Germany. The fennel-seed cultivated here is sweeter and more aromatic than that from abroad, probably in consequence of its greater freshness.

Fennel-seeds (half-fruits) are oblong oval, from one to three or four lines in length, flat on one side, convex on the other, not unfrequently connected by their flat surfaces, straight or slightly curved, of a dark gravish-green colour, with longitudinal yellowish ridges on the convex surface. There are two varieties; one of them from one to two lines long, dark-coloured, rather flat, almost always separate, and without footstalks; the other from three to five lines in length, lighter-coloured, with much more prominent ridges, often conjoined by their flat surface, and very frequently provided with a footstalk. They do not differ essentially in aromatic properties. The odour of fennel-seed is fragrant, its taste warm, sweet, and agreeably aromatic. It yields its virtues to hot water, but more freely to alcohol. The essential oil may be separated by distillation with water. (See *Oleum Fœniculi.*) The seeds contain also fixed oil. From 960 parts, Neumann obtained 20 parts of the former and 120 of the latter.

Medical Properties and Uses. Fennel-seed was used by the ancients, is one of our most grateful aromatics, and in this country is much employed as a carminative, and as a corrigent of other less pleasant medicines, particularly senna and rhubarb. It is recommended for these purposes by the absence of any highly excitant property. The infusion, prepared by introducing two or three drachms of the seeds into a pint of boiling water, is the form usually preferred. The dose of the bruised or powdered seeds is from a scruple to half a drachm. In infants the infusion is frequently employed as an enema for the expulsion of flatus.

FRASERA. *U. S. Secondary.*

American Columbo.

The root of Frasera Walteri. *U. S.*

Frasera. *Sex. Syst.* Tetrandria Monogynia. — *Nat. Ord.* Gentianaceæ.

Gen. Ch. Calyx deeply four-parted. *Corolla* four-parted, spreading; segments oval, with a bearded, orbicular gland in the middle of each. *Capsule* compressed, partly marginated, one-celled. *Seeds* few, imbricated, large, elliptical, with a membranaceous margin. *Nuttall.*

Frasera Walteri. Michaux, *Flor. Bor. Americ.* i. 96; Barton, *Med. Bot.* ii. 103. — *F. Carolinensis.* Walter. This is among our most elegant indigenous plants, and the only one of its genus. From the root, which is triennial, long, spindle-shaped, horizontal, fleshy, and yellow, a strong, succulent, solid, smooth stem rises, from five to ten feet in height. The leaves are sessile, entire, glabrous, of a deep-green colour, and disposed in whorls, which commence at the root, and ascend to the summit with successively diminishing intervals. The radical leaves, from five to twelve in number, are elliptical, obtuse, a foot or more in length by about four inches in breadth, and lie upon the ground in the form of a star. Those constituting the whorls are successively smaller as they ascend; the lowest oblong-lanceolate, the upper lanceolate and pointed. The flowers are numerous, large, yellowish-white, and disposed in a beautiful terminal pyramidal panicle, from one to five feet long, the branches of which spring from the axils of the upper leaves. The segments of the calyx are lanceolate, acute, and somewhat shorter than those of the corolla. The filaments are inserted into the base of the corolla, between its segments, which they do not equal in length. The anthers are oblong and notched at the base. The germ is oblong-ovate, compressed, and gradually tapers into the style, which ends in a bifid stigma. The fruit is an oval, acuminate, compressed, two-valved, one-celled, yellow capsule, containing from eight to twelve flat elliptical seeds.

The Frasera flourishes in the southern and western portions of the United States, and in many situations is very abundant, especially in Arkansas and Missouri. It prefers rich woodlands and moist meadows. The period of flowering is from May to July; but the stems and flowers are produced only in the third year, the radical leaves being the only part of the plant which previously appears above ground. From this manner of growth, it is inferred that the root should be collected in the autumn of the second, or spring of the third year. Before being dried, it should be cut into transverse slices

As formerly in the market, frasera was in pieces irregularly circular, an eighth of an inch or more in thickness, about an inch in diameter, somewhat shrunk in the middle, consisting of a central medullary matter and an exterior cortical portion, of a yellowish colour on the cut surfaces, with a light reddish-brown epidermis. In appearance these pieces somewhat resembled columbo, but were easily distinguishable by the greater uniformity of their internal structure, the absence of concentric and radiating lines, and their purer yellow colour without a greenish tinge. We have met with a parcel of the root sliced longitudinally, so as to imitate gentian, though not likely to be confounded with it by an experienced person. It was called *American gentian.* The taste of frasera is bitterish and sweet-

ish. Water and diluted alcohol extract its virtues; and the tincture lets fall a precipitate upon the addition of water, but is not disturbed by tincture of galls. The hot infusion is not precipitated by solution of gelatin, and gives with iodine no signs of starch. These reactions afford additional means of distinguishing the root from columbo. Mr. Higinbothom, of Bermuda, found in it gum, pectin, glucose, wax, resin, fatty matter, yellow colouring matter, bitter extractive, and an acid which was probably peculiar. (*Am. Journ. of Pharm.*, Jan. 1862, p. 23.)

Medical Properties and Uses. Frasera is a mild tonic, calculated to meet the same indications with the other simple bitters. It has been thought to resemble columbo in medical properties as well as in appearance, and hence has received the popular name of *American columbo;* but experience has not confirmed the high estimate at one time formed of its virtues; and though, perhaps, still occasionally used in some places, it has failed to supplant the tonic of Mozambique. It may be given in powder or infusion. The dose of the former is from thirty grains to a drachm; that of an infusion, made in the proportion of an ounce of the bruised root to a pint of boiling water, is one or two fluidounces, to be repeated several times a day. The fresh root is said to operate as an emetic and cathartic, and has been given with a view to the latter effect. W.

GALBANUM. *U. S., Br.*

Galbanum.

The concrete juice of an undetermined plant. *U. S.* A gum-resin, derived from an unascertained umbelliferous plant. *Br.*

Galbanum, *Fr.;* Mutterharz, *Germ.;* Galbano, *Ital., Span.*

It is uncertain from what plant galbanum is derived. At one time it was supposed to be the product of *Bubon Galbanum*, an umbelliferous plant of the eastern coast of Africa. It has also been referred to the *Ferula ferulago* of Linnæus, the *Ferula galbanifera* of Lobel, which inhabits the coasts of the Mediterranean, and is found also in Transylvania and the Caucasus. But no part of either of these plants has the odour of galbanum; and it is, therefore, scarcely probable that they yield the drug. Mr. Don, having found the seeds taken from a parcel of galbanum to belong to an undescribed genus of umbelliferous plants, and concluding that they came from the same source as the gum-resin itself, gave the title of Galbanum to the new genus, and named the species *Galbanum officinale.* This was rather hastily adopted by the London College; as it is by no means certain that the same plant produced the seeds and the gum-resin. Specimens of a plant were received in England from Persia having a concrete juice adhering to them, which was taken by Dr. Lindley for galbanum; and that botanist, finding that the plant belonged to an undescribed genus, named it *Opoïdia*, with the specific name *galbanifera.* Dr. Pereira, however, found the substance not to be galbanum; and this supposed origin of the drug, therefore, though admitted as probable by the Edinburgh College, and recognised by the Dublin, must be considered as more than doubtful. A German traveller, F. A. Bukse, who has resided in Persia, states that, in 1848, he met with the galbanum plant on the declivities of the Demawend, near the southern coast of the Caspian. He saw the gum-resin exuding spontaneously from the plant, and was informed by the natives that the drug was collected from it. The plant is a Ferula, and closely resembles the *F. erubescens* of Bossier, if not identical with it. (*Pharm. Cent. Blatt*, March 17, 1852, p. 206.) Galbanum is said to be obtained by making incisions into the stem, or cutting it off a short distance above the root. A cream-coloured juice exudes, which concretes upon exposure to the air. A portion of juice also exudes spontaneously from the joints, and hardens in the shape of tears. The drug is brought from India and the Levant.

Properties. Galbanum usually appears in the form of masses composed of whitish, reddish, or yellowish tears, irregularly agglutinated by a darker coloured yellowish-brown, or greenish substance, more or less translucent, and generally mixed with pieces of stalk, seeds, or other foreign matters. It is also found,

though rarely in our markets, in the state of distinct roundish tears, about as large as a pea, of a yellowish-white or pale brownish-yellow colour, shining externally as if varnished, translucent, and often adhering together. Galbanum has in cool weather the consistence of firm wax; but softens in summer, and by the heat of the hand is rendered ductile and adhesive. At 212° F it is sufficiently liquid to admit of straining; and it generally requires to be strained before it can be used. A dark-brown or blackish colour, a consistence always soft, the absence of whitish grains, a deficiency in the characteristic odour and taste, and the intermixture of earthy impurities are signs of inferiority.

The odour of galbanum is peculiar and disagreeable; its taste bitterish, warm, and acrid; its sp. gr. 1·212. Triturated with water, it forms an imperfect milky solution, which on standing deposits the greater portion of what was taken up. Wine and vinegar act upon it in a similar manner. Alcohol dissolves a considerable proportion, forming a yellow tincture, which has the smell and taste of galbanum, and becomes milky with water, but affords no precipitate. In dilute alcohol it is wholly soluble, with the exception of impurities. Ether dissolves the greater portion. Pelletier found in 100 parts, 66·86 parts of resin, 19·28 of gum, 6·34 of volatile oil including the loss, 7·52 of wood and impurities, with traces of supermalate of lime. A small proportion of bassorin was found by Meissner. The medicine is, therefore, a *gum-resin*. By distillation at the temperature of about 250° F., the volatile oil is obtained of a fine indigo-blue colour, which it imparts to alcohol. Procured by distillation with water, it is colourless, and becomes yellowish by age. It is lighter than water.

According to Ludewig, a gum-resin, designated as *Persian galbanum*, is received in Russia by the way of Astracan or Orenburg, and is the kind used in that country. It comes enclosed in skins, and is in masses of a reddish-brown colour with whitish streaks, of a disagreeable odour, somewhat like that of assafetida, and of an unpleasant, bitter, resinous taste. It is so soft as to melt with a slight elevation of temperature. It differs from common galbanum in its odour, in its colour, which is never greenish, and in the absence of tears, and is probably derived from a different plant. It abounds in impurities.

Medical Properties and Uses. Galbanum was known to the ancients. It is stimulant, expectorant, and antispasmodic; and is considered as intermediate in power between ammoniac and assafetida, though much less employed than either of these gum-resins. The complaints to which it has been thought applicable, are chiefly chronic affections of the bronchial mucous membrane, amenorrhœa, and chronic rheumatism. It is occasionally applied externally as a plaster to indolent swellings, with the view of promoting resolution or suppuration. The dose is from ten to twenty grains, and may be given in pill, or triturated with gum arabic, sugar, and water, so as to form an emulsion.

GALLA. *U. S., Br.*

Nutgall. Galls.

A morbid excrescence upon Quercus infectoria. *U. S.* Excrescences on Quercus infectoria, caused by the punctures and deposited ova of Diplolepis Gallæ tinctoriæ. *Br.*

Noix de galle, *Fr.;* Galläpfel, *Germ.;* Galla, *Ital.;* Agallas de Levante, *Span.*

Many vegetables, when pierced by certain insects, particularly those of the genus *Cynips*, are affected at the points of puncture with a morbid action, resulting in excrescences, which, as they are derived from the juices of the plant, partake more or less of its chemical character. Most of the oaks are occasionally thus affected; and the resulting excrescences, having in a high degree the astringency of the plant, have been employed for various practical purposes. They are known by the name of *galls*, a term which, as well as their use in

medicine, has been handed down from the ancients. *Quercus infectoria*, *Q. Ægilops*, *Q. excelsa*, *Q. Ilex*, *Q. Cerris*, and *Q. robur* have been particularized as affording this product; but it is now generally admitted, on the authority of Olivier, that the officinal galls are derived chiefly, if not exclusively, from *Q. infectoria;* and this is recognised as their source in the U. S. and Br. Pharmacopœias.*

QUERCUS. See QUERCUS ALBA.

Quercus infectoria. Willd. *Sp. Plant.* iv. 436; Olivier, *Voy. Orient* t. 14 *et* 15; Carson, *Illust. of Med. Bot.* ii. 40, pl. 85. The *dyers' oak* is a small tree or shrub, with a crooked stem, seldom exceeding six feet in height. The leaves are obtusely toothed, smooth, of a bright-green colour on both sides, and stand on short footstalks. The acorn is elongated, smooth, two or three times longer than the cup, which is sessile, somewhat downy, and scaly. This species of Quercus grows, according to Olivier, throughout Asia Minor, from the Archipelago to the confines of Persia. Captain M. Kinnier found it also in Armenia and Kurdistan; General Hardwicke observed it growing in the neighbourhood of Adwanie; and it probably pervades the middle latitudes of Asia.

The gall originates from the puncture of the *Cynips quercûsfolii* of Linnæus, the *Diplolepis gallæ tinctoriæ* of Geoffroy, a hymenopterous insect or fly, with a fawn-coloured body, dark antennæ, and the upper part of its abdomen shining brown. The insect pierces the shoots and young boughs, and deposits its egg in the wound. This irritates the part, and a small tumour quickly rises, which is the result of a morbid growth, exhibiting various cells under the microscope, but no proper vegetable fibre. The egg grows with the gall, and is soon converted into a larva, which feeds upon the vegetable matter around it, and thus forms a cavity in the centre of the excrescence. The insect at length becomes a fly, and escapes by eating its way out. The galls are in perfection when fully developed, before the egg has been hatched, or the fly has escaped. Collected at this period, they are called, from their dark colour, *blue*, *green*, or *black galls*, and are most highly esteemed. Those which are gathered later, and which have been injured by the insect, are called *white galls*. They are usually larger, less heavy and compact, and of a lighter colour than the former.

The galls collected in Syria and Asia Minor are brought to this country chiefly from the ports of Smyrna and Trieste, or from London. As they are produced abundantly near Aleppo, it has been customary to designate them

* Under the name of *Chinese galls*, a product has been brought from China, supposed to be caused by an insect allied to the Aphis, as such an insect has been found in the interior of them. A specimen, which came under our notice, consisted of irregularly spindle-shaped bodies, often more or less bent, with obtusely pointed protuberances, about two inches long by an inch in diameter at the central thickest part, of an ash colour and a soft velvety feel, very light, hollow, with translucent walls about a line in thickness, of a slight odour recalling that of ipecacuanha, and a bitter astringent taste. From an examination of fragments of leaves and petioles found among these galls, Dr. Schenck concluded that the tree on which they are found is a species of Rhus; but, according to M. Decaisne, professor at the Museum of Natural History in Paris, their true source is probably the *Distylium racemosum* of Zuccarini (*Flor. Japon.*, i. p. 178, t. 94), a large tree of Japan, the leaves of which produce a velvety gall, resembling the one in question. (Guibourt, *Hist. Nat. des Drogues*, A. D. 1850, iii. 703.) More recently, however, it has been asserted by Mr. Daniel Hanbury that this opinion of Decaisne is erroneous; as, in his examination of the packages imported from China and Japan, he has found remains of different parts of a species of Rhus, but never any of a Distylium. Besides, the form of the galls of the Distylium, as figured by Siebold and Zuccarini, is entirely different. The species of Rhus to which they are ascribed is the *R. semi-alata*. (*Pharm. Journ.*, Feb. 1862, p. 421.) The Chinese make great use of this product both in dyeing and as a medicine. L. A. Buchner, jun., has found it to contain 65 per cent. of tannic acid identical with that of the officinal galls. (*Pharm. Cent. Blatt*, July, 1851, p. 526.) It is recommended by Stenhouse for the manufacture of gallic acid, being preferable for this purpose to the officinal galls, in consequence of its less amount of colouring matter. (*Pharm. Journ.*, Dec. 1862, p. 330.)

An inferior kind of galls has been recently produced in great quantities in England, by the attack of another species of Cynips, the *C. Kollari* of Hartig, upon the common English oak. But they have been ascertained to contain little tannic acid, and will not, probably, supersede the galls of the Levant. (*Note to the twelfth edition.*)

by the name of that town; though the designation, however correct it may formerly have been, is now wholly inapplicable, as they are obtained from many other places, and the produce of different parts of Asiatic Turkey is not capable of being discriminated, at least in our markets. Great quantities of galls, very closely resembling those from the Mediterranean, have been brought to the United States from Calcutta. Dr. Royle states that they are taken to Bombay from Bussorah through the Persian Gulf. We are, nevertheless, informed that galls are among the products of Moultan. Those of France and other southern countries of Europe have a smooth, shining, reddish surface, are little esteemed, and are seldom or never brought to the United States.

Properties. Galls are nearly round, from the size of a pea to that of a very large cherry, with a surface usually studded with small tuberosities, in the intervals of which it is smooth. The best are externally of a dark-bluish or lead colour, sometimes with a greenish tinge, internally whitish or brownish, hard, solid, brittle, with a flinty fracture, a striated texture, and a small spot or cavity in the centre, indicating the presence of the undeveloped or decayed insect. Their powder is of a light yellowish-gray. Those of inferior quality are of a lighter colour, sometimes reddish or nearly white, of a loose texture, with a large cavity in the centre, communicating externally by a small hole through which the fly has escaped. Galls have a bitter, very astringent taste, and when whole are inodorous or nearly so, but bruised or in powder, they have a decided and peculiar though not very strong smell. From 500 parts Davy obtained 185 parts of matter soluble in water, of which, according to his analysis, 130 were tannin, 31 gallic acid with a little extractive, 12 mucilage and matter rendered insoluble by evaporation, and 12 saline matter and calcareous earth. Braconnot discovered the presence of a small quantity of an acid to which he gave the name *ellagic*, derived from *galle*, the French name for galls, by reversing the order of the letters. According to M. Pelouze, however, neither gallic nor ellagic acid pre-exists in galls, being formed by the reaction of atmospheric oxygen upon their tannin. (*Journ. de Pharm.*, xx. 359.) Galls also yielded to Professor Branchi, by distillation with water, a concrete volatile oil. Guibourt found 65 per cent. of tannic acid, 10·5 of lignin, 5·8 of gum, sugar, and starch, 4·0 of gallic, ellagic, and luteo-gallic acids, and 11·5 of water, besides extractive, chlorophyll, volatile oil, albumen, and salts. For some interesting views of the chemical nature of galls, see *Acidum Gallicum* in the second part of this work. All the soluble matter of galls is taken up by forty times their weight of boiling water, and the residue is tasteless. Alcohol dissolves seven parts in ten, ether five parts. (*Thomson's Dispensatory.*) A saturated decoction deposits upon cooling a copious pale-yellow precipitate. The infusion or tincture affords precipitates with sulphuric and muriatic acids, lime-water, and the carbonates of ammonia and potassa; with solutions of acetate and subacetate of lead, the sulphates of copper and iron, the nitrates of silver and mercury, and tartrate of antimony and potassa; with solution of gelatin; and with the infusions of Peruvian bark, columbo, opium, and many other vegetables, especially those containing alkaloids, with most of which tannic acid forms insoluble compounds. The infusion of galls reddens litmus paper, is rendered orange by nitric acid, milky by the corrosive chloride of mercury, and has its colour deepened by ammonia; but yields no precipitate with either of these reagents. Sulphate of zinc was said by Dr. A. T. Thomson to occasion a slow precipitate, but this result was not obtained by Dr. Duncan.

Medical Properties and Uses. Galls are powerfully astringent. They are little employed as an internal remedy, though occasionally prescribed in chronic diarrhœa and chronic dysentery. They have been recommended as an antidote to tartar emetic, and those vegetable poisons which depend for their activity upon organic alkalies; but, though the insoluble compounds which these principles form with galls may be less active than their soluble native compounds, they cannot be considered as inert. In the form of infusion or decoction, made in the proportion of half an ounce to a pint of water, galls may be advantageously

used as an astringent gargle, lotion, or injection; and, mixed with simple ointment, in the proportion of one part of galls, in very fine powder, to eight parts of the unguent, they are frequently applied to the anus and rectum in hemorrhoidal affections. The dose of powdered galls is from ten to twenty grains, to be repeated several times a day.*

GAMBOGIA. *U. S.*

Gamboge.

The concrete juice of an undetermined tree. *U. S.*

Off. Syn. CAMBOGIA. *Gamboge.* A gum-resin obtained from Garcinia Morella, *Desrous. var.* pedicellata. *Br.*

Gomme gutte, *Fr.;* Gummigutt, *Germ.;* Gomma-gotta, *Ital.;* Gutta gamba, *Span.*

Several plants belonging to the natural family of *Guttiferæ*, growing in the equatorial regions, yield on incision a yellow opaque juice, which hardens on exposure, and bears a close resemblance to gamboge; but it is only from a particular tree, growing in Siam, that the officinal gum-resin is procured. Formerly the United States and all the British Pharmacopœias ascribed it to *Stalagmitis Cambogioides*. This genus and species were established by Murray of Göttingen, in 1788, from dried specimens belonging to König, procured in Ceylon; and, from information derived from the same source, it was conjectured by Murray that the tree yielded not only the gamboge of Ceylon, but that also collected in Siam. On this authority, the British Colleges made the reference alluded to. But it was ascertained by Dr. Graham, of Edinburgh, that there is no such plant as Stalagmitis Cambogioides; the description of Murray having been drawn up from accidentally conjoined specimens of two trees belonging to different genera; one being the *Xanthochymus ovalifolius* of Roxburgh, and the other, the *Hebradendron Cambogioides* of Graham. By several botanists the gum-resin has been ascribed to *Garcinia Cambogia*, also a tree of Ceylon belonging to the Guttiferæ, and yielding a yellowish concrete juice; but a specimen of this juice, sent to Edinburgh, was found by Dr. Christison to differ from gamboge both in composition and appearance, being of a pale lemon-yellow colour. Thus it appears that neither of these references is correct; and, besides, the fact seems to have been overlooked, that commercial gamboge is never obtained from Ceylon, but exclusively from Siam and Cochin-China. A gum-resin from Ceylon having been found similar in composition to the gamboge of commerce, and the tree which produced it having been referred by Dr. Graham to a new genus, and named by him *Hebradendron Cambogioides*, the Edinburgh College, in the last edition of its Pharmacopœia, was induced to adopt this Ceylon gamboge as officinal, and to recognise the name proposed by Dr. Graham for the tree producing it. But, as this variety is never found in western commerce, and exists only in cabinets, or the bazaars of India, it scarcely merited a place in an officinal catalogue; and the sufficiency of the grounds upon which the proposed genus Hebradendron was separated from Garcinia is not universally admitted. At length, however, through the instrumentality mainly of Prof. Christison and Mr. Daniel Hanbury, the true gamboge plant seems to have been determined with considerable certainty. Several years since, Dr. Christi-

* The following preparation has been made in imitation of one much used by the late Dr. Physick and Dr. Jos. Parrish, of Philadelphia. Macerate for twenty-four hours half an ounce of powdered galls, two drachms of bruised cinnamon, and two drachms of bruised nutmeg, in half a pint of brandy; then percolate, and, when the liquor has ceased to pass, add enough diluted alcohol to yield half a pint of filtered liquor. Put this into a shallow capsule, suspend over it two ounces of sugar on a slip of wire-gauze, and set the tincture on fire. The sugar melts with the flame, and falls into the liquid beneath. When the combustion ceases, agitate and filter. A highly astringent aromatic syrup is obtained, which may be given in obstinate diarrhœas in the dose of a fluidrachm. (*Am. Journ. of Pharm.* xxvii. 416.)—*Note to the eleventh edition.*

son received from Singapore specimens of the gamboge plant cultivated in that island, and derived from Siam, which proved to be a Garcinia, differing from the *G. elliptica* of Wallich chiefly in having its male flower upon pedicels. More recently Mr. Hanbury obtained from the same source numerous specimens of the same plant, and was enabled to confirm the statement of Dr. Christison; but he also found that the plant approached as near to the *Garcinia Morella* of Desrousseaux, from which it could be distinguished only by its pedicellate flowers. These specimens were afterwards submitted to the inspection of Mr. Thwaites in Ceylon, who is perfectly familiar with the Garcinias of that island, and were pronounced by him to belong to a variety of G. Morella, scarcely differing from the Ceylon plant, except in having pedicelled instead of sessile flowers. Hence, in the existing edition of the British Pharmacopœia, the true Siam gamboge plant is recognised as the Garcinia Morella, *var.* pedicellata. Considering, however, the constancy of this peculiar character of the flower, and the fact that the gamboge of commerce is never brought from Ceylon, it appears to the author highly probable that the plant will be ultimately admitted as a distinct species, with the title of *Garcinia pedicellata.*

Gamboge is collected in Siam and Cochin-China. Similar products are obtained in Ceylon; but they do not appear to be sent out of the island. Milburn does not mention gamboge among the exports. It is said to be procured in Siam by breaking off the leaves and shoots of the tree, from which the juice issues in drops, and, being received in suitable vessels, gradually thickens, and at length becomes solid. Portions of it, when of the requisite consistence, are rolled into cylinders,and wrapped in leaves. The juice is sometimes received into the hollow joints of the bamboo, which give it a cylindrical form; and, as it contracts during concretion, the cylinder is often hollow in the centre. The name *gummi gutta*, by which it is generally known on the continent of Europe, probably originated from the circumstance that the juice escapes from the plant by drops. The officinal title was undoubtedly derived from the province of Cambodia, in which the gum-resin is collected. It was first brought to Europe by the Dutch about the middle of the 17th century. We import gamboge from Canton and Calcutta, whither it is carried by the native or resident merchants. There is no difference in the appearance or character of the drug as brought from these two ports; an evidence that it is originally derived from the same place.

Varieties. The best gamboge is in cylindrical rolls, from one to three inches in diameter, sometimes hollow in the centre, sometimes flattened, often folded double, or agglutinated in masses so that the original form is not always easily distinguishable. The pieces sometimes appear as if rolled, but are in general striated longitudinally from the impression made by the inner surface of the bamboo. They are externally of a dull-orange colour, which is occasionally displaced by greenish stains,or concealed by the bright-yellow powder of the drug, slightly adhering to the surface. In this form the drug is sometimes called *pipe gamboge.* Another variety is imported under the name of *cake* or *lump gamboge.* It is in irregular masses of two or three pounds or more, often mixed with sticks and other impurities, containing many air cells, less dense, less uniform in texture, and less brittle than the former variety, and breaking with a dull and splintery, instead of a shining and conchoidal fracture. The worst specimens of this variety, as well as of the cylindrical, are sometimes called by the druggists *coarse gamboge.* They differ, however, from the preceding, only in containing a greater amount of impurities. Indeed, it would appear, from the experiments of Christison, that all the commercial varieties of this drug have a common origin, and that cake or lump gamboge differs from the cylindrical, only from the circumstance that the latter is the pure concrete juice; while to the former, farinaceous matter and other impurities have been added for the purpose of adulteration. The inferior kinds of gamboge may be known by their greater hardness and coarser fracture; by the brownish or grayish colour of their broken surface, which is often marked with black spots; by their obvious impurities; and by the green colour which their decoction, after having been cooled, gives with

tincture of iodine. When pure, the gum-resin is completely dissolved by the successive action of ether and water.*

Properties. Gamboge, in its pure form, is brittle, with a smooth, conchoidal, shining fracture; and the fragments are slightly translucent at their edges. The colour of the mass when broken is a uniform reddish orange, which becomes a beautiful bright-yellow in the powder, or when the surface is rubbed with water. From the brilliancy of its colour, gamboge is highly esteemed as a pigment. It has no smell and little taste; but, after remaining a short time in the mouth, produces an acrid sensation in the fauces. Its sp. gr. is 1·221. Exposed to heat, it burns with a white flame, emitting much smoke, and leaving a light spongy charcoal. It is a gum-resin, without volatile oil. In 100 parts of it Braconnot found 19·5 parts of gum, 80 of resin, and 0·5 of impurities. John obtained 10·5 per cent. of gum, 89 of resin, and 0·5 of impurities. Christison has shown that the proportion of gum and resin varies in different specimens even of the purest drug. In one experiment, out of 100·8 parts he obtained 74·2 of resin, 21·8 of gum, and 4·8 of water. The gum is quite soluble in water, and of the variety denominated arabin. In a specimen of *cake gamboge* he found 11·2 per cent. of fecula and lignin, and in a very bad one of *coarse gamboge*, no less than 41 per cent. of the same impurities. In addition to gum and resin, Ph. Büchner found a small and variable proportion of a peculiar reddish-yellow colouring matter, soluble both in alcohol and water. (*Journ. de Pharm.*, 3e sér., iii. 303.) Gamboge is readily and entirely diffusible in water, forming a yellow opaque emulsion, from which the resin is very slowly deposited. It yields its resinous ingredient to alcohol, forming a golden-yellow tincture, which is rendered opaque and bright-yellow by the addition of water. Its solution in ammoniated alcohol is not disturbed by water. Sulphuric ether dissolves about four-fifths of it, taking up only the resin. It is wholly taken up by alkaline solutions, from which it is partially precipitated by the acids. The strong acids dissolve it; but the solution when diluted with water deposits a yellow sediment. The colour, acrimony, and medicinal power of gamboge reside in the resin. This has the neutralizing property of the acids, and has been named *gambogic acid.* It is obtained by evaporating an ethereal tincture of the gum-resin. In mass it is of a cherry-red colour, but becomes of a deep-orange in thin layers, and yellow when powdered. So intense is its colour, that one part of it communicates a perceptible yellowness to ten thousand parts of water or spirit. It is insoluble in water, but soluble in alcohol, and very soluble in ether, chloroform, and benzole. It forms with the alkalies dark-red solutions of *gambogiates*, from which the acids throw down gambogic acid of a yellow colour, and with the soluble salts of lead, copper, and iron, gambogiates of those metals respectively; the salt of lead being yellow, that of copper brown, and that of iron dark-brown. Its composition is given by Johnston as $C_{40}H_{23}O_8$. (*Lond. Philos. Trans.*, 1839.) In the dose of five grains it is said to produce copious watery stools, with little or no uneasiness. If this be the case, it is probable that, as it exists in the gum-resin, its purgative property is somewhat modified by the other ingredients.

Medical Properties and Uses. Gamboge is a powerful, drastic, hydragogue cathartic, very apt to produce nausea and vomiting when given in the full dose. In large quantities it is capable of producing fatal effects, and death has resulted from a drachm. It is much employed in the treatment of dropsy attended with torpid bowels, generally in combination with bitartrate of potassa or jalap. It is also prescribed in cases of obstinate constipation, and has frequently been found effectual in the expulsion of the tape-worm. It is often combined with other and milder cathartics, the action of which it promotes and accelerates, while its own is moderated. The full dose is from two to six grains, which in cases of

* *Ceylon gamboge*, derived from the *Hebradendron Cambogioides* of Graham (*Cambogia gutta*, Linn., *Garcinia Morella*, De Cand.), is procured by incisions, or by cutting away a portion of the bark, and scraping off the juice which exudes. The specimens sent to Dr. Christison were in flattish or round masses, eight or nine inches in diameter, apparently composed of aggregated irregular tears, with cavities which are lined with a grayish and brownish powdery incrustation. It resembled coarse gamboge, and was identical in composition. In Ceylon it is used as a pigment and purgative. (*Christison.*)

tænia has been raised to ten or fifteen grains. As it is apt to occasion much sickness and griping, the best plan, under ordinary circumstances, is to give it in small doses, repeated at short intervals till it operates. It may be given in pill or emulsion, or dissolved in an alkaline solution. The last method of administration has been recommended in dropsical complaints.

GAULTHERIA. *U. S.*

Gaultheria. Partridge-berry.

The leaves of Gaultheria procumbens. *U. S.*

Gaultheria. *Sex. Syst.* Decandria Monogynia. — *Nat. Ord.* Ericaceæ.

Gen. Ch. Calyx five-cleft, bibracteate at the base. *Corolla* ovate. *Capsule* five-celled, invested with the berried calyx. *Pursh.*

Gaultheria procumbens. Willd. *Sp. Plant.* ii. 616; Bigelow, *Am. Med. Bot.* iii. 27; Barton, *Med. Bot.* i. 171. This is a small, indigenous, shrubby, evergreen plant, with a long, creeping, horizontal root, which sends up at intervals one or two erect, slender, round, reddish stems. These are naked below, leafy at top, and usually less than a span in height. The leaves are ovate or obovate, acute, revolute at the edges with a few mucronate serratures, coriaceous, shining, bright-green above, paler beneath, of unequal size, and supported irregularly on short red petioles. The flowers, of which not more than from three to five are usually on each stem, stand upon curved, drooping, axillary peduncles. The calyx is white, five-toothed, and furnished at its base with two concave cordate bractes, described by some as an outer calyx. The corolla is white, ovate or urceolate, contracted at the mouth, and divided at the border into five small acute segments. The stamens have curved, plumose filaments, and oblong orange coloured anthers opening on the outside. The germ, which rests upon a ring having ten teeth alternating with the ten stamens, is roundish, depressed, and surmounted by an erect filiform style, ending in an obtuse stigma. The fruit is a small, five-celled, many-seeded capsule, with a fleshy covering, formed by the enlarged calyx, and presenting the appearance of a bright scarlet berry.

The plant extends from Canada to Georgia, growing in large beds in mountainous tracts, or in dry barrens and sandy plains, beneath the shade of shrubs and trees, particularly of other evergreens, as the Kalmiæ and Rhododendra. It is abundant in the pine-barrens of New Jersey. In different parts of the country, it is variously called *partridge-berry*, *deer-berry*, *tea-berry*, *winter-green*, and *mountain-tea*. The flowers appear from May to September, and the fruit ripens at corresponding periods. Though the leaves only are officinal, all parts of the plant are endowed with the peculiar flavour for which these are employed, and which is found in several other plants, particularly in the bark of *Betula lenta*, or sweet birch. The fruit possesses it in a high degree, and, being at the same time sweetish, is much relished by some persons, and forms a favourite article of food with partridges, deer, and other wild animals. To the very peculiar aromatic odour and taste which belong to the whole plant, the leaves add a marked astringency. The aromatic properties reside in a volatile oil, which may be separated by distillation. (See *Oleum Gaultheriæ.*)

Medical Properties and Uses. Gaultheria has the usual stimulant operation of the aromatics, united with astringency; and may, therefore, be used with advantage in some forms of chronic diarrhœa. Like other substances of the same class, it has been employed as an emmenagogue, and with the view of increasing the secretion of milk; but its chief use is to impart an agreeable flavour to mixtures and other preparations. It may be conveniently administered in the form of infusion, which, in some parts of the country, is not unfrequently used at the table as a substitute for common tea. The oil, however, is more used in regular practice than the leaves. Instances of death are on record, resulting from the taking of the oil, by mistake, in the quantity of about a fluidounce. On examination after death, strong marks of gastric inflammation were discovered.

GELSEMIUM. *U. S. Secondary.*

Yellow Jasmine.

The root of Gelsemium sempervirens (*Gray*). *U. S.*

Gelsemium. *Sex. Syst.* Pentandria Digynia. — *Nat. Ord.* Scrophulariaceæ Loganiaceæ. (Gray, *Man. of Bot.* pp. 296, 703.)

Gen. Ch. Calyx five-parted. *Corolla* funnel-form, with a spreading border, five-lobed, nearly equal. *Anthers* oblong, sagittate. *Style* long and slender. *Stigmas* two, two-parted. *Capsule* elliptical, flat, two-valved, two-celled. *Seeds* flat, attached to the margin of the valves.

Gelsemium sempervirens. Gray, *Man. of Bot.* — *Gelseminum nitidum.* Michaux. — *Bignonia sempervirens.* Willd. *Sp. Plant.* iii. 291. Figured in *Am. Journ. of Pharm.*, xxvii. 197. The *yellow* or *Carolina jasmine* is one of the most beautiful climbing plants of our Southern States, ascending lofty trees, and forming festoons from one tree to another, and in its flowering season, in the early spring, scenting the atmosphere with its delicious odour. The stem is twining, smooth, and shining; the leaves perennial, opposite, shortly petiolate, lanceolate, entire, dark-green above and paler beneath; the flowers in axillary clusters, large, of a deep-yellow colour, and fragrant, with a very small, five-leaved calyx, and a funnel-shaped corolla, having a spreading, five-lobed, nearly equal border. The fruit is a flat, compressed capsule, divisible into two parts, two-celled, and furnished with flat seeds, which adhere to the margins of the valves. The plant grows in rich moist soils along the sea-coast from Virginia to the south of Florida. The root is the part employed. The flowers are said to be poisonous.

Properties. As we have seen it in the shops, the root is sliced into pieces, about an inch in length, cylindrical or split, very light and fibrous, of a dirty yellowish-white colour, but darker where the epidermis remains, of a slight feebly narcotic odour, and a bitterish, not unpleasant taste. It yields its virtues to water, and readily to diluted alcohol. Analyzed by Mr. Henry Kollock, it was found to contain gum, starch, pectic acid, albumen, gallic acid, fixed oil, a fatty resin, a dry acrid resin, yellow colouring matter, volatile oil, extractive, lignin, a peculiar alkaloid called *gelseminia*, salts of potassa, lime, and magnesia, iron and silica. The alkaloid, however, was not obtained sufficiently pure to admit of a full investigation of its properties. (*Am. Journ. of Pharm.*, xxvii. 203.)

Medical Properties and Uses. From the accounts given by various authors of the effects of yellow jasmine, it appears to be a nervous and arterial sedative, without nauseating or purgative properties, but sometimes causing diaphoresis, especially in febrile diseases. In moderate doses it produces agreeable sensations of languor, with muscular relaxation, so that the patient finds some difficulty in moving the eyelids, and keeping the jaws closed. More largely taken it occasions dizziness, dimness of vision, dilated pupil, general muscular debility, and universal prostration; reducing the frequency and force of the pulse, and the frequency of respiration, and producing insensibility to pain; but without stupor or delirium. After a short time these symptoms pass off, leaving no unpleasant effects. It usually begins to act in half an hour, and ceases to act after one or two hours. It is no doubt capable of causing death in overdoses. Indeed, two cases of poisoning by a fluid extract of gelsemium, one of which proved fatal, and the other ended in recovery, have been reported by Dr. R. P. Davis, of Parkersburg, Va. The quantity taken was about a tablespoonful. In the case which ended favourably, an emetic was followed, after acting efficiently, by the free use of quinia and brandy. In the fatal case there was no opportunity for the effective application of remedies. (*Med. and Surg. Reporter*, May 11, 1867, p. 410.)

Gelsemium is said to have been long popularly employed as a vermifuge in the Southern and Southwestern States; but its more valuable properties have been known but for a few years. Their discovery was accidental. A planter of Missis-

sippi, labouring under an obstinate bilious fever, directed his servant to get a particular root from the garden, and prepare a tea from it. The tea was prepared accordingly, and drank by the invalid, who was soon afterwards affected with great prostration, and especially muscular debility, so that he could not raise a limb, but without stupor. These effects gradually passed off, and with them the fever. The servant had made a mistake in the root, and dug that of the Gelsemium instead of the one intended. The planter, having made this discovery, employed the root afterwards with success upon his own plantation and in the neighbourhood. The remedy passed into the hands of irregular practitioners, and was used by the "eclectic physicians" before its virtues came to the knowledge of the profession.* The diseases in which the medicine has been prescribed are intermittent, remittent, typhoid, and yellow fevers, †the irritative fevers of childhood, inflammation of the lungs and pleura, dysentery, rheumatism and other inflammatory affections, neuralgia, dysmenorrhœa, morbid wakefulness, ‡delirium tremens, §trismus nascentium, chorea, and epilepsy. It has been used also successfully in gonorrhœa by Dr. John Douglass, of Chester Dist., S. C.

The preparation usually employed is a tincture made by macerating for two weeks the fresh bark of the root, well bruised, in diluted alcohol, or some form of ardent spirit, and then expressing and filtering. It has a dark-red colour, and the bitterness of the root, and is probably saturated. The dose is from ten to fifty drops, every hour or two; but is of course somewhat indefinite, as there is no officinal formula for the tincture. A formula has been proposed by Dr. Mayes, according to which four ounces of the fresh root are macerated for fourteen days with a pint of diluted alcohol. The dose of this tincture is from twenty to fifty drops. Yellow jasmine would probably form a good subject for a fluid extract. According to Dr. Cleveland, death has been caused by an excessive use of the tincture. W.

Gentiana lutea. Willd. *Sp. Plant.* i. 1331; Woodv. *Med. Bot.* p. 273, t. 95; Carson, *Illust. of Med. Bot.* ii. 12, pl. 60. *Yellow gentian* is among the most remarkable of the species which compose this genus, both for its beauty and great comparative size. From its thick, long, branching, perennial root, an erect, round stem rises to the height of three or four feet, bearing opposite,

* Attention was called to it by a paper of Prof. Procter, in the *Am. Journ. of Pharmacy* for October, 1852 (*page* 307), who derived most of his information from the "*Eclectic Dispensatory,*" and a paper by F. D. Hill, in the "*Eclectic Medical Journal*" of Cincinnati. Communications have since been published in reference to it in the *Southern Journ. of Med. and Phys. Sciences* for Jan. 1853 (*page* 40) by Dr. W. S. Jenkins, of Castalian Springs, Tenn.; in the *Stethoscope* of Nov. 1853 (*page* 636) by Dr. H. M. Nash, of Norfolk, Va.; and in the *Iowa Med. Journ.* by Dr. Bachelor. (See *Charleston Med. Journ. and Rev.*, March 1854, *page* 243.) Confirmatory accounts have still more lately appeared by Dr. C. H Cleveland in the *Am. Med. Gaz.* (vi. 154), by Dr. J. A. Mayes in the *Charleston Med. Journ.* (xii. 180), and by Dr. F. F. Gary, of Cokesbury, S. C., in the *Med. and Surg. Reporter* (June 11, 1859, p. 226). An abstract, by Dr. John Bell, of the various papers which have appeared in relation to it is contained in the *N. Am. Med.-chirurg. Review* (Sept. 1858, p. 931). From these various sources we have derived the above account of the medical properties and uses of the root.

† Dr. H. Wardner, *Med. and Surg. Reporter*, March 30, 1867, p. 266.

‡ Dr. D. L. Phares, *Ibid.*, May 25, 1867, p. 442.

§ *Ibid.*, Oct. 26, 1867, p. 369.

sessile, oval, acute, five-nerved leaves, of a bright-green colour, and somewhat glaucous. The lower leaves, which spring from the root, are narrowed at their base into the form of a petiole. The flowers are large and beautiful, of a yellow colour, peduncled, and placed in whorls at the axils of the upper leaves. The calyx is monophyllous, membranous, yellowish, and semi-transparent, splitting when the flower opens, and reflected when it is fully expanded; the corolla is rotate, and deeply divided into five or six lanceolate, acute segments; the stamens are five or six, and shorter than the corolla. This plant grows among the Apennines, the Alps, the Pyrenees, and in other mountainous or elevated regions of Europe. The root is the only part used in medicine.

Several other species possess analogous virtues, and are used for similar purposes. The roots of *G. purpurea* and *G. punctata*, inhabiting the same regions as G. lutea, and of *G. Pannonica*, growing in Austria, are said to be often mingled with the officinal, from which they are scarcely distinguishable. The *G. macrophylla* of Pallas is used in Siberia; one indigenous species, *G. Catesbæi*, growing in the Southern States, has a place in the secondary catalogue of the U. S. Pharmacopœia; and *G. quinquiflora*, growing throughout the Northern and Northwestern States, is said to be much used in domestic practice.

Properties. As found in the shops, gentian is in pieces of various dimensions and shape, usually of considerable length, consisting sometimes of longitudinal slices, sometimes of the root cut transversely, twisted, wrinkled externally, sometimes marked with close transverse rings of a grayish-brown colour on the outside, yellowish or reddish within, and of a soft, spongy texture. The odour is feeble, but decided and peculiar. The taste is slightly sweetish and intensely bitter, without being nauseous. The powder is yellowish. Water and alcohol extract the taste and virtues of the root. Examined by MM. Henry and Caventou, it was found to contain, 1. a crystallizable principle which they supposed to be the chief active ingredient of the root, and therefore named *gentianin*, 2. a volatile odorous principle, 3. a substance identical with birdlime (*glu*), 4. a greenish fixed oil, 5. a free organic acid, 6. uncrystallizable sugar, 7. gum, 8. yellow colouring matter, and 9. lignin. Mr. Denis afterwards detected pectic acid; and the gentianin of Henry and Caventou was proved by Trommsdorff and Leconte to be, when quite pure, wholly destitute both of bitterness and medicinal power; so that it would not appear to merit the name given to it. M. Leconte proposed, accordingly, to call it *gentisin;* and, as it possesses the property of neutralizing the alkalies, it has received also the name of *gentisic acid.* It is obtained by treating the alcoholic extract of gentian, previously exhausted by water, with sulphuric ether, filtering the ethereal solution, and allowing it to evaporate spontaneously. It is in needle-shaped crystals, pale-yellow, insoluble in water, and soluble in alcohol. The same chemist believes that he has ascertained the *birdlime* or *glu* of Henry and Caventou to be a mixture of wax, oil, and caoutchouc. When distilled with water, gentian yields a minute proportion of a concrete oil, having a strong odour of the root. Professor Dulk, of Königsberg, gave a process for isolating the *bitter principle;* but the substance obtained was in all probability complex, and, therefore, not deserving of the name of gentianin bestowed upon it. In a note, we give the process and its results.* At length, Ludwig and Kromayer appear to have been successful in discover-

* The alcoholic extract is macerated in water, and the solution, having been subjected to the vinous fermentation in order to separate the sugar, is treated first with acetate of lead, and then, after filtration, with subacetate of lead and a very little ammonia, in order to precipitate the combination of the bitter principle with oxide of lead; care being taken not to use too much ammonia, lest by its stronger basic powers it should separate the vegetable principle from the oxide. The precipitate is washed with a little water, then mixed with a large proportion of the same fluid, and decomposed by hydrosulphuric acid. The liquid, having been filtered, is evaporated with a gentle heat to dryness, and the residue treated with alcohol of 0·820. The alcoholic solution, being evaporated, yields the gentianin. It is a brownish-yellow, uncrystallizable substance, having strongly the bitter taste of the root. It is almost insoluble in absolute alcohol, but soluble in ordinary alcohol, and very soluble in water. It reddens litmus, and appears to possess acid properties. (*Journ. de Pharm.*, xxiv. 638.)

ing the long sought for principle. They prepared an alcoholic extract of the fresh root, treated this with water, and the aqueous solution twice with animal charcoal which absorbed all the bitterness, extracted the bitterness from the charcoal with alcohol, evaporated the tincture, treated the residue in solution with oxide of lead to separate the precipitable matter, removed the lead by sulphuretted hydrogen, evaporated to the consistence of syrup, and agitated the residue with ether, which precipitated the bitter principle. This they named *gentiopicrin*, though its proper name would be *gentianin*. It is crystallizable, very bitter, soluble in water and alcohol, but not in ether, neutral, and not precipitable by tannin or subacetate of lead. It ranks with the glucosides; as it is resolved by the action of acids into glucose and an amorphous substance called *gentiogenin*. Its formula is $C_{40}H_{30}O_{24}$. (See *Am. J. of Pharm.*, xxxv. 330.) M. Louis Magnes found in the root, when perfectly dried at 212° F., 15 per cent. of glucose, and 12 per cent. in the root in its ordinary state. (*Am. Journ. of Pharm.*, July, 1868, pp. 333–4.) When gentian is macerated in cold water, it undergoes the vinous fermentation, in consequence of the presence of this saccharine principle. From the fermented infusion a spirituous liquor is obtained by distillation, which, though bitter and unpleasant to the smell, is said to be relished by the Swiss and Tyrolese. Infusion of gentian is precipitated by tannic acid and the soluble salts of lead, but is compatible with the salts of iron.

Medical Properties and Uses. Gentian possesses, in a high degree, the tonic powers which characterize the simple bitters. It excites the appetite, invigorates digestion, moderately increases the temperature of the body and the force of the circulation, and operates in fact as a general corroborant. In very large doses, however, it is apt to load and oppress the stomach, to irritate the bowels, and even to occasion nausea and vomiting. It has been known as a medicine from the highest antiquity, and is said to have derived its name from Gentius, a king of Illyria. Many of the complex preparations handed down from the Greeks and Arabians contain it among their ingredients; and it enters into most of the stomachic combinations employed in modern practice. It may be used in all cases of pure debility of the digestive organs, or requiring a general tonic impression. Dyspepsia, atonic gout, amenorrhœa, hysteria, scrofula, intermittent fever, diarrhœa, and worms are among the many affections in which it has proved useful; but it is the condition of the stomach and of the system generally, not the name of the disease, which must be taken into consideration in prescribing it; and there is scarcely a complaint in which it can be advantageously given under all circumstances. Its powder has been applied externally to malignant and sloughing ulcers. It is usually administered in the form of infusion or tincture. A syrup may be prepared by forming a saturated infusion by means of percolation, and incorporating this at a boiling heat with simple syrup; or, perhaps more eligibly, by dissolving two drachms of the extract of gentian, and afterwards fifteen ounces of sugar, in half a pint of water. The dose of the powder is from ten to forty grains. In consequence of the porous property of the root, which causes it to expand with moisture, it has been employed, as a substitute for sponge tent, in the enlargement of strictured passages.

GENTIANA CATESBÆI. *U. S. Secondary.*

Blue Gentian.

The root of Gentiana Catesbæi. *U. S.*

GENTIANA. See GENTIANA.

Several indigenous species of gentian approach more or less nearly to *Gentiana lutea* in the bitterness of their roots; but *G. Catesbæi*, which resembles it most closely, is the only one medicinally employed.

Gentiana Catesbæi. Walter, *Flor. Car.* 109; Bigelow, *Am. Med. Bot.* iii. 137. The blue gentian has a perennial, branching, somewhat fleshy root, and a simple, erect, rough stem, rising eight or ten inches in height, and bearing opposite leaves, which are ovate-lanceolate, acute, and rough on their margin. The flowers are of a palish-blue colour, crowded, nearly sessile, and axillary or terminal. The divisions of the calyx are linear-lanceolate, and longer than the tube. The corolla is large, ventricose, plaited, and divided at its border into ten segments, of which the five outer are more or less acute, the five inner bifid and fringed. The number of stamens is five, and the two stigmas are seated on the germ. The capsule is oblong, acuminate, with two valves, and a single cell.

G. Catesbæi grows in the grassy swamps of North and South Carolina, where it flowers from September to December. It was named by Walter and Elliot in honour of Catesby, by whom it was delineated nearly a century ago. Pursh confounds it with *G. Saponaria*, to which it is closely allied.

Properties. By Dr. Bigelow we are told that the dried root of this plant has at first a mucilaginous and sweetish taste, which is soon succeeded by an intense bitterness, approaching nearly to that of the officinal gentian. Alcohol and boiling water extract its virtues, and the tincture and decoction are even more bitter than the root in substance.

Medical Properties. As a medicine it is little inferior to the European gentian, and may be employed for similar purposes. In the Northern and Middle States it is not used; but it is said to be occasionally prescribed by the practitioners of the South in dyspepsia, and other cases of stomachic and general debility. It may be given in powder in the dose of from fifteen to thirty grains, or in the form of extract, infusion, wine, or tincture, which may be prepared in the manner directed for the similar preparations of foreign gentian. W.

GERANIUM. *U. S.*

Cranesbill.

The rhizoma of Geranium maculatum. *U. S.*

GERANIUM. *Sex. Syst.* Monadelphia Decandria. — *Nat. Ord.* Geraniaceæ.

Gen. Ch. Calyx five-leaved. *Corolla* five-petaled, regular. *Nectary* five melliferous glands, united to the base of the longer filaments. *Arilli* five, one-seeded, awned, at the base of a beaked receptacle; awns simple, naked, neither spiral nor bearded. *Willd.*

Geranium maculatum. Willd. *Sp. Plant.* iii. 705; Bigelow, *Am. Med. Bot.* i. 84; Barton, *Med. Bot.* i. 149. This plant has a perennial, horizontal, fleshy root, which is furnished with short fibres, and sends up annually an herbaceous stem, with several radical leaves. The stem is erect, round, dichotomously branched, from one to two feet high, of a grayish-green colour, and thickly covered, in common with the petioles and peduncles, with reflexed hairs. The leaves are deeply divided into three, five, or seven lobes, which are variously incised at their extremities, hairy, and of a pale-green colour, mottled with still paler spots. Those which rise from the root are supported on footstalks eight or ten inches long; those of the stem are opposite, the lower petiolate, the upper nearly sessile, with lanceolate or linear stipules. The flowers are large, and usually of a purple colour. The peduncles spring from the forks of the stem, and severally support two flowers upon short pedicels. The calyx is composed of five oblong, ribbed, cuspidate leaves; the petals are five, obovate, and entire; the stamens ten, with oblong, deciduous anthers, the five alternate filaments being longer than the others, and having glands at their base; the germ is ovate, supporting a straight style as long as the stamens, and surmounted by five stigmas. The fruit consists of five aggregate, one-seeded capsules, attached by a beak to the persistent style, curling up and scattering the seeds when ripe.

The cranesbill is indigenous, growing throughout the United States, in moist woods, thickets, and hedges, and generally in low grounds. It flowers from May to July. The root should be collected in autumn.

This, when dried, is in pieces from one to three inches long, from a quarter to half an inch in thickness, somewhat flattened, contorted, wrinkled, tuberculated, and beset with slender fibres. It is externally of an umber-brown colour, internally reddish-gray, compact, inodorous, and of an astringent taste, without bitterness or other unpleasant flavour. Water and alcohol extract its virtues. According to Dr. Edward Staples, it contains tannic and gallic acids, mucilage, red colouring matter, resin, and a crystallizable vegetable principle. (*Journ. of Phil. Col. of Pharm.*, Oct. 1829, p. 171.) The Messrs. Tilden found, besides tannic and gallic acids, gum, pectin, sugar, starch, albumen, resin soluble in ether, resin soluble in alcohol, oleo-resin soluble in ether only, colouring matter, chlorophyll, lignin, and various salts. (*Pharm. Journ.*, July, 1863, p. 22.) Tannic and gallic acids are probably the sole active ingredients.

Medical Properties and Uses. Geranium is one of our best indigenous astringents, and may be employed for all the purposes to which these medicines are applicable. The absence of unpleasant taste, and other offensive qualities, renders it peculiarly serviceable in the cases of infants, and persons of very delicate stomach. Diarrhœa, chronic dysentery, cholera infantum in the latter stages, and the various hemorrhages are the forms of disease in which it is most commonly used, and with greatest advantage; but care should be taken, before it is administered, that the condition of the system and of the part affected is such as not to contraindicate the use of astringents. As an application to indolent ulcers, an injection in gleet and leucorrhœa, a gargle in relaxation of the uvula and aphthous ulcerations of the throat, it answers the same purpose as kino, catechu, and other medicines of the same class. It is a popular domestic remedy in various parts of the United States, and is said to be employed by the Indians. It may be given in substance, decoction, tincture, or extract. The dose of the powder is twenty or thirty grains, that of a decoction, made by boiling an ounce of the root in a pint and a half of water to a pint, from one to two fluidounces. The medicine is sometimes given to children, boiled in milk. W.

GEUM. *U. S. Secondary.*

Water Avens.

The root of Geum rivale. *U. S.*

Benoite aquatique, *Fr.;* Wiesen Benediktenwurzel, *Germ.*

GEUM. *Sex. Syst.* Icosandria Polygynia. — *Nat. Ord.* Rosaceæ.

Gen. Ch. Calyx ten-cleft. *Petals* five. *Seeds* with a bent awn. *Willd.*

Several species belonging to this genus have been medicinally employed; but two or three only are deserving of particular notice—*Geum rivale*, which has a place in the secondary list of the United States Pharmacopœia, *G. urbanum*, formerly recognised by the Dublin College, and perhaps *G. Virginianum*, an indigenous species, the root of which has been recommended in dysentery by Dr. W. A. Gibson, of St. Louis. (*The Med. Record*, Oct. 5, 1868, p. 384, from the *St. Louis Med. Reporter.*)

Geum urbanum, or *avens*, is a native of Europe, where it grows wild in shady places. The root, which is the part used, consists of a short oblong body, from a quarter to half an inch in thickness, externally brown, internally white towards the circumference and reddish at the centre, and furnished with numerous long descending fibres. When quite dry it is nearly inodorous; but in the recent state has a smell like that of cloves, whence it is sometimes called *radix caryophillatæ*. The taste is bitterish and astringent. It imparts its virtues to water and alcohol, which it tinges red. Distilled with water it yields a thick, greenish-yellow volatile oil, and gives a pleasant flavour to the liquid. It contains, besides, according to Trommsdorff, tannic acid, which is abundant, a tasteless resin, gum, bassorin, and lignin. It has been much used in Europe as a tonic and astringent, in chronic and passive hemorrhages, chronic dysentery and diarrhœa, leucorrhœa, intermittent fever, &c. The dose is from thirty grains to a drachm of the powder three or four times a day, or an equivalent quantity in decoction.

Geum rivale. Willd. *Sp. Plant.* ii. 1115; *Engl. Bot.* 106. *Water avens* has a perennial, horizontal, jointed, scaly, tapering root, about six inches long, of a reddish-brown colour externally, white internally, and furnished with numerous descending yellowish fibres. One or more stems rise from the same root, which also sends up numerous leaves. The stems are about a foot and a half high, simple, erect, pubescent, and of a purplish colour. The radical leaves are interruptedly pinnate, with large terminal leaflets, and long, hairy footstalks; those of the stem are petiolate, and divided into three serrate, pointed segments. The flowers are few, solitary, nodding, yellowish-purple, and supported on axillary and terminal peduncles. The colour of the stems and flowers gave rise to the name of *purple avens*, sometimes applied to the plant. The calyx is inferior, with ten lanceolate, pointed segments, of which the five alternate are smaller than the others. The petals are five, and as long as the calyx. The seeds are oval, with plumose awns, minutely uncinate, and nearly naked at the summit.

This species of Geum is common to Europe and the United States; though the plant of this country has smaller flowers, with petals more rounded on the top, and leaves more deeply incised than the European. It delights in wet, boggy meadows, and extends from Canada into New England, New York, and Pennsylvania. Its flowers appear in June and July. The dried root is hard, brittle, easily pulverized, of a reddish or purplish colour, without smell, and of an astringent, bitterish taste. Boiling water extracts its virtues.

Medical Properties and Uses. Water avens is tonic and powerfully astringent. It may be used with advantage in chronic or passive hemorrhages, leucorrhœa, and diarrhœa; and is said to be beneficially employed in the Eastern States, as a popular remedy in the debility of phthisis pulmonalis, in simple dyspepsia, and in visceral diseases consequent on disorder of the stomach. In Europe it is sometimes substituted for the root of *common avens*, or Geum urbanum, but is less esteemed. The dose of the powdered root is from a scruple to a drachm, to be repeated three times a day. The decoction, which is usually preferred, may be made by boiling an ounce of the root in a pint of water, and given in the quantity of one or two fluidounces. A weak decoction is sometimes used by invalids in New England as a substitute for tea and coffee. W.

GILLENIA. *U. S.*

Gillenia.

The root of Gillenia trifoliata, and of Gillenia stipulacea. *U. S.*
Indian physic, American ipecacuanha.

Gillenia. *Sex. Syst.* Icosandria Pentagynia.—*Nat. Ord.* Rosaceæ.

Gen. Ch. Calyx tubular campanulate, border five-toothed. *Corolla* partly unequal. *Petals* five, lanceolate, attenuated at the base. *Stamens* few, included. *Styles* five. *Capsules* five, connate at the base, opening on the inner side, each two-seeded. *Torrey.*

This genus was separated by Moench from *Spiræa.* It is exclusively North American, and includes only two discovered species—*G. trifoliata* and *G. stipulacea*—both of which are recognised in our Pharmacopœia.

1. *Gillenia trifoliata.* Bigelow, *Am. Med. Bot.* iii. 10; Barton, *Med. Bot.* i. 65; Carson, *Illust. of Med. Bot.* i. 40, pl. 34. This is an herbaceous plant, with a perennial root, consisting of many long, slender, brown branches, proceeding from a thick, tuber-like head. The stems, several of which usually rise from the same root, are two or three feet high, erect, slender, smooth, flexuose, branched, and commonly of a reddish colour. The leaves are ternate, with very short petioles, and small linear-lanceolate stipules. The leaflets are ovate-lanceolate, sharply serrate, and acuminate. The flowers grow in a loose terminal nodding panicle, with long peduncles. The calyx is tubular campanulate, ventricose, and terminates in five-pointed segments. The corolla is composed of five linear-lanceolate, recurved petals, the two upper separated from the three lower, white, with a reddish tinge on their border, and of three times the length of the calyx.

The stamens are twenty, the filaments short, the anthers small and yellow. Each flower is succeeded by five capsules, connate at the base, oblong, acuminate, gibbous without, acute within, two-valved, one-celled, opening inward, and containing each one or two oblong seeds.

This species of Gillenia grows throughout the United States, east of the Alleghany ridge, and, in Pennsylvania, may also be found abundantly west of these mountains. Pursh found it in Florida, and it extends as far north as Canada. It frequents light soils, in shady and moist situations, and flowers in June and July. The root should be gathered in September.

2. *G. stipulacea.* Barton, *Med. Bot.* i. 71. This species is also herbaceous and perennial, though much taller and more bushy than the preceding. The stems are brownish and branched. The upper leaves are ternate, lanceolate, serrate; the lower more deeply incised, becoming towards the root pinnatifid, and of a reddish-brown colour at the margin. The stipules are ovate, acuminate, deeply serrate, resembling leaves, and marking the species at the first glance. The flowers are smaller than those of *G. trifoliata*, and grow on long slender peduncles in a lax corymb.

In the valley of the Mississippi, this plant occupies the place of G. trifoliata, which is not found beyond the Muskingum. It grows as far north as the State of New York, extends through Ohio, Indiana, Illinois, and Missouri, and probably into the States south of the Ohio, as it has been found in Western Virginia. Its root is precisely similar to that of the eastern species, and is reputed to possess the same properties.

The dried root of Gillenia is not thicker than a quill, wrinkled longitudinally with occasional transverse fissures, and, in the thicker pieces, presenting in some places an irregular, undulated, somewhat knotty appearance, arising from indentations on one side corresponding with prominences on the other. It is externally of a light-brown colour, and consists of a thick, somewhat reddish, brittle, cortical portion, with an interior slender, tougher, whitish, ligneous cord. The bark, which is easily separable, has a bitter, not disagreeable taste; the wood is nearly insipid and comparatively inert, and should be rejected. The powder is of a light-brownish colour, and possesses a feeble odour, which is scarcely perceptible in the root. The bitterness is extracted by boiling water, which acquires the red colour of wine. The root yields its bitterness also to alcohol. By various experimenters it has been shown to contain gum, starch, gallo-tannic acid, fatty matter, wax, resin, colouring matter, albumen, and lignin, besides salts. (*Am. Journ. of Pharm.*, xxvi. 490.) The name of *gillenin* has been given, by Mr. W. B. Stanhope, to a substance obtained by first preparing an alcoholic extract, treating this with water, which took up various substances with a little of the active matter, then macerating the residue for ten days in water acidulated with sulphuric acid, saturating with magnesia, evaporating to dryness, and finally treating with alcohol, filtering, and allowing the alcoholic solution to evaporate spontaneously. The substance thus obtained was whitish, very bitter, slightly odorous, permanent in the air, soluble in water, alcohol, ether, and the dilute acids, and neutral to test-paper. Nitric acid rendered it blood-red, chromic acid green. Tannic acid produced no effect. It gave white precipitates with potassa, subacetate of lead, and tartar emetic. Half a grain of it produced nausea and retching. (*Ibid.*, xxviii. 202.)

Medical Properties and Uses. Gillenia is a mild and efficient emetic, and, like most substances belonging to the same class, occasionally acts upon the bowels. In very small doses it has been thought to be tonic. It is much used by some practitioners in the country as a substitute for ipecacuanha, which it is said to resemble in its mode of operation. It was employed by the Indians, and became known as an emetic to the colonists at an early period. Linnæus was aware of its reputed virtues. The dose of the powdered root is from twenty to thirty grains, repeated at intervals of twenty minutes till it vomits. W.

GLYCERINA. *U. S.*

Glycerin.

Off. Syn. GLYCERINUM. *Glycerine.* A sweet principle, $C_6H_8O_6$, obtained from fats and fixed oils, and containing a small percentage of water. *Br.*

In the U. S. Pharmacopœia of 1850 a process was given for the preparation of glycerin; but it is now so exclusively a product of wholesale manufacturing, that it was deemed proper, in the late revision of the work, to transfer it to the Materia Medica Catalogue, where it also stands in the British Pharmacopœia. The following is the process referred to.

"Take of Lead Plaster, recently prepared and yet fluid, Boiling Water, each, *a gallon.* Mix them, stir briskly for fifteen minutes, then allow them to cool, and pour off the supernatant liquid. Evaporate this until it has the specific gravity 1·15, and pass a current of sulphohydric acid slowly through it until a black precipitate is no longer produced. Filter, and apply heat until the sulphohydric acid is driven off. Lastly, evaporate the liquid until it ceases to lose weight."

In the process for making lead plaster, litharge, olive oil, and water are boiled together, with the result of decomposing the oil, the oily acids of which unite with the oxide of lead to form the plaster. At the same time the sweet principle of the oil, called glycerin, which was previously united to the oily acids to constitute the oil, is set free, becomes hydrated, and dissolves in the water. (See *Emplastrum Plumbi.*) It follows, therefore, that the plaster, while still hot and in the liquid state, contains an aqueous solution of glycerin, diffused through it. It was the plaster in this state that was made use of for preparing glycerin in the former U. S. formula. Accordingly, when the liquid plaster is mixed with an equal measure of boiling water, and the mixture stirred briskly, a solution of glycerin is obtained; which, after having been decanted, and evaporated to a limited extent, is freed from lead by sulphuretted hydrogen The liquid is then filtered to separate sulphuret of lead, heated to free it from sulphuretted hydrogen, and finally evaporated to expel the free water, which is known to be all removed when it ceases to lose weight.

Glycerin was discovered in 1789 by Scheele, by whom it was called the *sweet principle of oils.* It is produced not only during the saponification of the fats and oils by oxide of lead in forming lead plaster, but also during the same process, when effected by potassa and soda in the manufacture of soap; the alkalies uniting with the oily acids, and setting the glycerin free. Hence soap-makers' waste is an abundant source of glycerin; but, thus originating, it is apt to have more or less odour, which even percolation through animal charcoal does not always remove. A method of purifying glycerin from soap-makers' waste is given by M. Bruère-Perrin. (*Am. Journ. of Pharm.*, xx. 549.)* The process of

* Dr. Campbell Morfit has given the following process for making pure glycerin on the large scale. Melt *one hundred pounds* of tallow, lard, or pressed lard, in a clean iron-bound barrel, by the direct application of a current of steam, and add to the melted liquid *fifteen pounds* of lime, previously slaked and made into a milk with *two and a half gallons* of water. Then cover the vessel, and continue the steaming for several hours, or until the completion of the saponification. This is known to be completed, when a portion of the cooled soap gives a smooth shining surface on being scraped with the nail, and breaks with a cracking noise. By this treatment the fat is decomposed, the oily acids unite with the lime to form an insoluble lime soap, and the liberated glycerin remains in solution in the water, along with the excess of lime. After the liquid has been sufficiently boiled, it is allowed to cool and settle, and then strained through a crash cloth. The strained liquid, containing only the glycerin and excess of lime, is carefully concentrated by steam heat, treated with a current of carbonic acid to remove the lime as carbonate of lime, boiled again to decompose any bicarbonate of lime that may have been formed, and allowed to repose. The supernatant clear liquid is finally decanted or strained off from the precipitated carbonate of lime, and concentrated, if necessary, to expel any excess of water. The residue of the process, the lime soap, is sold to the stearic candle makers, or reconverted into saleable fat. Dr. Morfit has found his process for glycerin to combine the advantages of saving time, labour, and money. (*Silliman's Journal*, 2d ser., xv. 429.) —*Note to the tenth edition.*

Mr. Richard A. Tilghman, of this city, patented, Jan. 9, 1854, consists in subjecting fatty bodies to the action of water at a high temperature under pressure, whereby their constituents combine with water, so as to form free fatty acids, and solution of glycerin. (*Am. Journ. of Pharm.*, March, 1855, p. 121.) Thus obtained it is called *distilled glycerin*, and is produced at once in the purest form. This process is used at the great candle manufactory of Price & Co., London, whence our markets have been largely supplied with glycerin. Through a distillatory apparatus containing palm oil, heated steam between 550° and 600° is passed. The oil is decomposed into its oily acids and glycerin, which, together with water, distil over, and, condensing in the receiver, separate into two layers, the lower of which is glycerin. If this, as first procured, contain too much water, it must be concentrated; if discoloured, it must be redistilled with vapour. (*Pharm. Journ.*, Jan. 1861, p. 350.) Ordinary impure glycerin may be purified by distillation with steam under pressure. Though, when distilled alone, it is partially decomposed, giving out pungent vapours of *acrolein*, yet, in a current of superheated steam, it passes over unchanged at temperatures between 400° and 500°. (*Brande & Taylor.*) Very pure glycerin is now prepared in the U. States.

Properties, &c. Glycerin is a thick syrupy liquid, either colourless or of a slight amber colour, without smell when pure, unctuous to the touch, and of a very sweet taste. In properties it is intermediate between water and the oils. When exposed to the air it gradually absorbs moisture. As already stated, though decomposed by a high heat in its unmixed state, yet with water under pressure it is volatilizable unchanged at a temperature between 400° and 500° F. Cooled down in its ordinary state to zero, it only becomes more viscid, without congealing; but, under certain not well-understood circumstances, it appears to be capable of crystallization, forming hard, brilliant crystals of a probably octohedral form, which on melting maintain a temperature of 45° F.* (*Amer. Journ. of Pharm.*, March, 1867, p. 163.) Its sp. gr. is 1·25, *U. S.*, *Br.* According to Mr. G. F. Wilson, glycerin, when of the density 1·24, contains 94 per cent. of anhydrous glycerin; when of the density 1·26, 98 per cent. It is soluble in all proportions in water and alcohol, but insoluble in ether. Glycerin possesses extensive powers as a solvent, and is an excellent excipient for many medicinal substances. It dissolves bromine and iodine, the iodide of sulphur, the chlorides of potassium and sodium, the fixed alkalies, some of the alkaline earths, and a large number of neutral salts. It also dissolves the vegetable acids, particularly tannic acid, and either suspends or dissolves the vegetable alkalies. Many of the salts of the vegetable alkalies are soluble in it, forming convenient solutions for external application. Such solutions are now made for medicinal purposes with some of the salts of morphia, quinia, strychnia, veratria, and atropia. Prof. J. S. Blockey, of London, has ascertained that certain neuter vegetable substances are far more soluble in glycerin than in water. Thus, salicin dissolves in eight parts of cold glycerin, and santonin in eighteen parts when boiling. The latter solution, when of half this strength, forms on cooling an almost solid mass. Glycerin, next to alcohol, is the best solvent of iodine. Iodine and iodide of potassium, when dissolved in it, form *iodized glycerin*, the medical applications of which are given under iodine. (See *Iodinium.*)† Glycerin is not susceptible of becoming rancid, or of fermenting spontaneously; but will generate a portion of alcohol under the

* Mr. Wm. Crookes gives an account, in the *Chem. News* of Jan. 18, 1867, of 5 tons of glycerin imported into London from Germany in casks of 8 cwt. each, which, though when it left the continent it was in its ordinary state of a viscid liquid, was found, on reaching London, to have become solidified into a mass of very hard, brilliant crystals. The same result has been noticed in Vienna in a mass of glycerin which had been in an iron tank more than a year. (*Chem. News*, April 5, 1867, p. 174.) The crystalline mass noticed by Mr. Crookes yielded pure glycerin when melted. (*Note to the thirteenth edition.*)

† In relation to its solvent powers the reader is referred to an elaborate paper by MM. Cap and Garot, published in the *Journ. de Pharm.* for Aug. 1854, p. 81.

combined influence of chalk, and of a ferment formed of cheese or animal tissue. During this change there is no intermediate formation of glucose, provided carbonate of lime is present. (*Berthelot.*) Glycerin does not evaporate when exposed to the air; nor can it be distilled without decomposition, unless in the presence of water or steam. When decomposed by heat, it emits extremely irritating vapours. At a full red heat it takes fire, and burns with a blue flame. In consequence of the high temperature required for its volatilization, it has been proposed to use it for an evaporating bath, in which a heat beyond that of boiling water is required. Glycerin is antiseptic, and has been recommended by Mr. Warington and M. Demarquay to preserve alimentary substances and objects of natural history, and to inject bodies for dissection. According to Dr. W. Frazer, it does not answer to keep pathological preparations; as they are completely softened by its action. M. Berthelot, of Paris, has succeeded in combining glycerin with a number of acids, both mineral and organic, forming three distinct series of neutral compounds. Among others he has united it with the fatty acids, producing, by synthesis, the organic fatty substances, stearin, margarin, olein, &c. Glycerin has been recently formed artificially, by a complicated process, by M. A. Wurtz. (See *Chem. Gaz.*, June 1, 1857, p. 205.) By Pasteur it has been ascertained to be one of the products of the vinous fermentation. Glycerin consists of one eq. of the hypothetical radical *glyceryl* (C_6H_7), five eqs. of oxygen, and one of water. Its formula is, therefore, $C_6H_7O_5+HO$.

The solvent and preservative properties, as well as agreeable taste and permanent consistence of glycerin, render it very useful as a menstruum in pharmacy; and a class of preparations consisting of medicinal substances dissolved in it has come into extensive use. The British Pharmacopœia has adopted such a class, under the name of *glycerina* or *glycerines*. The title of *glyceroles*, adopted from the French, is objectionable, as the termination has been used as designative of certain proximate principles. We prefer the name of *glycerates*, suggested in a previous edition of this work; and, though this name belongs to the salts of glyceric acid, yet this acid is comparatively seldom referred to, and might readily be styled glycerinic acid, so as to leave the convenient name of glycerates for this large and much used class of substances.

Impurities and Tests. Glycerin is occasionally deficient in density and consistency. According to M. Dalpiaz, it is sometimes perfectly colourless from being bleached by chlorine, when it is apt to contain chloride of calcium, as well as free chlorine. The latter may be detected by rendering the suspected sample slightly blue by a few drops of sulphate of indigo, and then adding a little sulphuric acid, when, if free chlorine be present, the blue colour will disappear. Lime may be detected by oxalate of ammonia; lead by hydrosulphate of ammonia, and sulphuric acid by a soluble salt of baryta. Diluted, and boiled with a solution of potassa, it is not altered in colour, showing the absence of glucose. Trommer's test is probably still more effectual. The absence of cane sugar is proved by the complete solubility of the glycerin in chloroform, which does not dissolve sugar (*Chem. News*, no. 205, p. 217); also, if, upon the addition of two drops of concentrated sulphuric acid, and the application of heat, no brown discoloration is observed. (*Journ. de Pharm.*, Nov. 1863, p. 405.) The chloroform test, however, was not found satisfactory by Prof. Procter, who states that commercial glycerin is not soluble in chloroform. He believes that the most satisfactory method of detecting cane sugar is to dilute a little glycerin with three parts of water, then add a few grains of tartaric acid, and boil for a short time. Cane sugar, if present, is thus converted into glucose, which may be detected by adding first a solution of sulphate of copper, and then the solution of potassa to the heated liquid, when the formation of the reddish suboxide of copper will afford the requisite proof. (Procter, *Am. Journ. of Pharm.*, March, 1867, p. 110.) Diluted with water, glycerin should give no precipitate with hydrosulphate of ammonia, or ferrocyanide of potassium, showing the absence generally of metallic salts. If a drop be rubbed on the hand, no odour should be perceived. One volume of glycerin should dissolve completely in one volume of alcohol,

acidulated with 1 per cent. of sulphuric acid, without affording any precipitate of sulphate of lime, even after standing for twelve hours. For the tests of pure glycerin, given more in detail, see the paper of M. Cap in the *Journal de Pharmacie* (Mars, 1856, p. 212).

Among the most injurious impurities of glycerin are thought to be oxalic and formic acids, the latter of which is especially irritating to the skin, so as to unfit glycerin for some of the purposes for which it is most employed. The oxalic acid is said to result from the action of sulphuric acid employed in purifying glycerin; the formic, from the reaction between glycerin and oxalic acid. The oxalic acid may be detected by boiling a very little glycerin with a solution of chloride of calcium to which water of ammonia has been added, which causes a deposition of oxalate of lime; the formic acid, by a black deposit produced by allowing a mixture of glycerin and solution of nitrate of silver to stand for a long time. (Hager, *Journ. de Pharm. et de Chim.*)* Mr. Henry Bower, of Philadelphia, who manufactures very pure glycerin, says that nitrate of silver is the most reliable test. Glycerin, which shows no reaction with this salt, he considers suitable for all uses. (*Am. Journ. of Pharm.*, May, 1868, p. 265.)

Medical Properties, &c. The uses of glycerin as a vehicle of other medicines have been already given. Employed *internally* as a therapeutic agent, it is deemed alterative, nutrient, and demulcent. Dr. J. L. Crawcour, of New Orleans, has used it with supposed advantage in phthisis, and prefers it to cod-liver oil. Dr. R. P. Cotton, however, has tried it in the Consumption Hospital at Brompton, and concluded that it has generally but little influence, and that, as a remedial agent, it will bear no comparison with cod-liver oil. Dr. W. Lauder Lindsay made experiments with it, to determine its alterative and nutrient properties, and found it to increase the weight of the body; but his experiments were not made on a sufficient scale to be conclusive. It sometimes appeared to act beneficially in tuberculous and strumous affections, forming a useful succedaneum for cod-liver oil, when the latter could not be borne by the stomach.

Glycerin has come into extensive use as an *external* remedy. Its emollient virtues and undrying property adapt it to the treatment of skin diseases, in which a softening and soothing application is required. It appears to have been first employed externally, in 1846, by Mr. Thomas De la Rue, of London, whose observation of its utility led Mr. Startin to try it in the Hospital for Skin Diseases, where it came into extensive use. The principal cutaneous diseases in which it has been found beneficial are pityriasis, lepra, herpes, eczema, psoriasis, prurigo, and lichen. It is a useful addition to lotions in the incrusted form of lupus, and in various syphilitic and strumous eruptions. It is also useful in chapped skin and excoriated surfaces. Added to poultices, in a proportion varying from one-fourth to one-sixteenth, it has the effect of keeping them soft for a long time. To collodium it gives a plasticity which renders it often better suited to skin affections. Incorporated in very small proportion with extracts and pills, it keeps them soft and free from mouldiness. M. Devergie, in giving the results of his trials of glycerin in skin diseases, thinks its virtues have been exaggerated, and that it is not superior to pure lard and similar fatty substances; though it has the advantages of liquidity and freedom from odour. In cases of deafness, from deficiency, accumulation, or hardness of the cerumen, and attended with dryness of the meatus, glycerin is an excellent remedy, introduced into the canal by means of raw cotton, saturated with it. In relation to the uses

* As impure glycerin is often irritant to the skin, and thus unfitted for some of the most important uses of this principle, it is very important to have a test by which this kind of impurity may be detected. According to M. Hager, if equal volumes of the irritating glycerin and pure sulphuric acid be mixed in a glass tube, there will be an immediate disengagement of gas; and, after the escape of gas has ceased, and the mixture allowed to rest, a renewed agitation will cause a new development of gas; and this phenomenon may be repeated several times; whereas, if the glycerin be pure and unirritant, there is a rise of temperature, and there may be a slight discoloration, but no effervescence, and only the production of a few bubbles of air on agitation. (*Journ. de Pharm. et de Chim.*, Nov. 1867, p. 360.)—*Note to the thirteenth edition.*

of glycerin in diseases of the ear, the reader is referred to a paper by Mr. Thomas Wakley, in the London *Lancet* for June, 1849. Glycerin may be prepared as an ointment, for which formulas are given by Mr. J. Laidley, and by Mr. J. H. Ecky.* (*Am. Journ. of Pharm.*, xxii. 118, and xxv. 27.) It is recommended, in its perfectly pure state, by Dr. Foucher, as a vehicle in collyria, agreeing with all the substances used locally in diseases of the eye, except nitrate of silver, which it decomposes. (*Chem. News*, Dec. 8, 1860, p. 306.) Under the name of *plasma*, a preparation was brought into notice, in the year 1858, by Mr. G. F. Schacht, as a substitute for ointments, the emollient and demulcent properties of which it possesses, without their inconvenience, whether used simply, or as a vehicle for other substances to be employed locally. It is a compound of glycerin and starch, and is prepared, according to Mr. Schacht, by mixing 70 grains of starch in powder, and a fluidounce of glycerin, heating to 240° until the union is effected, and stirring constantly. After the vessel is removed from the fire, the stirring should be continued moderately, during the cooling process, to secure a proper consistence. As the plasma is liable to absorb moisture, it should be kept in well-closed vessels. (*Pharm. Journ. and Trans.*, Oct. 1866, p. 210.)

Glycerin has been used by M. Demarquay, of Paris, as a dressing in hospital gangrene, and in wounds in general. The wound is covered with folds of linen, dipped in the glycerin, over which lint is applied, and secured by a bandage. The advantages claimed for this dressing are that it lessens suppuration, promotes cicatrization, and, when removed, leaves the wound clean. Glycerin, used in this way, has been tried by two London surgeons, Mr. Skey and Mr. Hutchinson, and both conclude that it possesses no particular virtues. It is conceded, however, that it is an agreeable application, causes no smarting, excludes the air, keeps the sore moist, and does not adhere to its edges; and these are no small recommendations. It has the advantage over bland oils that it may be readily washed from the wound, on account of its solubility in water. (See *Am. Journ. of Med. Sci.*, July, 1856, p. 253.)† The vaccine lymph and scab have been dissolved in glycerin with a view to the preservation of the virus, and Dr. Andrews, of Chicago, has successfully vaccinated with the solution; but the expedient, to say the least, is of doubtful advantage.

* Mr. Ecky's *glycerin ointment* is made as follows. Take of spermaceti *half an ounce;* white wax *a drachm;* oil of almonds *two fluidounces;* glycerin *a fluidounce.* Melt the spermaceti and wax with the oil of almonds by a moderate heat. Then, having poured the melted liquid into a Wedgwood mortar, add the glycerin, and rub until the ingredients are thoroughly mixed and cool. This ointment may be used with advantage in chaps and excoriations.

† *Glyconine.* Under this name has been several years employed, in France, both for medical purposes and for those of the toilet, an emulsion made of glycerin and the yelk of eggs. When these two substances are rubbed together, they unite to form a very intimate mixture, which remains transparent. It has the consistence of honey, and forms an opaque emulsion with water. It may be preserved almost indefinitely. The usual proportions of the ingredients are four parts of the yelk of eggs, and five parts of very pure glycerin. It is largely used in the hospitals as a dressing for burns, and a local application in erysipelas, fissures of the nipples, and various cutaneous affections. (*Arch. Général. de Méd.*, Mai, 1868, p. 640.)—*Note to the thirteenth edition.*

Gen. Ch. Calyx bilabiate; upper lip three-cleft, lower undivided. *Legume* ovate compressed. *Willd.*

Glycyrrhiza glabra. Willd. *Sp. Plant.* iii. 1144; Woodv. *Med. Bot.* p. 420, t. 152; Carson, *Illust. of Med. Bot.* i. 38, pl. 32. The liquorice plant has a perennial root, which is round, succulent, tough, and pliable, furnished with sparse fibres, rapid in its growth, and in a sandy soil penetrates deeply into the ground. The stems are herbaceous, erect, and usually four or five feet in height, have few branches, and are garnished with alternate, pinnate leaves, consisting of several pairs of ovate, blunt, petiolate leaflets, with a single leaflet at the end, of a pale-green colour, and clammy on their under surface. The flowers are violet or purple, formed like those of the pea, and arranged in axillary spikes supported on long peduncles. The calyx is tubular and persistent. The fruit is a compressed, smooth, acute, one-celled legume, containing from one to four small kidney-shaped seeds.

The plant is a native of the south of Europe, Barbary, Syria, and Persia; and is cultivated in England, the north of France, and Germany. Much of the root imported into this country comes from Messina and Palermo in Sicily. It is also largely produced in the north of Spain, where it is an important article of commerce. It is not improbable that a portion of the root from Italy and Sicily is the product of *G. echinata*, which grows wild in Apulia. This species is also abundant in the south of Russia, where, according to Hayne, sufficient extract is prepared from it to supply the whole Russian empire.

A species of Glycyrrhiza, *G. lepidota*, grows abundantly about St. Louis, in the State of Missouri, and flourishes along the banks of the Missouri river to its source. It is probably the same as the liquorice plant mentioned by Mackenzie as growing on the northern coast of this continent. Mr. Nuttall states that its root possesses in no inconsiderable degree the taste of liquorice.

Properties. The liquorice root of the shops is in long pieces, varying in thickness from a few lines to more than an inch, fibrous, externally grayish-brown and wrinkled by desiccation, internally yellowish, without smell, and of a sweet mucilaginous taste, mingled with a slight degree of acrimony. It is often worm-eaten and more or less decayed. The best pieces are those which have the brightest yellow colour internally, and of which the layers are distinct. The powder is of a grayish-yellow colour, when the root is pulverized without being deprived of its epidermis; of a pale sulphur-yellow, when the epidermis has been removed. Robiquet found the following ingredients in liquorice root; 1. a peculiar transparent yellow substance, called *glycyrrhizin* or *glycion*, of a sweet taste, scarcely soluble in cold water, very soluble in boiling water, with which it gelatinizes on cooling, thrown down from its aqueous solution by acids, readily soluble in cold alcohol, insusceptible of the vinous fermentation, yielding no oxalic acid by the action of the nitric, and therefore wholly distinct from sugar; 2. a crystallizable principle named *agedoïte* by Robiquet, but subsequently proved to be identical with *asparagin;* 3. starch; 4. albumen; 5. a brown acrid resin; 6. a brown azotized extractive matter; 7. lignin; 8. salts of lime and magnesia, with phosphoric, sulphuric, and malic acids. Robiquet prepared *glycyrrhizin* by subjecting a strong cold infusion of the root to ebullition, in order to separate the albumen; then filtering, precipitating with acetic acid, and washing the precipitate with water to remove any adhering acid. It may be still further purified by solution in absolute alcohol, and evaporation at a very gentle heat. According to Dr. T. Lade, glycyrrhizin, as it exists in the root, is rendered soluble in water by combination with inorganic bases, such as lime and ammonia, from which it is separated by the addition of an acid. From the observations of Dr. Lade, it is to be inferred that this principle has no affinity for the acids, but combines with salifiable bases, forming salts of various degrees of solubility. Its sweetness is retained in the compounds which it forms with the alkalies. It consists of carbon, hydrogen, and oxygen, and ranks among the glucosides. Its formula, according to M. Gorup-Besanez, is $C_{48}H_{36}O_{18}$, according to Vogel, $C_{16}H_{12}O_6$. (*Journ de Pharm.*, Juillet, 1861, p. 72.)

An extract of liquorice root is brought from Spain and Italy, and much used under the name of liquorice. (See *Extractum Glycyrrhizæ.*)

Medical Properties and Uses. Liquorice root is an excellent demulcent, well adapted to catarrhal affections, and to irritations of the mucous membrane of the bowels and urinary passages. It is best given in the form of decoction, either alone, or combined with other demulcents. It is frequently employed as an addition to the decoctions of acrid or irritating vegetable substances, such, for example, as seneka and mezereon, the acrimony of which it covers, while it renders them more acceptable to the stomach. Before being used, it should be deprived of its cortical part, which is somewhat acrid, without possessing the peculiar virtues of the root. The decoction may be prepared by boiling an ounce of the bruised root, for a few minutes, in a pint of water. By long boiling, the acrid resinous principle is extracted. Perhaps, however, to this principle may in part be ascribed the therapeutical virtues of liquorice root in chronic bronchial diseases. The powder is used in the preparation of pills, either to give due consistence, or to cover their surface and prevent them from adhering together.

In consequence of changes produced in the plants of this genus by cultivation, botanists have found great difficulty in determining which are distinct species, and which merely varieties. De Candolle describes thirteen species in his Prodromus, and mentions six others; but considers them all uncertain. Royle describes eight and admits others. Schwartz thinks they may all be referred to one original species. The plants inhabit different parts of tropical Asia and Africa, and many of them are cultivated for their cotton in climates adapted to their growth. The species from which most of the cotton of commerce has been thought to be obtained, is the one specially indicated by the U. S. Pharmacopœia. According to Dr. Royle, it is the India cotton which is produced by *G. herbaceum,* while *G. Barbadense* furnishes all the cotton of N. America, and *G. Peruvianum* that produced in Brazil, Peru, and other parts of S. America. (See *Am. Journ. of Pharm.,* July, 1858, p. 339.) Dr. A. W. Chapman, however, in his *Flora of the Southern United States* (N. Y., A. D. 1860, p. 58), states that the numerous varieties of the cotton-plant are now referred to two species, the *long-staple* or *sea-island,* to *G. album* (Haw.), and the *short-staple* or *upland,* to *G. nigrum* (Haw.).

Gossypium herbaceum. Linn. *Sp.* 975; De Cand. *Prodrom.* i. 456. This is

a biennial or triennial plant, with a branching stem from two to six feet high, and palmate hoary leaves, the lobes of which are somewhat lanceolate and acute. The flowers are pretty, with yellow petals, having a purple spot near the claw. The leaves of the involucel or outer calyx are serrate. The capsule opens when ripe, and displays a loose white tuft of long slender filaments, which surround the seeds, and adhere firmly to the outer coating. The plant is a native of Asia, but is cultivated in most tropical countries. It requires a certain duration of warm weather to perfect its seeds, and, in the United States, cannot be cultivated advantageously north of Virginia.

The herbaceous part of the plant contains much mucilage, and has been used as a demulcent. The seeds yield by expression a fixed oil of the drying kind, which is employed for making soap and other purposes.* The root has been supposed to possess medical virtues, and is now recognised by the U. S. Pharmacopœia. Another officinal portion, and that for which the plant is cultivated, is the filamentous substance surrounding the seeds. This when separated constitutes the cotton of commerce.

Cotton consists of filaments, which, under the microscope, appear to be flattened tubes, with occasional joints indicated by transverse lines. It is without smell or taste, insoluble in water, alcohol, ether, the oils, and vegetable acids, soluble in strong alkaline solutions, and decomposed by the concentrated mineral acids. In chemical character, it bears a close analogy to lignin. By nitric acid it is converted into that remarkable explosive substance denominated gun cotton, for an account of which, as well as of a valuable adhesive preparation made by dissolving it in ether, the reader is referred to the articles *Gun Cotton* and *Collodium.* For medical use it should be carded into thin sheets; or the wadding

* *Cotton-seed Oil.* This is obtained by expression from the seeds previously deprived of their shells. In this state, they yield two gallons of oil to the bushel. As first obtained, it is thick and turbid, but deposits a portion of its impurities on standing. Besides this crude oil, there are three varieties in the shops of the South, more or less purified, recognised as the *clarified*, the *refined*, and the *winter-bleached.* The last-mentioned is of a pale-straw colour, a mild peculiar odour, and a bland sweetish taste, not unlike that of almond oil. The oil is used in the preparation of woollen cloth and morocco leather, and for oiling machinery. There seems to be some doubt of its drying qualities. It has been found to be an excellent substitute for almond and olive oil in most pharmaceutical preparations in which they are employed; but does not answer well in the formation of the lead plaster. Citrine ointment carefully prepared with it, too great heat being avoided, retains long a rich-orange colour and proper unctuous consistence. Its sp. gr. is stated at 0·921. It is insoluble in alcohol, soluble in not less than its own bulk of ether, and dissolved in all proportions by chloroform. By sulphuric acid it is made deep-red, almost brown; but it is not obviously affected by nitric and muriatic acids. These interesting facts have been extracted from a dissertation by Mr. Wm. Henry Weatherby, whose residence in a cotton-growing district of the South gave him peculiar opportunities. (See *Am. Journ. of Pharm.*, May, 1861, p. 208.)—*Note to the twelfth edition.*

Since the above remarks were made, the subject of cotton-seed oil has been examined by Dr. A. Adriani, the results obtained by whom have been published in the London *Chemical News* (Jan. 7, 1865, p. 5), to which the reader is referred. The following are among the more important statements contained in Dr. Adriani's paper. The product of the expressed seeds is from 15 to 18 per cent. In its impure state it is dark reddish-brown, not quite clear, and contaminated with mucilage and albumen. In this state, its sp. gr. varies from 0·930 to 0·932, which is increased, by washing with boiling water, to 0·934. The latter sp. gr. is very nearly that of linseed oil, which this oil also closely resembles in taste and odour, and in its drying property. The colour is not essential to the oil, being dependent on the oxidation of a peculiar substance contained in the seeds.

The oil is clarified by first boiling it with water to separate the mucilage, and then heating it with a weak solution of caustic potassa, by which the colouring matter is removed. As this oil is said to be much used in England for adulterating olive oil, a test to distinguish it is very desirable; and, according to Mr. R. Reynolds, nitrate of mercury will answer the purpose. Of this a test-solution may be made by dissolving, without heat, 6 parts of mercury in 7·5 parts of nitric acid of 1·36. This salt has the effect, when mixed with olive oil, of entirely solidifying and hardening it upon standing; while under the same circumstances the cotton-seed oil remains fluid. If the two oils are mixed, an intermediate effect is produced; the oil, though possibly solidified, remaining soft and pasty, and not becoming hard like pure olive oil. (*Pharm. Journ. and Trans.*, 2d ser., vii. 226.)—*Note to the thirteenth edition.*

of the milliners may be employed, consisting of sheets somewhat stiffened, and glazed on the surface by starch. In the latter case, the sheets should be split open when applied. It is said that air, passed through cotton, loses the property of inducing the putrefactive fermentation in animal substances.

Medical Properties, &c. Cotton has been used from time immemorial for the fabrication of cloth; but it is only of late that it has entered the catalogue of medicines. It is chiefly employed in recent burns and scalds; an application of it adopted from popular practice. It is said to relieve the pain, diminish the inflammation, prevent vesication, and very much to hasten the cure. Whatever advantages result from it are probably ascribable to the absorption of effused liquids, and the protection of the part affected from the air. It is applied in thin and successive layers; and benefit is said to result from the application of a bandage when the skin is not too much inflamed. We have, however, seen cotton do much harm in burns, by becoming consolidated over a vesicated surface, and acting as a mechanical irritant. Such a result may be prevented by first dressing the burn with a piece of fine linen spread with simple ointment. Cotton is also recommended in erysipelas, and as a dressing for blisters; and we have found it useful, applied in a large batch over parts affected with rheumatism, especially in lumbago.

The root of the cotton plant has been employed by Dr. Bouchelle, of Mississippi, who believes it to be an excellent emmenagogue, and not inferior to ergot in promoting uterine contraction. He states that it is habitually and effectually resorted to by the slaves of the South for producing abortion; and thinks that it acts in this way without injury to the general health. To assist labour, he employs a decoction made by boiling four ounces of the inner bark of the root in a quart of water to a pint, and gives a wineglassful every twenty or thirty minutes. (*West. Journ. of Med. and Surg.*, Aug. 1840.) Dr. T. J. Shaw, of Tennessee, thinks it superior, in the treatment of amenorrhœa, to any other emmenagogue, and equal to ergot as a parturient, while attended with less danger. He uses a tincture made by macerating eight ounces of the dried bark of the root in two pounds of diluted alcohol for two weeks, and gives a drachm three or four times a day. (*Nashv. Journ. of Med. and Surg.*, July, 1855.) Mr. Weatherby denies the statement that the root is used for producing abortion among the slaves, at least within his observation. Dr. Bellamy, of Columbus, Geo., who has had much experience with the root, fully confirms the favourable statement of Dr. Bouchelle. He thinks it most effectual when collected as late in the autumn as possible, before frost. (*Atlanta Med. and Surg. Journ.*, Oct. 1866.)

Cotton seeds have been employed in our Southern States with great asserted success in the treatment of intermittents. In a communication from Prof. H. R. Frost to the *Charleston Medical Journal* for May, 1850, it is stated, on the authority of Dr. W. K. Davis, of Monticello, that this application of the cotton seed originated with a planter in Newberry District, S. Carolina, who had often used the remedy in intermittents, and never failed to effect a cure. A pint of the seeds is boiled in a quart of water to a pint, and a teacupful of the decoction is given to the patient in bed, an hour or two before the expected return of the chill.

PUNICA. *Sex. Syst.* Icosandria Monogynia. — *Nat. Ord.* Myrtaceæ.

Gen. Ch. Calyx five-cleft, superior. *Petals* five. *Pome* many-celled, many-seeded. *Willd.*

Punica Granatum. Willd. *Sp. Plant.* ii. 981; Woodv. *Med. Bot.* p. 531, t. 190; Carson, *Illust. of Med. Bot.* i. 45, pl. 38. The pomegranate is a small shrubby tree, attaining in favourable situations the height of twenty feet, with a very unequal trunk, and numerous branches, which sometimes bear thorns. The leaves are opposite, entire, oblong or lance-shaped, pointed at each end, smooth, shining, of a bright-green colour, and placed on short footstalks. The flowers are large, of a rich scarlet colour, and stand at the end of the young branches. The petals are roundish and wrinkled, and are inserted into the upper part of the tube of the calyx, which is red, thick, and fleshy. The fruit is a globular berry, about the size of an orange, crowned with the calyx, covered with a reddish-yellow, thick, coriaceous rind, and divided internally into many cells, which contain an acidulous pulp, and numerous oblong, angular seeds.

This tree grows wild upon both shores of the Mediterranean, in Arabia, Persia, Bengal, China, and Japan, has been introduced into the East and West Indies, and is cultivated in all civilized countries, where the climate is sufficiently warm to allow the fruit to ripen. In higher latitudes, where it does not bear fruit, it is raised in gardens and hot-houses for the beauty of its flowers, which become double, and acquire increased splendour of colouring by cultivation. Doubts have been entertained as to its original country. The name of *Punicum malum*, applied by the ancients to its fruit, implies that it was abundant at an early age in the vicinity of Carthage. The fruit, for which the plant is cultivated, varies much in size and flavour. It is said to attain greater perfection, in both these respects, in the West Indies than in its native country. The pulp is red, succulent, pleasantly acid, and sweetish, and is used for the same purposes as the orange. The rind of the fruit and bark of the root are the parts indicated in the U. S. Pharmacopœia, the latter only in the British. The flowers were formerly recognised by the Dublin College, and the seeds are officinal in France.

Rind of the Fruit. This is presented in commerce under the form of irregular fragments, hard, dry, brittle, of a yellowish or reddish-brown colour externally, paler within, without smell, and of an astringent, slightly bitter taste. It contains a large proportion of tannin, and in countries where the tree abounds has been employed for tanning leather.

Flowers. The flowers, sometimes called *balaustines*, are inodorous, have a bitterish, astringent taste, and impart a violet-red colour to the saliva. They contain tannic and gallic acids, and were used by the ancients in dyeing.

Bark of the Root. The roots of the pomegranate are hard, heavy, knotty, ligneous, and covered with a bark which is yellowish-gray or ash-gray on the outer surface, and yellow on the inner. As found in the shops, the bark is in quills or fragments, breaks with a short fracture, has little or no smell, colours the saliva yellow when chewed, and leaves in the mouth an astringent taste without disagreeable bitterness. It contains, according to M. Latour de Trie, fatty matter, tannin, gallic acid, a saccharine substance having the properties of *mannite*, resin, wax, and chlorophyll, besides insoluble matters. The name of *punicin* has been given by Giovanni Righini to a peculiar principle which he extracted from the bark. It has the aspect of an oleo-resin, affects the nostrils somewhat like medicinal veratria, and is of an acrid taste. It may be obtained by rubbing a hydro-alcoholic extract of the bark with one-eighth of hydrate of potassa, heating the mixture with eight parts of pure water gradually added, and then dropping in dilute sulphuric acid to saturate the potassa. The punicin subsides, and may be separated by filtration. (*Journ. de Pharm.*, 3e sér., v. 298.) The infusion of the bark yields a deep-blue precipitate with salts of iron, and a yellowish-white precipitate with solution of gelatin. The inner surface of the bark, steeped in water and then rubbed on paper, produces a yellow stain, which, by the contact of sulphate of iron, is rendered blue, and by that of nitric acid acquires a slight rose tint, which soon vanishes. (*Ibid.*, xvii. 438.) These

properties serve to distinguish this bark from those of the box root and barberry, with which it is said to be sometimes adulterated. When used it should be separated from the ligneous portion of the root, as the latter is inert.

Medical Properties and Uses. The rind of the fruit is astringent, and in the form of decoction is sometimes employed in diarrhœa and colliquative sweats, and, more frequently, as an injection in leucorrhœa, and as a gargle in sorethroat in the earlier stages, or after the inflammatory action has in some measure subsided. The powdered rind has also been recommended in intermittent fever The flowers have the same medical properties, and are used for the same purposes. The bark of the root was used by the ancients as a vermifuge, and is recommended in the writings of Avicenna; but was unknown in modern practice till brought into notice by Dr. F. Buchanan, who learned its powers in India. The Mahometan physicians of Hindostan consider it a specific against tænia. One of these practitioners, having relieved an English gentleman in 1804, was induced to disclose his secret, which was then made public. Numerous cures were subsequently effected in Europe; and there can be no doubt of the occasional efficacy of the remedy. The French writers prefer the product of the wild pomegranate, growing on the borders of the Mediterranean, to that of the plant cultivated in gardens for ornamental purposes. The bark may be administered in powder or decoction; but the latter form is usually preferred. The decoction is prepared by macerating two ounces of the bruised bark in two pints of water for twenty-four hours, and then boiling to a pint. Of this a wineglassful may be given every half hour, hour, or two hours, until the whole is taken. It often nauseates and vomits, and usually purges. Portions of the worm often come away soon after the last dose. It is recommended to give a dose of castor oil, and to diet the patient strictly on the day preceding the administration of the remedy; and, if it should not operate on the bowels, to follow it by castor oil, or an enema. If not successful on the first trial, it should be repeated daily for three or four days, until the worm is discharged. It appears to have been used by the negroes of St. Domingo before its introduction into Europe.

The dose of the rind and flowers in powder is from twenty to thirty grains. A decoction may be prepared in the proportion of an ounce of the medicine to a pint of water, and given in the dose of a fluidounce. The seeds are demulcent

GUAIACUM. *Sex. Syst.* Decandria Monogynia. — *Nat. Ord.* Zygophyllaceæ.

Gen. Ch. Calyx five-cleft, unequal. *Petals* five, inserted into the calyx. *Capsule* angular, three or five-celled. *Willd.*

Guaiacum officinale. Willd. *Sp. Plant.* ii. 538; Woodv. *Med. Bot.* p. 557, t. 200; Carson, *Illust. of Med. Bot.* i. 25, pl. 17. This is a large tree, of very slow growth. When of full size it is from forty to sixty feet high, with a trunk four or five feet in circumference. The branches are knotted, and covered with an ash-coloured striated bark. That of the stem is of a dark-gray colour, variegated with greenish or purplish spots. The leaves are opposite, and abruptly pinnate, consisting of two, three, and sometimes four pairs of leaflets, which are obovate, veined, smooth, shining, dark-green, from an inch to an inch and a half long, and almost sessile. The flowers are of a rich blue colour, stand on long peduncles, and grow to the number of eight or ten at the axils of the upper leaves. The seeds are solitary, hard, and of an oblong shape.

G. officinale grows in the West Indies, particularly in Hayti and Jamaica, and is found also in the warmer parts of the neighbouring continent. All parts of the tree are possessed of medicinal properties; but the wood and the concrete

juice only are officinal. The bark, though much more efficacious than the wood, is not kept in the shops. It is said that other species of Guaiacum contribute to the supplies brought into the market. *G. sanctum* of Linnæus, and *G. arboreum* of De Candolle, are particularly specified. The former, however, is said by Woodville not to be sufficiently characterized as a distinct species. Fée states that the wood of *G. sanctum* is paler, and less heavy and hard than the officinal.

Guaiacum wood is imported from Hayti and other West India islands, in the shape of logs or billets, covered with a thick gray bark, which presents on its inner surface, and upon its edges when broken, numerous shining crystalline points. These were supposed by Guibourt to be benzoic acid, by others a resinous exudation from the vessels of the plant; but Dr. Otto Berg has determined that they are crystals of sulphate of lime. The billets are used by the turners for the fabrication of various instruments and utensils, for which the wood is well adapted by its extreme hardness and density. It is kept by the druggists and apothecaries in the state of shavings or raspings, which they obtain from the turners. It is commonly called *lignum vitæ*, a name which obviously originated from the supposition that the wood was possessed of extraordinary remedial powers.

Properties. The colour of the sap-wood is yellow, that of the older and central layers greenish-brown, that of the shavings a mixture of the two. It is said that, when the wood is brought into a state of minute division, its colour is rendered green by exposure to the air, and bluish-green by the action of nitric acid fumes; and the latter change may be considered as a test of its genuineness. (*Duncan.*) An easier test is a solution of corrosive sublimate, which, added to the shavings and slightly heated, causes a bluish-green colour in the genuine wood. (*Chem. Gaz.*, no. 80, Feb. 1846.) Guaiacum wood is almost without smell unless rubbed or heated, when it becomes odorous. When burnt it emits an agreeable odour. It is bitterish and slightly pungent, but requires to be chewed for some time before the taste is developed. It contains, according to Trommsdorf, 26 per cent. of resin, and 0·8 of a bitter pungent extractive, upon both of which, probably, though chiefly on the former, its medicinal virtues depend. (See *Guaiaci Resina.*) It yields its virtues but partially to water. One pound of the wood afforded to Geiger two ounces of extract. In this extract M. Thierry discovered a volatilizable acid, which he considered peculiar, and named *guaiacic acid* (*acide gayacique*). He obtained it by treating the extract with ether, evaporating the liquid, and carefully subliming the residue. The acid condenses in small, brilliant needles. If the heat be pushed too far, an oil is also produced which colours the crystals. He procured the same acid from the *guaiac* of the shops. (*Journ. de Pharm.*, xxvii. 381.) According to Jahn, however, this substance is nothing more than benzoic acid, rendered impure by adhering volatile oil and resin. (*Pharm. Central Blatt*, 1843, p. 309.)

Medical Properties and Uses. Guaiacum wood ranks among the stimulant diaphoretics. It is said to have been introduced to the notice of European practitioners by the natives of Hispaniola, soon after the discovery of America. It was used in Europe so early as 1508, and attained great celebrity as a remedy for lues venerea; but more extended experience has proved it to be wholly inadequate to the cure of that disease; and it is now employed simply to palliate the secondary symptoms, or to assist the operation of other and more efficient remedies. It is thought to be useful also in chronic rheumatism and gout, scrofula, certain cutaneous eruptions, ozæna, and other protracted diseases dependent on a depraved or vitiated condition of the system. It is usually exhibited in decoction, and in combination with other medicines, as in the compound decoction of sarsaparilla. As but a small proportion of the guaiac contained in it is soluble in water, the probability is that its virtues have been greatly overrated, and that the good which has followed its employment resulted rather from the more active medicines with which it is associated, or from the attendant regimen, than from the wood itself. The simple decoction may be prepared by boiling an ounce in a pint and a half of water down to a pint, the whole of which

may be administered in divided doses during the twenty-four hours. An aqueous extract is directed by the French Codex.

GUAIACI RESINA. *U. S., Br.*

Guaiac.

The concrete juice of Guaiacum officinale. *U. S.* The resin obtained from the stem by natural exudation, by incisions, or by heat. *Br.*

Résine de gayac, *Fr.;* Guajakharz, *Germ.;* Resina de guajaco, *Ital.;* Resina de guayaco, *Span.*

For a description of *Guaiacum officinale*, see GUAIACI LIGNUM.

Guaiac is the concrete juice of this tree. It is obtained in several different modes. The most simple is by spontaneous exudation, or by incisions made into the trunk. Another method is by sawing the wood into billets about three feet long, boring them longitudinally with an auger, then placing one end of the billet on the fire, and receiving in a calabash the melted guaiac, which flows out through the hole at the opposite extremity. But the plan most frequently pursued is probably to boil the wood, in the state of chips or sawdust, in a solution of common salt, and skim off the matter which rises to the surface. Guaiac is brought to this market from the West Indies. It is usually in large irregular pieces of various size, in which small fragments of bark, sand, and other impurities are mixed with the genuine guaiac, so as to give to the mass a diversified appearance. Sometimes we find it in small roundish homogeneous portions, separate or agglutinated; sometimes in homogeneous masses, prepared by melting and straining the drug in its impure state. It is probable that the guaiac, obtained from the billets in the manner above described, is of uniform consistence.

Properties. The masses are of a deep greenish-brown or dark-olive colour on their external surface, and internally wherever the air could penetrate. The predominant hue of those parts not exposed to the air is reddish-brown or hyacinthine, diversified, however, with shades of various colours. The odour is feeble but fragrant, and is rendered stronger by heat. The taste, which is at first scarcely perceptible, becomes acrid after a short period; and a permanent sense of heat and pungency is left in the mouth and fauces. Guaiac is brittle, and when broken presents a shining glass-like surface, conchoidal or splintery, with the smaller fragments more or less translucent. It is readily pulverized; and the powder, at first of a light-gray colour, becomes green on exposure to the light. Its sp. gr. varies from 1·2 to 1·23. It softens in the mouth, and melts with a moderate heat. According to Mr. Brande, it consists of 91 per cent. of a peculiar substance analogous to the resins, and 9 per cent. of extractive. Buchner found 79·8 parts of pure resin, and 20·1 of bark consisting of 16·5 of lignin, 1·5 of gum, and 2·1 of extractive; but he must have operated on the unstrained guaiac. An acid discovered by M. Thierry is asserted by Jahn to be benzoic acid. Water dissolves a small proportion of guaiac, not exceeding nine parts in 100, forming an infusion of a greenish-brown colour and sweetish taste, which, upon evaporation, yields a brown substance soluble in hot water and alcohol, but scarcely so in ether. Alcohol takes up the whole with the exception of impurities. The tincture is of a deep-brown colour, is decomposed by water, and affords blue, green, and brown precipitates, with the mineral acids. It is coloured blue by nitric acid and by chlorine, and usually by spirit of nitrous ether; and is similarly changed when treated successively by dilute hydrocyanic acid, and solution of sulphate of copper. Either in substance or tincture, guaiac gives a blue colour to gluten and substances containing it, to mucilage of gum arabic, to milk, and to various freshly cut roots, as the potato, carrot, and horseradish. It is soluble also in ether, alkaline solutions, and sulphuric acid. The solution in sulphuric acid is of a rich claret colour, deposits, when diluted with water, a lilac precipitate, and, when heated, evolves charcoal. Exposed to air and light,

guaiac absorbs oxygen and becomes green, and the change takes place rapidly in the sunshine. Tincture of guaiac has been used for the detection of blood stains, which it does by the blue colour produced by it, when in contact with the red colouring matter of blood, in connection with some ozonized substance, especially peroxide of hydrogen. (*Guy's Hosp. Reports*, 3d ser., xiii. 432.)

Guaiacin is a name given to the pure resinoid principle of guaiac. It is insoluble in water, but is dissolved readily by alcohol, and less readily by ether. It combines with the alkalies, forming soluble compounds, which are decomposed by the mineral acids and by several salts. Hence it has been called *guaiacic acid.* It has been obtained in crystals by Prof. Hlasiwetz by first forming a soap with potassa, dissolving this in hot solution of potassa, precipitating with muriatic acid, washing the precipitated resin, and then dissolving it in alcohol, which yields it crystallized by spontaneous evaporation. (*Annal. der Chem. und Pharm.*, cxii. 183.) It differs from most of the resins in being converted by nitric acid into oxalic acid instead of artificial tannin. It is also peculiar in the changes of colour, already alluded to, which it undergoes under the influence of various reagents. By nitric acid and chlorine it is made to assume successively a green, blue, and brown colour. These changes are ascribed by Mr. Brande to the absorption of oxygen, which forms variously coloured compounds according to the quantity absorbed. M. Kossman considers guaiacin to be a glucoside, having, by heating it with dilute sulphuric acid, succeeded in converting it into glucose, and a peculiar principle which he names *gaïaretine.* (*Journ. de Pharm.*, Août, 1860, p. 83.) According to Jahn, guaiac resin consists of three distinct bodies, viz.: 1. a soft resin soluble in ether and ammonia, and constituting 18·7 per cent.; 2. another soft resin, soluble in ether, but with difficulty dissolved by ammonia, amounting to 58·3 per cent.; and 3. a hard resin, insoluble in ether, but soluble in ammonia, in the quantity of 11·3 per cent. The same chemist found in guaiac traces of benzoic acid, and 11·7 per cent. of impurities. (*Pharm. Cent. Blatt*, 1843, p. 317.)*

It will be inferred, from what has been said, that the mineral acids are incompatible with the solutions of guaiac.

This drug is sometimes adulterated with the resin of the pine. The fraud may be detected by the terebinthinate odour exhaled when the sophisticated guaiac is thrown upon burning coals, as well as by its partial solubility in hot oil of turpentine. This liquid dissolves resin, but leaves pure guaiac untouched. Amber is said to be another adulteration. Nitric acid affords an excellent test of guaiac. If paper moistened with the tincture be exposed to the fumes of this acid, it speedily becomes blue.

Medical Properties and Uses. Guaiac is stimulant and alterative, producing, when swallowed, a sense of warmth in the stomach, with dryness of the mouth and thirst, and promoting various secretions. If given to a patient when covered warm in bed, especially if accompanied with opium and ipecacuanha, or the antimonials, and assisted by warm drinks, it often excites profuse perspiration; and hence has been usually ranked among the diaphoretics. If the patient be kept cool during its administration, it is sometimes directed to the kidneys, the action of which it promotes. In large doses it purges; and it is thought by some practitioners to be possessed of emmenagogue powers. The complaint in which it has been found most beneficial is rheumatism. In the declining stages of the acute form of this disease, after due depletion, it is given in combination with opium, ipecacuanha, nitre, and the antimonials; and in the chronic form is frequently useful without accompaniment. It is also advantageously prescribed in

* By the destructive distillation of guaiac, Unverdorben obtained two volatile oils; one heavier than water, and variously called *pyrogayic acid*, *gayacol*, and *hydruret of gayacyl*, the last of which names was given by MM. Pelletier and Deville, who determined its resemblance to creasote; the other called by Voelkel, who has particularly investigated it, *gayol*, and having an odour which recalls that of bitter almonds. (*Journ. de Pharm.*, Mai, 1854, p. 396.) Ebermayer has obtained, by the dry distillation of the same resin, a crystallized product which he calls *pyroguaiacine.* (*Chem. Gaz.* Oct. 16, 1854, p. 386.)—*Note to the eleventh edition.*

gouty affections, and is occasionally used in secondary syphilis, scrofulous diseases, and cutaneous eruptions; though the guaiacum wood is more frequently resorted to in these latter complaints. It was much relied upon by the late Dr. Dewees in the cure of amenorrhœa and dysmenorrhœa. Dr. D. Lewis has found it useful in the hay-fever, given at bedtime, for six successive nights, in the dose of twenty grains, in a cup of warm tea. Dr. James Jackson, of Boston, recommends it occasionally as a laxative, in the dose of a drachm.

The medicine is given in substance or tincture. The dose of the powder is from ten to thirty grains, which may be exhibited in pill or bolus, or in the shape of an emulsion formed with gum arabic, sugar, and water. An objection to the form of powder is that it quickly aggregates. Guaiac is sometimes administered in combination with alkalies, with which it readily unites. Several European Pharmacopœias direct a *soap of guaiac*, under the name of *sapo guaiacinus*, to be prepared by diluting the liquor potassæ with twice its weight of water, boiling lightly, then adding guaiac gradually, with continued agitation, so long as it continues to be dissolved, and finally filtering, and evaporating to the pilular consistence. One scruple may be taken daily in divided doses.

GUTTA-PERCHA. *U. S.*

Gutta-percha.

The concrete juice of Isonandra gutta. (Hooker, *Loudon's Journal of Botany*, 1848.) *U. S.*

This valuable product of the East Indies was first brought into notice by Dr. Wm. Montgomerie, a British army surgeon, who became acquainted with its singular properties in the year 1842, at Singapore, and in the following year sent specimens of it to Europe. It is the product of a large tree growing in the southern extremity of the Malayan Peninsula, the islands of Singapore and Borneo, and probably many other islands in the neighbourhood. This tree belongs to the Linnæan class and order Decandria Monogynia, natural family Sapotaceæ, and genus Isonandra of Dr. Wight, and has received the name of *Isonandra gutta*. It is of considerable magnitude, with a trunk commonly three feet, and sometimes as much as six feet in diameter, having numerous ascending branches, which are crowded with leaves at their extremities. The flowers are small and white; the leaves petiolate, oblong, four or five inches long by two in breadth, bright-green above and brownish beneath.*

Dr. Montgomerie states that the natives procure the gutta-percha by the very wasteful mode of cutting down the tree, stripping off the bark, and then collecting the milky juice, which is put into convenient recipients, and coagulates on exposure to the air. Twenty or thirty pounds are thus collected from each tree; but the probability is that the product would be much greater if obtained by tapping the tree, and thus preserving it for future use. In consequence of the abundance in which it is collected, and the wasteful methods pursued, fears are entertained that the tree will before long be extirpated. Large quantities of gutta-percha are
